Preface

We began the first edition of *Treatment of Skin Disease* with the following question: ‘Now what do I do?’ Now, over two decades later, our book enters its sixth edition and is published in Chinese, English, Polish, Portuguese, and Spanish. With the first five editions, we hope we have helped many of our colleagues and their patients. With those editions, we were privileged to work with Professor John Berth-Jones, who contributed enormously to the success of our book; however, John has decided to step down. In his place, we have been fortunate to recruit Dedee Murrell, Professor and Chair of the Department of Dermatology at St. George Hospital, UNSW, Sydney, Australia.

The next question to be asked is: ‘Do we need another edition of this book?’ Has enough changed in the treatment of skin diseases to justify another edition? Indeed, the rapid pace of advances in dermatology has improved the way we practice and justifies an updated version of *Treatment of Skin Disease*. Treatments like guselkumab, risankizumab, and tildrakizumab were unheard of a few years ago and are now routine. Biologics were introduced first for psoriasis and now for atopic dermatitis and are being used in a host of other diseases, including pyoderma gangrenosum, sarcoidosis, granuloma annulare, balanitis xerotica obliterans, necrobiosis lipoidica diabetorum, and many others. In upcoming editions, we will be using Janus kinase inhibitors for alopecia areata, vitiligo, sarcoidosis, psoriasis, and atopic dermatitis. Interleukin (IL)-17 blockers, now available for psoriasis, will be used in the future to treat hidradenitis suppurativa. Bimekizumab and other IL-17A and IL-17F blockers will change the way we treat

psoriasis. Lebrikizumab, tralokinumab, and nemolizumab will be used for atopic dermatitis. These treatments undoubtedly will also be applied to conditions like idiopathic pruritus, prurigo nodularis, and severe hand eczema.

When we assigned chapters for the sixth edition, no one had even heard of COVID-19. For this edition, not only have we updated treatments for all the diseases covered, but we also have a new chapter on COVID-19 dermatoses, including the associated pediatric multisystem inflammatory syndrome.

As in prior editions, it is our fervent hope that our book will help our colleagues around the world take better care of their patients. It is that common goal that unites physicians worldwide, and we hope this edition continues to fulfil that goal.

In addition to acknowledging Professor John Berth-Jones for his work on prior editions, we want to acknowledge the authors of chapters in previous editions that have been the basis of the current edition chapters (see ExpertConsult.com). We also want to acknowledge the many individuals who have helped us by providing photographs for the current edition (see page xxix). And, most of all, we would like to acknowledge the patients who have inspired us in our clinical work and in our efforts to spread best practices among our colleagues.

Mark G. Lebwohl, MD
Warren R. Heymann, MD
Ian H. Coulson, MD
Dedee F. Murrell, MD

List of Contributors

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Anthony Abdullah, BSc (Hons), MB, ChB (Hons), FRCP (London), DTM&H
Consultant Dermatologist
The Birmingham Skin Centre and the Birmingham Regional Skin Laser Centre
Sandwell and West Birmingham Hospitals NHS Trust
Birmingham, UK

Mary Kathryn Abel, AB
Medical Student
University of California, San Francisco
School of Medicine
San Francisco, CA, USA

Boya Abudu, MD, MPH
Resident Physician
Department of Dermatology
University of California, Davis
Sacramento, CA, USA

Mohannad Abu-Hilal, MD, MRCP
Assistant Professor
Division of Dermatology, Department of Medicine
McMaster University
Hamilton, ON, Canada

Anwar Al Hammadi, MD, FRCPC, FAAD
Consultant Dermatologist
DermaMed Clinic
Adjunct Clinical Associate Professor of Dermatology
Mohammed Bin Rashid University of Medicine and Health Sciences
Dubai, UAE

Ameen Al Awadhi, MD
International Dermatopathology Fellow
Department of Dermatology
Mount Sinai Hospital New York
New York, NY, USA

Andrew F. Alexis, MD, MPH
Vice-Chair for Diversity and Inclusion
Department of Dermatology
Weill Cornell Medicine
New York, NY, USA

Khadija Aljefri, MBChB, MSc, MRCP(UK), CCT(UK)
Consultant Dermatologist
Dermatology Department
DermaMed Clinic
Dubai, UAE

Huda Al-Kutubi, MBCh, MSc (Dist), MRCP
Clinical Fellow Dermatology
The Birmingham Skin Centre
Sandwell and West Birmingham Hospitals NHS Trust
Birmingham, UK

Professor
Klinik für Dermatologie, Venerologie und
Allergologie
Charité – Universitätsmedizin Berlin
Berlin, Germany

Acknowledgments

The editors want to acknowledge the extraordinary support they have received from Elsevier staff, including Julie Taylor, Joanne Scott, Dolores Meloni, Trinity Hutton, and Charlotta Kryhl. Authors of prior editions are acknowledged in the online version

because their chapters created an excellent foundation which served as a firm basis for our new chapters.

Finally, we are grateful to our colleagues and residents who provided many of the photos used in this edition.

Dedication

We dedicate this book to our spouses (Madeleine Lebwohl, Rhonda Schnur, Susan Christopher-Coulson, and George Murrell) and our families for their support during many hours of

writing and editing; to our mentors who motivated us to teach; to our colleagues who contributed so much to this work; and to our patients who inspire us every day.

Acknowledgments

The editors want to acknowledge the extraordinary support they have received from Elsevier staff, including Julie Taylor, Joanne Scott, Dolores Meloni, Trinity Hutton, and Charlotta Kryhl. Authors of prior editions are acknowledged in the online version

because their chapters created an excellent foundation which served as a firm basis for our new chapters.

Finally, we are grateful to our colleagues and residents who provided many of the photos used in this edition.

Dedication

We dedicate this book to our spouses (Madeleine Lebwohl, Rhonda Schnur, Susan Christopher-Coulson, and George Murrell) and our families for their support during many hours of

writing and editing; to our mentors who motivated us to teach; to our colleagues who contributed so much to this work; and to our patients who inspire us every day.

Evidence Levels

Each therapy covered has been assigned a letter from A (most evidence) to E (least evidence), signifying the amount of published evidence available to support its use. The following criteria were used in making this classification.

A: Double-Blind Study

At least one prospective randomized, double-blind, controlled trial without major design flaws (in the author's view).

B: Clinical Trial ≥ 20 Subjects

Prospective clinical trials with 20 or more subjects; trials lacking adequate controls or another key facet of design that would normally be considered desirable (in the author's opinion).

C: Clinical Trial < 20 Subjects

Small trials with fewer than 20 subjects with significant design limitations, very large numbers of case reports (at least 20 cases in the literature), or retrospective analyses of data.

D: Series ≥ 5 Subjects

Series of patients reported to respond (at least five cases in the literature).

E: Anecdotal Case Reports

Individual case reports amounting to published experience of fewer than five cases.

Acanthosis nigricans

Lawrence S. Feigenbaum, Ponciano D. Cruz Jr.

Acanthosis nigricans is characterized by hyperpigmented, verrucous or velvety plaques that usually appear on flexural surfaces and in intertriginous regions. It is most commonly seen in individuals with insulin resistance states, especially obesity and diabetes, and less frequently in association with other metabolic disorders, genetic syndromes, drugs, and malignancy. Although hyperinsulinemia, hyperandrogenemia, circulating anti-insulin receptor antibodies, tyrosine kinase receptor abnormalities (IGF1R and EGFR), and mutations in fibroblast growth factor receptor have been implicated as causal factors, the precise pathogenesis is not yet known.

MANAGEMENT STRATEGY

The management of patients with acanthosis nigricans addresses the underlying cause, the identification of which requires a salient history, a targeted physical examination, focused diagnostic laboratory tests, and, occasionally, radiologic evaluation.

Relevant historical information includes age at onset, speed of progression from onset, presence or absence of family history, medications, transplant history, and presence or absence of symptoms related to hyperinsulinemia, hyperandrogenemia, hypercortisolism, and internal malignancy.

Drugs reported in association with acanthosis nigricans include niacin, corticosteroids, estrogens, testosterone, insulin, aripiprazole, fusidic acid, protease inhibitors, triazinate, diethylstilbestrol, palifermin, and recombinant growth hormone. Acanthosis nigricans has also been associated with renal and lung transplantation.

Physical examination should document obesity, masculinization, hirsutism, lymphadenopathy, Cushingoid features, and

organomegaly. Initial laboratory screening should include fasting blood glucose and serum insulin tested concurrently to confirm or exclude insulin resistance.

Because obesity is the most common cause of both insulin resistance and acanthosis nigricans, it is the likely cause of acanthosis nigricans in overweight patients with no historical suggestion of culprit drugs or evidence of malignancy.

Rare causes of insulin resistance and acanthosis nigricans include the type A and B syndromes, the former characterized by defective insulin receptors and the latter by circulating anti-insulin receptor antibodies in association with autoimmune disorders such as lupus erythematosus. Other causes of insulin resistance and acanthosis nigricans are polycystic ovarian disease, HAIR-AN syndrome, familial lipodystrophies, and various endocrinopathies.

The most commonly associated malignancy is gastric adenocarcinoma. Less frequent associations are endocrine, genitourinary, lung, and gastrointestinal carcinomas, and, even more rarely, melanoma and cutaneous T-cell lymphomas/Sézary syndrome. Malignant acanthosis nigricans may coexist with other cutaneous markers of internal malignancy, such as tripe palms, the sign of Leser-Trélat, florid cutaneous papillomatosis, and hyperkeratosis of the palms and soles. If malignancy-associated acanthosis nigricans is suspected, age-appropriate cancer screening should be performed. Additional laboratory tests may include a complete blood count, stool test for occult blood, and chest and gastrointestinal radiographs, as well as gastrointestinal endoscopy. Referral to the appropriate specialist would be indicated.

In the absence of objective evidence for a specific cause, the acanthosis nigricans may be labeled as idiopathic, which may or may not be familial. Treatment of the underlying cause, if identified, often leads to the resolution of the acanthosis nigricans. Otherwise, most published treatment modalities are symptomatic and/or cosmetic.

Specific Investigations

- Document obesity based on ideal body weight, height/weight, body mass index (BMI)
- Document blood pressure
- Determine fasting blood glucose and insulin levels in parallel. Consider ordering HbA_{1c}, alanine aminotransferase (ALT), and fasting lipoprotein profile in obese patients
- Consider screening for other endocrine and metabolic diseases
- Consider malignancy: if suspected, refer to the appropriate specialist for the best diagnostic procedure
- Consider drugs as a cause
- Consider transplantation as a cause
- Consider familial/genetic disorders as a cause

Treatment of acanthosis nigricans of the axillae using a long-pulsed (5-msec) alexandrite laser. Rosenbach A, Ram R. Dermatol Surg 2004; 30: 1158–60.

A woman with axillary acanthosis nigricans was treated with long-pulsed alexandrite laser on one axilla, with the other axilla as an untreated control. The treated axilla showed significant improvement.

Acne keloidalis nuchae

Ahuva D. Cices, Andrew F. Alexis

Acne keloidalis nuchae (AKN) is a chronic disorder predominantly affecting males with Afro-textured hair characterized by inflammatory changes of hair follicles on the posterior neck and scalp that result in fibrotic papules and cicatricial alopecia. Erythematous papules and pustules are the primary inflammatory lesions of AKN. At the time of presentation, most patients will have scarring as a result of the extensive inflammation seen in AKN, manifesting as keloid-like, dome-shaped papules, plaques, or nodules, and scarring alopecia in the affected area. Tufted hairs arising from keloid-like lesions may also be present. AKN is a misnomer without true acne or keloids. The pathogenesis of AKN is poorly understood, but is likely multifactorial, including genetic, immunologic, and environmental factors.

MANAGEMENT STRATEGY

Effective management starts with an accurate diagnosis. AKN is diagnosed clinically by the presence of inflammatory papules, pustules, and scar-like lesions on the occipital scalp and posterior neck of males with Afro-textured hair. Rarely, AKN occurs in females or individuals of non-African descent. The diagnosis is made clinically, without need for biopsy in the vast majority of cases. Characteristic histopathologic features include acute and chronic folliculitis, ruptured pilosebaceous units, and dermal fibrosis. When pustules, scale, or crust is present, bacterial and fungal cultures aid to rule out bacterial folliculitis and/or superinfection, or tinea capitis, respectively. Pustules due to *Staphylococcus aureus* folliculitis can resemble early AKN, but are more superficial, lack induration or keloid-like features, and respond rapidly to appropriate antibiotics.

Treatment of AKN requires suppressing active inflammation and fibrosis as well as avoidance of exacerbating factors using a combination of medical therapies, procedural interventions, and behavioral modification. Disease management is heavily based on clinician experience due to limited evidence or controlled studies and lack of consensus guidelines.

The initial approach comprises *avoidance of close shaving, friction, and rubbing* to prevent disease exacerbations in combination with medical treatments. Mild disease is managed with a combination of topical therapies including *high-potency topical corticosteroids* (group 1 or 2, e.g., clobetasol 0.05% gel or foam), *antimicrobial washes* (e.g., chlorhexidine wash), *topical antibiotics* (e.g., clindamycin phosphate 1% gel or foam), and *topical retinoids* (e.g., tazarotene 0.05% or 0.1% gel). Topical corticosteroids are applied once or twice daily and alternating in 2-week cycles to minimize effects of chronic steroid use. Twice daily application of clobetasol propionate 0.05% foam in alternating 2-week cycles was shown to be effective in a 20-subject, open-label, clinical trial. Improvement is typically achieved in 6–8 weeks and therapy is continued until signs (e.g., papules/pustules) and symptoms (e.g., pruritus, pain) have improved, with reinstitution of therapy for flares. This author (AFA) favors clobetasol propionate 0.05% foam twice daily or a *fixed combination halobetasol 0.01%-tazarotene 0.045% lotion* once daily for 2 weeks followed by application three times weekly.

Antimicrobial washes including *chlorhexidine* and *povidone iodine* are used to prevent secondary infection. If superinfection is suspected, cultures and appropriate antibiotic therapy should be completed prior to initiating steroids. When pustules are present, topical antibiotics are recommended. No formal studies have been completed to evaluate the efficacy of topical antibiotics for AKN. This author (AFA) favors *topical clindamycin 1% gel or foam for treatment of mild pustules*. Efficacy of once-daily topical retinoids, including adapalene, tretinoin, and tazarotene, is unclear, though they are theorized to improve AKN through antiinflammatory effects and prevention of follicular occlusion.

Persistent inflammatory lesions as well as keloid-like scars of AKN can be effectively treated with *intralesional triamcinolone* at varying concentrations ranging from 2.5 to 40 mg/mL with higher concentrations (>20 mg/mL) reserved for large (>3 cm), keloid-like lesions. *Cryosurgery* has also been used successfully, though no studies have evaluated specific parameters for AKN, and hypopigmentation or depigmentation are risks in patients with skin of color.

Failure of the above therapies or moderate-to-severe disease warrants systemic treatments. *Oral antibiotics* are used for several weeks to months to control inflammatory flares. *Tetracyclines* such as *doxycycline* or *minocycline* are the mainstay of oral antibiotic therapy of AKN; however, published evidence is limited. This author (AFA) favors oral doxycycline for its antiinflammatory and antimicrobial effects. When *Staphylococcus aureus* superinfection is present, a course of a first-generation *cephalosporin* or doxycycline at antimicrobial doses (50–100 mg twice daily) is recommended. As an adjunct to topical and intralesional therapy, *subantimicrobial doxycycline* (40 mg/day) for 12–16 weeks is useful in this author's experience. Select cases show effective treatment of refractory inflammatory lesions with *oral retinoids* starting at 0.25–0.6 mg/kg daily followed by lower doses for maintenance.

Light and energy based therapies are effective for long-term disease control. Long-pulse, *long-wave lasers* including *alexandrite 755 nm*, *diode 800–810 nm*, and *neodymium:yttrium-aluminum-garnet (Nd:YAG) 1064 nm* are effective treatment for AKN due to their ability to completely destroy the hair follicle. The 1064-nm Nd:YAG laser has the most favorable profile for hair removal in darker-skinned patient populations: deepest penetration and

least absorption by melanin, thereby maximizing efficacy and minimizing risk of dyspigmentation. Its efficacy has been demonstrated in a prospective controlled trial. *Er:YAG* has been shown to have the same efficacy as *Nd:YAG* for papular disease as well as beneficial effects on larger plaques in a comparative trial. A 12-subject AKN trial showed targeted *ultraviolet B (UVB) phototherapy* administered three times weekly is effective and well tolerated.

Surgical excision, including scalpel, electrosurgical, or laser excision, followed by primary closure or secondary intention healing is effective for refractory and severe disease. Regardless of the surgical technique utilized, successful treatment requires complete removal of hair follicles to prevent recurrence. Horizontal ellipse excision followed by secondary intention healing is recommended for optimal cosmetic outcomes. Postsurgical adjuvant therapies have included intralesional or topical steroids and radiotherapy; however, these are not indicated given the low recurrence rate. Local radiation therapy with 3 Gy and 6 MeV $\times$ 10 sessions on alternating days was successful in treating a case of refractory AKN that recurred after therapy with topicals, oral antibiotics, isotretinoin, and partial excision.

Specific Investigations

- Pustule swab
- Punch biopsy

First-Line Therapies

• Counseling	E
• High-potency topical steroid (class I or II)	B
• Topical antibiotic	E
• Antimicrobial cleansers	E
• Oral antibiotic	E
• Topical retinoid	E

Pseudofolliculitis barbae. Chu T. Practitioner 1989; 233: 307–9.

Topical clindamycin 1% was effective for pseudofolliculitis and acne keloidalis in a limited open-label study.

An open label study of clobetasol propionate 0.05% and betamethasone valerate 0.12% foams in the treatment of mild to moderate acne keloidalis. Callender VD, Young CM, Haverstock CL, et al. Cutis 2005; 75(6): 317–21.

Open-label study in 20 African American patients that showed efficacy and tolerability of topical steroids for treatment of mild-to-moderate scalp AKN. Clobetasol propionate ointment 0.05% foam used twice daily alternating 2 weeks on and 2 weeks off for a total of 8 weeks showed statistically significant improvement of papule/pustule count and pruritus scores. In the second phase, subjects with residual disease ($n = 11$) were treated with betamethasone valerate 0.12% foam twice daily from weeks 8–12 with no statistically significant change in lesion count from weeks 8–12.

Folliculitis keloidalis nuchae and pseudofolliculitis barbae: are prevention and effective treatment within reach? Alexis A, Heath CR, Halder RM. Dermatol Clin 2014; 32(2): 183–91.

Review of treatment options for AKN, which include counseling on preventative measures to avoid disease exacerbations (e.g., avoiding mechanical irritation and manipulation) and medical

treatments including antimicrobial cleansers (e.g., chlorohexidine), topical and oral antibiotics, topical steroids, and topical retinoic acid. Additionally, surgical and laser therapies are also addressed.

Second-Line Therapies

• Alexandrite laser	C
• Targeted UVB	C
• <i>Nd:YAG</i>	C
• <i>Er:YAG</i>	C
• Oral retinoid	E
• Diode laser	E
• Intralesional steroids	E

Improving acne keloidalis nuchae with targeted ultraviolet B treatment: a prospective, randomized, split-scalp comparative study. Okoye GA, Rainer BM, Leung SG, et al. Br J Dermatol 2014; 171(5): 1156–63.

Split-scalp study in 11 patients with AKN treated with targeted UVB (290–320 nm) up to three times weekly for 8 weeks, followed by 8 weeks of full scalp treatment with statistically significant decreased lesion count on treated side at 8 weeks. Authors also noted improvement in clinical appearance and patient satisfaction without tolerability limitations.

Successful treatment of acne keloidalis nuchae with erbium:YAG laser: a comparative study. Gamil HD, Khater EM, Khattab FM, et al. J Cosmet Laser Ther 2018; 20(7–8): 419–23.

In this comparative study, 30 male subjects with AKN were randomly assigned to six sessions *Er:YAG* 2490 nm, 3-mm spot size, pulse duration 300 msec, frequency 5 Hz, and pulse 800–900 mJ in partially overlapping mode or *Nd:YAG* 1064 nm, 13-mm spot size, pulse duration of 35 msec, and a fluence of 30–35 J/cm² in partially overlapping mode. Following treatment, both groups received ice compresses, and topical fusidic acid and betamethasone topically for 3 days posttreatment. Both groups had improvement in papular disease (91.8% vs. 88%). Significant improvement in plaques only in the *Er:YAG*-treated group.

Nd:YAG and *Er:YAG* can be used to treat early papular lesions of AKN. *Er:YAG* is more effective than *Nd:YAG* for the treatment of more advanced disease.

Keratosis follicularis spinulosa decalvans and acne keloidalis nuchae. Goh MS, Magee J, Chong AH. Australas J Dermatol 2005; 46(4): 257–60.

Rapid improvement of inflammatory lesions in biopsy-confirmed concomitant suppurative AKN and keratosis follicularis spinulosa in a 27-year-old Caucasian male with oral isotretinoin 20 mg (0.25 mg/kg) daily for 12 months. Maintenance of response with 20 mg every 2–3 days at 1 year.

Use of imiquimod and pimecrolimus cream in the treatment of acne keloidalis nuchae. Barr J, Friedman A, Balwin H. J Am Acad Dermatol 2005; 52(3 Suppl): 64.

Small open-label study with five subjects randomized to topical imiquimod applied once daily or pimecrolimus twice daily for 8 weeks. All five patients had significant improvement in pruritus and decreased lesion counts.

Imiquimod and pimecrolimus can be used topically for subjects with AKN who fail first-line topical agents and prefer to be managed with topical agents.

A novel treatment of acne keloidalis nuchae by long-pulsed alexandrite laser. Tawfik A, Osman MA, Rashwan I. *Dermatol Surg* 2018; 44(3): 413–20.

Seventeen male subjects with AKN received six sessions of 755-nm alexandrite laser therapy. There was a significant improvement in mean papule and pustule counts, keloidal plaque size, and pliability at the fourth and sixth laser sessions compared with baseline. Improvement in early papule/pustule lesions was significantly greater than improvement in later keloid-like lesions. Adverse effects included reduction of hair density in the treatment areas as well as temporary hair loss in four subjects.

Efficacy of diode laser for treating acne keloidalis nuchae. Shah GK. *Indian J Dermatol Venereol Leprol* 2005; 71(1): 31–4.

Two cases of AKN with 90–95% clearance of AKN after four treatments at 4–6-week intervals with diode laser.

Third-Line Therapies

- Surgical excision with secondary intention healing **B**
- Radiotherapy **E**

The surgical management of extensive cases of acne keloidalis nuchae. Gloster HM Jr. *Arch Dermatol* 2000; 136: 1376–9.

A referred sample of 25 Black men with refractory, extensive AKN were treated as follows: excision with layered closure in stage 1 (20 subjects), stage 2 excision with layered closure (4 subjects), and excision with second intention healing (1 subject). Surgeries

were performed in a sterile fashion, to a depth below hair follicles to fascia or deep fat, with a no. 10 scalpel blade or with an electrosurgical device. All subjects rated cosmetic results favorably and none had full recurrence; 15 patients had mild papules and pustules in the first 4 months and five patients treated with single-stage excision developed hypertrophic scars. Both groups were successfully treated with twice-daily high-potency topical steroids and monthly intralesional triamcinolone.

Surgical excision is the most studied treatment option for severe or refractory AKN. In clinical practice recurrences are seen due to residual hair follicles.

Treatment of acne keloidalis nuchae with carbon dioxide laser. Kantor GR, Ratz JL, Wheeland RG. *J Am Acad Dermatol* 1986; 14(2 Pt 1): 263–7.

Series of six patients treated with CO₂ laser excision at 64,000 watts/cm², one of which had a satellite lesion treated with vaporization and two additional subjects treated with vaporization at 130 to 105 watts/cm². Patients treated with laser excision had no recurrence at time of follow-up (ranging from 3–47 months postoperatively), though two subjects used prophylactic betamethasone valerate ointment 0.1% twice daily. Two of the three subjects treated with vaporization had disease recurrence. Two of these patients successfully treated with laser excision developed mild hypertrophic scars at 3 months postoperatively that responded to intralesional triamcinolone 20–40 mg/mL.

Refractory acne keloidalis nuchae treated with radiotherapy. Millán-Cayetano JF, Repiso-Jiménez JB, Del Boz J, et al. *Australas J Dermatol* 2017; 58(1): e11–e13.

Case report of refractory AKN successfully treated with 3 Gy and 6 MeV × 10 sessions on alternating days.

Radiation therapy is an alternative treatment modality for refractory AKN when other treatments have been ineffective.

3

Acne vulgaris

Leah Lalor, Andrea L. Zaenglein

Acne vulgaris is a chronic inflammatory disorder of the pilosebaceous unit with multifactorial pathogenesis. Numerous immune mechanisms are involved and are influenced by factors such as diet, genetics, and environment. There are four main pathogenic factors leading to the development of acne: 1) increased sebum production; 2) abnormal keratinization of the follicular infundibulum; 3) *Cutibacterium acnes*-mediated responses; and 4) inflammation.

Acne ranges from mild to severe and fulminant. Types of acne lesions (open or closed comedones, inflammatory papules or pustules, nodules), extent of distribution, involvement of the chest, shoulders and back as well as presence of scarring, postinflammatory hyperpigmentation and erythema should be taken into consideration when choosing an acne treatment regimen.

MANAGEMENT STRATEGY

An effective treatment strategy targets multiple pathogenic factors. Other than the systemic retinoid isotretinoin, there are no other single acne treatments that address all four pathogenic factors. Thus, combination therapy, typically a *retinoid with benzoyl peroxide (BP)* ± *topical or systemic antibiotic*, is used first line to achieve optimal improvement in mild to moderate–severe acne.

Mild Acne

In mild forms of acne, topical therapy is most appropriate. First-line treatment includes a topical retinoid often with BP, or a topical *fixed-dose combination product* (such as *adapalene/BP*). Topical retinoids (*adapalene, tretinoin, tazarotene, trifarotene*) have both comedolytic and antiinflammatory properties. Additionally, topical retinoids have demonstrated efficacy in preventing atrophic acne scarring. All topical retinoids are effective as single agents in treatment of acne, although they are usually combined with BP for its additive

antimicrobial effects. The efficacy of combination therapy is superior to any single agent. Convenient fixed-dose combinations include *adapalene 0.1%/BP 2.5% gel, adapalene 0.3%/BP 2.5% gel and tretinoin 0.025%/clindamycin 1.2% gel*. Topical retinoids differ in strength and tolerability, which can be affected by vehicle, concentration, and skin type. In several randomized, parallel-group studies, adapalene 0.1% gel has consistently demonstrated greater tolerability than tretinoin cream or tazarotene, whereas tazarotene 0.1% gel has had greater reported efficacy than adapalene 0.1% gel and tretinoin 0.025% gel. Trifarotene 0.005% cream, with selective RAR- γ binding, was recently Food and Drug Administration (FDA) approved for use in acne vulgaris involving the face, shoulders, chest, and back. Side effects from all retinoids include local redness, peeling, itching, and stinging at sites of application, particularly within the first 2 weeks. Irritation typically improves with continued use and can usually be controlled with use of a gentle cleanser and daily moisturizer. Sun sensitivity is also reported with topical retinoid use and sun protection measures should be advised. Generic tretinoin formulations are not stable in ultraviolet light or with concomitant BP application; therefore, they should be applied at night and separately from BP. Adapalene 0.1% gel is the only retinoid currently available over the counter without prescription.

Topical antibiotics (erythromycin, clindamycin) have long been used as adjunctive therapies for mild-to-moderate acne, exerting antimicrobial and antiinflammatory effects, thus overlapping mechanisms of action with BP and topical retinoids. *Topical minocycline 4% foam* was recently FDA approved for use in moderate-to-severe acne, demonstrating efficacy in reducing both inflammatory and non-inflammatory lesions. While clinical trials have documented the efficacy of topical antibiotics as single treatment agents, due to widespread antibiotic resistance, topical antibiotics should not be used as monotherapy. If used, they should be combined with BP, either as separate formulations or in fixed-dose combination products (*BP/clindamycin* or *BP/erythromycin*) to prevent the development of antimicrobial resistance. Additionally, randomized, double-blind, placebo-controlled trials comparing fixed-dose combination products (e.g., *BP/clindamycin*) with individual components and placebo have demonstrated greater efficacy in combination than as solo agents. Continuous, long-term use of any antibiotic, topical or systemic, for acne is not recommended.

Alternative treatment options for mild acne include *topical dapsone, azelaic acid, and salicylic acid*. Dapsone is a topical sulfone antimicrobial agent that comes in two concentrations (5% and 7.5%). Its mechanism of action in acne treatment is poorly understood but presumptively antiinflammatory. It is effective in treating inflammatory acne, particularly in women and skin of color. BP should not be applied at the same time as dapsone gel as it may cause a temporary orange discoloration of the skin and fabrics. Azelaic acid 20% cream has efficacy as a comedolytic, antibacterial, and antiinflammatory agent when used twice daily. Additionally, there are limited clinical trials demonstrating the efficacy and tolerability of azelaic 15% foam and gel for the treatment of acne. Lesser strength formulations of azelaic acid are available in many over-the-counter preparations. It is typically less irritating than topical retinoids, though less effective as a comedolytic. Azelaic acid is often used to treat postinflammatory hyperpigmentation. There is limited clinical data to support the use of salicylic acid in acne; however, it is widely available without a prescription, has a reasonable safety profile, and may be a reasonable option for patients with very mild acne.

Moderate Acne

For moderate acne, topical combination therapy (retinoid and BP) as described above is recommended as initial management, with

or without the addition of a systemic antibiotic depending on relative severity. Current acne management guidelines from the US, EU, UK, and Canada recommend that all antibiotics should not be used as monotherapy but used in conjunction with a topical retinoid and BP. Additionally, topical antibiotics should also not be combined with oral antibiotic therapy due to risk of bacterial cross resistance. Tetracyclines (*doxycycline*, *minocycline*, *tetracycline*, *sarecycline*) are considered the first-line antibiotic choice for moderate-to-severe acne due to their lipophilic absorption property allowing greater penetration of the pilosebaceous unit, their antimicrobial effects on *C. acnes*, and their antiinflammatory properties. Systemic doxycycline is typically preferred over systemic minocycline due to a higher risk of rare but serious side effects reported with minocycline, including pseudotumor cerebri, drug rash with eosinophilia and systemic symptoms (DRESS), and drug-induced lupus. Doxycycline and minocycline are typically given at a dose of 100 mg by mouth daily to twice daily. They can be given with food to decrease gastrointestinal upset. Subantimicrobial doxycycline dosing regimens (20 mg twice daily or 40 mg daily) have also shown efficacy in limited studies of moderate and moderate-to-severe acne. Side effects of doxycycline include gastrointestinal upset and photosensitivity, and it is not recommended for pregnant women or children younger than 8 years old due to effects on bones and teeth. Tetracycline, 500 mg twice daily, can alternately be used but must be taken on an empty stomach. Sarecycline, 100 mg daily, has a narrower antimicrobial spectrum than the other tetracyclines, with targeted bactericidal effects on *C. acnes*. Subsequently, it has less potent antimicrobial activity against intestinal microbial flora, including aerobic Gram-negative bacilli and anaerobic bacteria. Importantly, all current acne management guidelines recommend that the use of systemic antibiotics should be limited to 3–4 months whenever possible. Therefore, once improvement in acne is attained, systemic antibiotics should be discontinued, while maintaining the use of a topical retinoid and BP. If acne is not controlled, isotretinoin or hormonal agents (for adolescent girls and women) should be considered. Macrolide antibiotics (*erythromycin*, *azithromycin*) are typically used for pediatric patients and those intolerant of or allergic to tetracyclines. Use of systemic erythromycin is limited due to antimicrobial resistance. In limited randomized, double-blind, non-inferiority studies, azithromycin demonstrated variable equivalent efficacy for acne when compared with doxycycline. Published dosing regimens vary widely and are not standardized. *Azithromycin 500 mg/day, 3 days a week*, is the most commonly reported dosing regimen. Due to greater risk of severe adverse events, particularly DRESS, *trimethoprim-sulfamethoxazole (TMP-SMX)* should be used only in patients intolerant of or unresponsive to tetracyclines. Amoxicillin and cephalexin have little data to support their use in the treatment of acne, with no controlled trials to document safety or efficacy, and are not typically recommended except in pregnant women and patients with drug allergy prohibiting alternate antibiotic therapy.

Hormonal agents are an effective treatment option for females with moderate-to-severe papulopustular acne. *Combination oral contraceptive pills (COCs)* contain both an estrogen and a progestin and control acne by their antiandrogenic effects. There are four COCs approved by the FDA for treatment of acne (in addition to pregnancy prevention), though most COCs with third- and fourth-generation progestins (*norgestimate*, *desogestrel*, *gestodene*, *drospirenone*) have demonstrated efficacy in females with acne. COCs are taken daily, and improvement in acne can be expected 3–6 months after initiation. Two major side effects of concern with COCs are venous thromboembolic events and myocardial infarction. Absolute contraindications to their use include personal history of thromboembolic disorders, cerebrovascular or

coronary artery disease, migraine with aura, hypertension, breast cancer, undiagnosed abnormal genital bleeding, and liver tumors.

An alternative hormonal agent, *spironolactone*, can also be considered for females with acne. Spironolactone is an aldosterone receptor antagonist with potent antiandrogen effects, and in retrospective case series it has been shown effective in adult women with acne and females with polycystic ovarian syndrome/androgen excess. Typical dosing ranges from 50 mg to 200 mg per day as monotherapy or in combination with other acne treatments with improvement in acne noted in 4–8 weeks of treatment. It is typically well-tolerated, with common dose dependent side effects being diuresis, menstrual irregularities, and breast tenderness. Side effects may be ameliorated with concomitant use of a third- or fourth-generation progestin-containing COC. There is a hypothetical risk of feminization of a male fetus if spironolactone is taken during pregnancy and thus its use should be avoided in pregnant patients. Spironolactone is also a potassium-sparing diuretic. In young, healthy patients without renal or cardiovascular disease, serum potassium monitoring is not required while on spironolactone. Potassium levels should be monitored in those with cardiac or renal disease, orthostatic instability, and for those on medications that affect the renin–angiotensin–aldosterone system. Safety and efficacy in pediatric and adolescent acne patients have not been established.

Severe Acne

First-line treatment for severe acne should include topical combination therapy (retinoid and BP) plus an oral antibiotic (see moderate acne). In several studies, approximately 70% of patients with severe acne can achieve clear to almost clear skin with use of an oral antibiotic, topical retinoid, and BP. For severe, nodulocystic acne, acne with severe scarring, or in those intolerant of tetracycline, *isotretinoin* should be considered first line. Systemic isotretinoin is the most effective antiacne drug available and has the potential to induce a durable remission even after discontinuation. Current acne management guidelines recommend initiating isotretinoin at 0.5 mg/kg/day for the first month to prevent isotretinoin-induced flaring and increasing to 1 mg/kg/day thereafter as tolerated, continuing therapy until a total cumulative dose of 120–150 mg/kg is achieved in order to obtain a durable remission. Individual patients may require longer treatment courses to achieve adequate improvement. Prospective case series report efficacy of low-dose (0.1–0.2 mg/kg daily) regimens over variable time frames (6 months to 120 mg/kg cumulative dose to clearance plus one additional month) in patients with moderate acne. Lower dose regimens are associated with a greater tolerability. Lower starting doses and concomitant *prednisone* therapy may be required for those with severe inflammatory acne at risk of isotretinoin-induced acne fulminans. Studies examining relapse rates after a course of isotretinoin have variable definitions of recurrence and are difficult to compare; however, in general, about 20% of patients will need additional acne treatment at 2 years post isotretinoin treatment. Increased risk of recurrence is reported more likely in younger patients, adult females, smokers, patients with macrocomedones and truncal acne, and those with underlying, untreated hyperandrogenism.

Common adverse effects of oral isotretinoin include characteristic dose-dependent mucocutaneous side effects (cheilitis, xerosis, dry mucosae, conjunctivitis, epistaxis), elevation of serum lipids, arthralgia, and myalgia. Rare liver function abnormalities, pseudotumor cerebri, and hyperostosis or extraskeletal calcification have been reported. Routine monitoring of liver function tests, serum cholesterol, and triglycerides at baseline and again once treatment dose is attained (typically at 2 months)

is recommended. A *lidose isotretinoin* formulation allows greater absorption without the need to take with a high fat meal.

Of most importance, the dose-independent teratogenic potential of isotretinoin, which is associated with a high rate of spontaneous abortion and life-threatening congenital malformations, demands the use of highly effective forms of contraception when it is prescribed for persons of reproductive potential. This includes female to male transgender patients who have not undergone gender affirming surgery. All persons of reproductive potential must commit to two forms of contraception or abstinence for 1 month before initiation of treatment, during the entire period of drug administration, and for 1 month after discontinuation. All patients in the US treated with isotretinoin must adhere to the FDA-mandated iPLEDGE risk management program. Oral isotretinoin is strictly contraindicated in pregnancy and during lactation, and should be used with caution in those with severe hepatic dysfunction. Coadministration of additional vitamin A, beyond the recommended daily allowance, is contraindicated. Although a causal relationship has not been decidedly established, deterioration of preexisting depression, suicidal ideation, anxiety, bipolar disorder, psychosis, and schizophrenia have been reported during treatment and psychiatric symptoms should be monitored closely at each visit. An association between inflammatory bowel disease (IBD) and isotretinoin use was suggested; however, large, case-controlled studies and subsequent meta-analysis have refuted an increased risk of IBD in patients treated with isotretinoin.

Regarding cutaneous procedures during and after isotretinoin treatment, limited case reports suggested that isotretinoin use could be associated with development of excessive granulation tissue and scarring after dermatologic procedures. Current expert recommendations suggest only mechanical dermabrasion and fully ablative laser procedures should be avoided until 6–12 months after isotretinoin use.

Acne conglobata is a severe form of acne characterized by polyporous comedones and deep, coalescing nodulocystic lesions involving the face, trunk, buttocks, and thighs. Scarring is severe. Isotretinoin should be used first-line and may require prolonged administration.

Acne fulminans (AF) is a severe variant of acne characterized by abrupt onset of papules, pustules, and nodules with characteristic granulomatous lesions over the face, chest, back, and shoulders. Systemic symptoms of fever and joint pain are common but not seen in all patients, while laboratory and radiographic studies may show leukocytosis, elevated inflammatory markers, and osteolytic bone lesions. AF may occur spontaneously or be isotretinoin-induced, typically occurring within the first month of starting the medication. At the onset of AF, systemic prednisone at a dose of 0.5–1 mg/kg/day is recommended for at least 2–4 weeks until crusted lesions are healed, at which time isotretinoin can be initiated or re-initiated. Isotretinoin should be initiated at a low dose (0.1 mg/kg/day) with overlap with prednisone for at least 4 weeks. Tapering of prednisone over 4–8 weeks is recommended as tolerated, and similarly an increase in isotretinoin is recommended slowly as tolerated. An alternate reported regimen is isotretinoin 0.5 mg/kg divided twice daily and prednisolone 10 mg three times daily. *Topical clobetasol or intralesional corticosteroid injection, in addition to pulsed-dye laser*, can be used to treat the granulation tissue. In patients unresponsive to or intolerant of isotretinoin, alternative treatments include *tumor necrosis factor (TNF) inhibitors (adalimumab, infliximab)*, *cyclosporin*, *methotrexate*, *azathioprine*, systemic dapsone, tetracyclines, and azithromycin.

Maintenance Therapy (Clear/Almost Clear)

Once improvement in acne is attained, topical retinoids are the mainstay of maintenance therapy. To prevent recurrence, daily

retinoid use should be maintained along with BP if a part of the acne treatment regimen.

Cutaneous sequelae from acne include postinflammatory hyperpigmentation (PIH) and erythema and scarring, and should continue to be managed once acne clearance is achieved (see Chapter 200).

Acne scarring is a common sequela occurring in 43% of patients presenting for treatment. Early and aggressive treatment of acne is needed to prevent scarring.

Procedural treatments of atrophic acne scars include selective use of *micro-needling*, *subcision*, *injection of platelet-rich plasma*, and *chemical reconstruction of skin scars (CROSS) with 100% trichloroacetic acid*. Several lasers have demonstrated efficacy in the treatment of acne scarring, including fractional *carbon dioxide lasers*, *1450-nm diode laser*, and *Nd:YAG*. Management of keloidal acne scars includes *intralesional corticosteroid injection* often in combination with laser treatments.

Other Acne Treatments

While there is limited published evidence to support the use of comedone extraction, it is generally considered in expert consensus to be beneficial in select patients. There is limited evidence to support recommendations for *sulfur*, *nicotinamide*, and *sodium sulfacetamide* in the treatment of acne.

Serial chemical peels, including 40% *glycolic acid* and 20–30% *salicylic acid*, may be beneficial in mild-to-moderate comedonal acne. Some laser and light devices have data to support use in active acne treatment. A split-face study of *pulsed-dye laser (PDL)* showed that it is effective in reducing acne lesions with no differences in purpuric and subpurpuric fluences. Photodynamic therapy has also shown efficacy in the treatment of acne.

Published studies suggest a role for high glycemic load diets and dairy consumption, particularly skim milk, in the pathogenesis of acne. However, currently there is not enough evidence to recommend any specific dietary changes in healthy acne patients. In patients with clinical and laboratory evidence of metabolic dysregulation, including insulin resistance and polycystic ovarian syndrome (PCOS), a *low-glycemic load diet* may result in improvements in acne. However, standard acne treatment should be used concomitantly.

Acne in pregnancy can be challenging to manage, as many standard acne treatments are contraindicated or not recommended in pregnancy. Topical treatment options include azelaic acid, erythromycin, and clindamycin, all of which are pregnancy category B. For moderate-to-severe acne in pregnancy not controlled with topicals, short courses of *oral erythromycin* or *cephalexin* may be utilized. Similarly, for severe or fulminant acne in pregnancy, consideration could be given to a short course of oral prednisolone. Management decisions should be made with the patient's obstetrician. Importantly, tazarotene and isotretinoin are both classified as pregnancy category X and are absolutely contraindicated in pregnancy.

Neonatal acne (birth to 6 weeks of age) can affect up to 20% of newborns and may not be true acne. It typically presents without comedones and may be driven at least partially by yeast colonization. Spontaneous resolution will occur, but treatment with a *topical antifungal* (clotrimazole, ketoconazole) could be considered.

In infantile acne (6 weeks–2 years of age) comedones predominate with variable inflammatory lesions noted. Pitted scarring is common. While measurable hormonal abnormalities are very rare in this age group, these infants should be examined for physical signs of hyperandrogenism, including evaluation of growth charts, testicular and breast development, and examination for hirsutism, pubic hair, clitoromegaly, and abnormal genitalia. If any concerning physical signs are present, a referral to a pediatric endocrinologist is warranted. Off-label management can be initiated according to the

above recommendations based on severity of acne, with infant-compatible formulations (i.e., lower strength retinoids and BP, avoiding washes that may get in the baby's eyes). Systemic *azithromycin* or *erythromycin* are used for moderate-to-severe acne. Tetracycline antibiotics must be avoided due to effects on bones and staining of teeth.

Mid-childhood acne (1–7 years of age) is rare as androgen levels are normally low during this stage. Therefore, all patients with mid-childhood acne should undergo endocrinological evaluation to rule out causes of hyperandrogenism. Treatment is indicated based on severity of acne as above, though remains off-label. Tetracycline antibiotics must be avoided due to effects on bones and teeth.

Preadolescent acne (7–12 years of age) is increasingly common and often the first sign of pubertal maturation. Endocrinologic workup is typically unnecessary except in cases of severe, abrupt onset. Early acne may be a sign of more severe adolescent acne. Treatment is indicated based on severity of acne, as above. Safety and efficacy have been established in this age group with tretinoin 0.05% gel (10 years and older) and fixed combination adapalene 0.1%/BP 2.5% gel (9 years and older), though others may be used off-label. Tetracycline antibiotics can be used after age 8 years, depending on permanent tooth development.

Specific Investigations

- Typical presentations of acne do not require any routine investigation
- For sudden-onset severe acne or signs of androgen excess, endocrinologic evaluation is warranted to rule out adrenal or gonadal tumors
- For females with signs of hyperandrogenism (hirsutism, androgenetic alopecia) and menstrual irregularities, PCOS should be considered. Endocrinologic evaluation may include serum DHEA-S, free and total testosterone, LH, and FSH, or referral to a specialist
- Consider microbiology to exclude Gram-positive, Gram-negative, and pityrosporum folliculitis
- Consider skin-scraping to exclude demodicosis
- For pediatric patients under age 7 years, physical examination for signs of pubertal development should be performed. If present, the child should be referred for endocrinologic evaluation

Standardized laboratory monitoring with use of isotretinoin in acne. Hansen TJ, Lucking S, Miller JJ, et al. *J Am Acad Dermatol* 2016; 75(2): 323–8.

Retrospective review of laboratory monitoring in 515 patients with acne treated with isotretinoin. Their conclusions were to check a baseline lipid panel and liver function tests repeated after 2 months of isotretinoin therapy. If findings are normal, they recommend no further testing for healthy patients.

Does exposure to isotretinoin increase the risk for the development of inflammatory bowel disease? A meta-analysis. Lee SY, Jamal MM, Nguyen ET, et al. *Eur J Gastroenterol Hepatol* 2016; 28(2): 210–6.

A meta-analysis of six published studies examining the possible association of IBD with isotretinoin use. The results of the pooled data supported the previous conclusions that there is no increased risk of developing IBD in patients exposed to isotretinoin compared with patients not exposed to isotretinoin.

Clinical practice: polycystic ovary syndrome. McCartney CR, Marshall JC. *N Engl J Med* 2016; 375(1): 54–64.

A concise review of PCOS, including clinical features, diagnostic workup, and treatment.

First-Line Therapies

Mild acne

- Topical retinoid (adapalene, tretinoin, tazarotene, trifarotene) **A**
- Benzoyl peroxide **A**
- Fixed-dose combination adapalene/benzoyl peroxide **A**
- Fixed-dose combination tretinoin/clindamycin **A**
- Benzoyl peroxide, topical retinoid, and topical antibiotic **B**
- Topical dapsone **A**
- Azelaic acid **A**
- Salicylic acid **B**

Moderate acne

- Topical retinoid and BP **A**
- BP and topical antibiotic **A**
- Fixed-dose combination adapalene/benzoyl peroxide **A**
- Fixed-dose combination tretinoin/clindamycin **A**
- Topical retinoid, BP, and topical antibiotic **A**
- Topical retinoid, BP, and oral antibiotic **A**
- Topical retinoid, BP, topical antibiotic, and oral antibiotic **A**
- Fixed-dose combination adapalene/benzoyl peroxide and doxycycline **A**
- Fixed-dose combination tretinoin/clindamycin, BP and minocycline **B**

Severe acne

- Fixed-dose combination adapalene/benzoyl peroxide and doxycycline **A**
- Fixed-dose combination tretinoin/clindamycin, BP and minocycline **B**
- Topical retinoid and BP, and oral antibiotic **A**
- Oral isotretinoin **B**

Acne fulminans

- Oral isotretinoin with oral corticosteroids **C**

Guidelines of care for the management of acne vulgaris. Zaenglein AL, Pathy AL, Schlosser BJ, et al. *J Am Acad Dermatol* 2016; 74: 945–73.

The American Academy of Dermatology's evidence-based guidelines reviewing grading, topical, and systemic management of acne.

Treatment of acne in pregnancy. Chien AK, Qi J, Rainer B, et al. *J Am Board Fam Med* 2016; 29: 254–62.

A review on the safety profiles of common therapies used in pregnancy.

Evidence-based recommendations for the diagnosis and treatment of pediatric acne. Eichenfield LF, Krakowski AC, Piggott C, et al. *Pediatrics* 2013; 131(Suppl 3): S163–86.

Evidence-based recommendations regarding the classification, diagnosis, evaluation, and management of pediatric acne, based on age and pubertal status.

Comparing 2.5%, 5%, and 10% benzoyl peroxide on inflammatory acne vulgaris. Mills OH, Kligman AM, Pochi P, et al. *Int J Dermatol* 1986; 25: 263–7.

Three double-blind studies comparing daily benzoyl peroxide 2.5%, 5%, and 10% with their vehicles in patients with

mild-to-moderate acne, demonstrating equivalent efficacy of all concentrations with higher risk of irritation with higher concentrations.

Adapalene–benzoyl peroxide, a fixed-dose combination for the treatment of acne vulgaris: results of a multicenter, randomized, double-blind, controlled study. Thiboutot DM, Weiss J, Bucko A, et al. *J Am Acad Dermatol* 2007; 57(5): 791–9.

This randomized, double-blind controlled trial compared daily adapalene–benzoyl peroxide combination to adapalene, benzoyl peroxide, or vehicle alone in the treatment of acne vulgaris. The fixed-dose combination gel of daily adapalene and benzoyl peroxide was significantly more effective than respective monotherapies.

Treatment of acne with a combination clindamycin/benzoyl peroxide gel compared with clindamycin gel, benzoyl peroxide gel and vehicle gel: combined results of two double-blind investigations. Lookingbill DP, Chalker DK, Lindholm JS, et al. *J Am Acad Dermatol* 1997; 37(4): 590–5.

In the treatment of acne, the topical combination clindamycin/benzoyl peroxide gel was well tolerated and superior in efficacy to either ingredient alone.

Two randomized, double-blind, split-face studies to compare the irritation potential of two topical acne fixed combinations over a 21-day treatment period. Bhatia N, Bhatt V, Martin G, et al. *J Drugs Dermatol* 2016; 15: 721–6.

Clindamycin–BPO 3.75% gel is better tolerated than adapalene 0.3%–BP 2.5% gel in moderate-to-severe acne.

Efficacy and safety of clindamycin phosphate 1.2%/tretinoin 0.025% formulation for the treatment of acne vulgaris: pooled analysis of data from three randomised, double-blind, parallel-group, phase III studies. Dréno B, Bettoli V, Ochsendorf E, et al. *Eur J Dermatol* 2014; 24(2): 201–9.

Combination clindamycin/tretinoin was found to be safe and to have superior efficacy to its individual components and vehicle in the treatment of acne.

A treatment for severe nodular acne: a randomized investigator-blinded, controlled, noninferiority trial comparing fixed-dose adapalene/benzoyl peroxide plus doxycycline vs. oral isotretinoin. Tan J, Humphrey S, Vender R, et al. *Br J Dermatol* 2014; 171(6): 1508–16.

Multicenter randomized controlled non-inferiority trial involving 266 subjects treating severe nodular acne with either doxycycline plus adapalene/benzoyl peroxide or isotretinoin. Combination treatment showed a favorable composite efficacy and safety profile compared with isotretinoin and is an alternative to isotretinoin patients intolerant to or unable or unwilling to take isotretinoin.

Effective and safe combination therapy for severe acne vulgaris: a randomized, vehicle-controlled, double-blind study of adapalene 0.1%-benzoyl peroxide 2.5% fixed-dose combination gel with doxycycline hyclate 100 mg. Gold LS, Cruz A, Eichenfield L, et al. *Cutis* 2010; 85(2): 94–104.

This randomized, double-blind study compared the combination of adapalene/benzoyl peroxide plus oral doxycycline to oral doxycycline plus vehicle and found superior efficacy for the combination therapy in severe acne vulgaris.

Isotretinoin for acne vulgaris—10 years later: a safe and successful treatment. Layton AM, Knaggs H, Taylor J, et al. *Br J Dermatol* 1993; 129(3): 292–6.

Ten-year prospective study following patients with severe acne vulgaris treated with oral isotretinoin showing sustained benefit in the majority of patients and favorable safety profile.

Dairy intake and acne vulgaris: a systematic review and meta-analysis of 78,529 children, adolescents, and young adults. Juhl CR, Bergholdt HKM, Miller IM, et al. *Nutrients* 2018; 10(8): 1049.

A meta-analysis of available data on the association between dairy consumption and acne. The authors concluded that any dairy (milk, yogurt, and cheese) was associated with an increased OR for acne. However, they cautioned that heterogeneity and bias across studies prohibit any firm recommendations.

Second-Line Therapies

Mild acne

- Topical dapsone A
- Azelaic acid A

Moderate acne

- Combined oral contraceptive pills (females) A
- Oral spironolactone (females) B
- Oral isotretinoin A

Efficacy and safety of once-daily dapsone gel, 7.5% for treatment of adolescents and adults with acne vulgaris: first of two identically designed, large, multicenter, randomized, vehicle-controlled trials. Stein Gold LF, Jaratt MT, Bucko AD, et al. *J Drugs Dermatol* 2016; 15: 553–61.

A 12-week, randomized, double-blind, vehicle-controlled, multicenter clinical trial of patients ≥12 years with moderate inflammatory acne, where dapsone gel 7.5% applied topically once daily was shown to be an effective, safe, and well-tolerated regimen.

Efficacy and safety of topical azelaic acid (20 percent cream): an overview of results from European clinical trials and experimental reports. Graupe K, Cunliffe WJ, Gollnick HP, et al. *Cutis* 1996; 57(Suppl 1): 20–35.

Review of studies using azelaic acid in the treatment of mild-to-moderate acne vulgaris indicating favorable efficacy and safety profile compared to other standard acne treatments.

Efficacy and safety of 3 mg drospirenone/20 mcg ethinyl-estradiol oral contraceptive administered in 24/4 regimen in the treatment of acne vulgaris: a randomized, double-blind, placebo-controlled trial. Koltun W, Lucky AW, Thiboutot D, et al. *Contraception* 2008; 77: 249–56.

This non-androgenic progestin-containing contraceptive with strong antiandrogenic activity (drospirenone 3 mg) but reduced concentration of ethinyl estradiol (20 µg) has been shown to be effective and may replace the classic cyproterone acetate/ethinyl estradiol and chlormadinone acetate/ethinyl estradiol oral contraceptives due to an improved side-effect profile.

Meta-analysis comparing efficacy of antibiotics versus oral contraceptives in acne vulgaris. Koo EB, Petersen TD, Kimball AB. *J Am Acad Dermatol* 2014; 71(3): 450–9.

Systemic antibiotics had greater efficacy at 3 months; however, improvement in acne was equivalent between COC and antibiotics at 6 months. The authors concluded that COCs could be used first line as an alternative to systemic antibiotics for the long-term treatment of acne in women.

Low-dose adjunctive spironolactone in the treatment of acne in women: a retrospective analysis of 85 consecutively treated patients. Shaw JC. *J Am Acad Dermatol* 2000; 43(3): 498–502.

Retrospective review of 85 cases of women treated for acne vulgaris with 50–100 mg spironolactone daily as monotherapy or as an adjunct with other acne treatments, showing efficacy and safety in the majority of treated women.

Treatment of acne with spironolactone: a retrospective review of 395 adult patients at Mayo Clinic, 2007–2017. Roberts EE, Newshean S, Davis MDP, et al. *J Eur Acad Dermatol Venereol* 2020 Feb 20. [Epub ahead of print].

Retrospective review of adult women treated for acne vulgaris with spironolactone as monotherapy or as adjunctive treatment. Over 90% of patients had improvement in their acne across all acne grades and had a favorable safety profile.

Effectiveness of conventional, low-dose, and intermittent oral isotretinoin in the treatment of acne: a randomized, controlled comparative study. Lee JW, Yoo KH, Park KY, et al. *Br J Dermatol* 2011; 164(6): 1369–75.

Randomized trial comparing three different dosing regimens for isotretinoin to determine safety and efficacy in patients with moderate acne vulgaris. Both conventional (0.5–0.7 mg/kg daily for 24 weeks) and low-dose (0.25–0.4 mg/kg daily for 24 weeks) regimens were effective with durable remissions, with a more favorable side-effect profile for low-dose treatment. One week per month dosing (0.5–0.7 mg/kg daily) was ineffective.

Third-Line Therapies	
Mild acne	
• Spironolactone (females)	B
• Low-dose isotretinoin	B
• Photodynamic therapy (PDT)	B
• Serial chemical peels (glycolic acid, salicylic acid, others)	B
• Tea tree oil	B
• Nicotinamide	B
Moderate acne	
• Azelaic acid	A
• PDT	B

Low-cumulative dose isotretinoin treatment in mild-to-moderate acne: efficacy in achieving stable remission. Borghi A, Mantovani L, Minghetti S, et al. *J Eur Acad Dermatol Venereol* 2011; 25(9): 1094–8.

In this prospective clinical trial, 150 patients with mild-to-moderate acne were treated with isotretinoin until complete recovery plus an additional 1 month, independent of the total cumulative dose reached, followed by 1 year of topical adapalene 0.1% cream as maintenance. They were followed for an additional 1 year without treatment. At the end of the study, only 13 patients (9.25%) relapsed.

Comparison of a salicylic acid cleanser and a benzoyl peroxide wash in the treatment of acne vulgaris. Shalita AR. *Clin Ther* 1989; 11(2): 264–7.

Very short crossover study comparing salicylic acid and benzoyl peroxide wash for use in acne vulgaris. There was reduction in number of comedones when using salicylic acid as compared to benzoyl peroxide.

The efficacy of 5% topical tea tree oil gel in mild to moderate acne vulgaris: a randomized, double-blind placebo-controlled study. Enshaieh S, Jooya A, Hossein Siadat A, et al. *Indian J Dermatol Venereol Leprol* 2007; 73: 22–5.

This is a single-center controlled trial of 5% topical tea tree oil, applied twice daily for 20 minutes and then washed off, in 60 patients (30 treatment, 30 control) with mild-to-moderate acne. After 45 days, the treatment group experienced a 43.6% reduction in total lesion counts (21.16 before treatment to 11.33 after treatment) versus 12.0% in the placebo group (19.53 before treatment to 17.23 after treatment). Ten percent of the treatment group experienced pruritus.

Clinical evaluation of glycolic acid chemical peeling in patients with acne vulgaris: a randomized, double-blind, placebo-controlled, split-face comparative study. Kaminaka C, Uede M, Matsunaka H, et al. *Dermatol Surg* 2014; 40: 314–22.

A prospective, randomized, double-blind, placebo-controlled, split-face clinical trial of 26 patients with moderate acne who were treated with 40% glycolic acid (pH 2.0) on half the face and placebo on the other half five times at 2-week intervals showed significant improvement of moderate acne in Asians.

Randomized trial comparing a chemical peel containing a lipophilic hydroxy acid derivative of salicylic acid with a salicylic acid peel in subjects with comedonal acne. Levesque A, Hamzavi I, Seite S, et al. *J Cosmet Dermatol* 2011; 10: 174–82.

A split-face study. Twenty subjects received a total of six peels at 2-week intervals. There was no significant difference in response. Lipohydroxy acid is a lipophilic derivative of salicylic acid with comedolytic properties.

A comparative split-face study using different mild purpuric and subpurpuric fluence level of 595-nm pulsed-dye laser for treatment of moderate to severe acne vulgaris. Voravutinnon N, Rojanamatin J, Sadhwani D, et al. *Dermatol Surg* 2016; 42(3): 403–9.

In a split-face study of 62 patients with moderate-to-severe acne, each side of the face was treated with a 595-nm pulsed-dye laser with a 10 mm spot size at either purpuric (pulse duration of 6 milliseconds, fluence from 6 to 7.5 J/cm²) or subpurpuric (pulse duration of 6 milliseconds, fluence of 4 J/cm²). Both treatment protocols resulted in moderate, statistically significant decreases in acne (about 40% reduction in total lesion counts).

Photodynamic therapy for the treatment of different severity of acne: a systematic review. Keyal U, Bhatta AK, Wang XL. *Photodiagnosis Photodyn Ther* 2016; 14: 191–9.

PDT can control inflammatory and non-inflammatory acne lesions and can improve all acne lesions, ranging from mild to severe. More trials are needed to establish standard guidelines regarding concentrations and the incubation period of photosensitizers and optimal parameters of light sources.

Daylight photodynamic therapy with 1.5% 3-butenyl 5-aminolevulinic acid gel as a convenient, effective and safe therapy in acne treatment: a double-blind randomized controlled

trial. Kwon HH, Moon KR, Park SY, et al. *J Dermatol* 2016; 43: 515–21.

A study on the efficacy and safety of daylight PDT in acne treatment. The novel variant of 5-aminolevulinate (ALA)-ester, 1.5% 3-butenyl ALA-bu gel, was applied using daylight only as the potential visible light source. Forty-six acne patients were randomly assigned to either ALA-bu or vehicle application group in a double-blind fashion. Both groups applied the allocated gel to facial acne lesions every other day for 12 weeks. Daylight PDT was effective, very well tolerated, and convenient for treating inflammatory acne lesions.

Topical nicotinamide compared with clindamycin gel in the treatment of inflammatory acne vulgaris. Shalita AR, Smith JG, Parish LC, Sofman MS, Chalker DK. *Int J Dermatol*. 1995; 34(6): 434-7.

A double-blind, comparative trial of nicotinamide 4% gel and clindamycin 1% gel over 8 weeks. Both treatments had comparable efficacy.

Acrodermatitis enteropathica

Joanna E. Gach

Acrodermatitis enteropathica (AE) OMIM 201100 is a rare, autosomal-recessive, inherited disorder of zinc deficiency. It is caused by mutations in the *SLC39A4* gene located on 8q24.3, which encodes for *ZIP4* intestinal zinc transporter expressed in enterocytes that absorb dietary zinc from the small intestine. The estimated prevalence is 1 in 500,000 children worldwide, without apparent predilection for race or gender. AE manifests itself shortly after birth in a bottle-fed infant and sometime soon after weaning in a breast-fed infant. Zinc within breast milk is more bioavailable to infants than within bovine milk due to binding to a low-molecular-weight ligand secreted by the pancreas. Characteristic clinical signs are lesions in acral and periorificial sites; the first signs are eczematous, pink, scaly plaques that can become vesicular, bullous, pustular, or desquamative. They can resemble the severe diaper dermatitis of infancy or biotin deficiency. Angular cheilitis and paronychia can also be seen early. If left untreated, AE usually causes diarrhea, irritability, and alopecia, and skin lesions become secondarily infected with bacteria and *Candida albicans*. Impaired physical and mental development is seen in advanced disease. Appropriate supplementation of zinc in the infant's diet results in a rapid improvement.

The diagnosis of AE is applied only to *inherited* zinc deficiency; non-inherited zinc deficiency is called *acquired zinc deficiency*. Transient neonatal zinc deficiency OMIM 608118, caused by mutations of the *ZnT2/SLC30A2* in mothers, occurs in breast-fed, full-term infants due to low zinc concentrations in the mother's breast milk. Clinical symptoms identical to AE are alleviated with zinc supplementation to the infant, but not to the mother. Long-term therapy and management of zinc deficiency vary depending on the severity of the disorder.

MANAGEMENT STRATEGY

Chronic dermatitis in periorificial and acral areas should suggest the possibility of zinc deficiency but establishing the diagnosis of AE may be difficult. The first step is laboratory determination of blood plasma or serum zinc levels. A blood sample needs to be drawn into a trace element-free bottle with a stainless steel needle. Avoid contact with rubber stoppers as they contain zinc, avoid hemolysis, use zinc-free anticoagulants, and separate plasma or serum from cells within 45 minutes. Zinc levels will decrease in states of hypoalbuminemia because zinc binds albumin in the circulation. If the diagnosis of zinc deficiency has been confirmed, management becomes relatively simple: *oral zinc supplementation* produces dramatic resolution of the problem. High-dose supplementation will allow for increased paracellular zinc absorption despite the absence of a functional *ZIP4* zinc transporter.

The patient or his or her family must understand the need for lifelong management of the disorder in terms of zinc supplementation and medical supervision. Discuss *foods rich in zinc, such as shellfish, nuts, and green leafy vegetables*. Bioavailability of zinc can be reduced by phytates, which naturally occur in plant fibers, and with regular iron supplementation. With age and a more varied diet, the dose of daily zinc supplementation may be reduced. Zinc therapy should be monitored periodically with a morning fasting specimen, full blood count, serum copper level, and stool examination for occult blood. Zinc supplementation has a theoretical risk of reducing copper absorption, leading to refractory microcytic anemia that will not respond to iron therapy until the serum copper level is normalized.

Specific Investigations

- Morning fasting blood plasma or serum zinc levels
- Urine zinc excretion
- Serum albumin and alkaline phosphatase
- Serum copper levels
- Genetic studies

The normal plasma zinc level is 70–110 mcg/dL and in serum 80–120 mcg/dL. Urinary zinc can be measured but is not definitive for diagnosis.

Homozygosity mapping places the acrodermatitis enteropathica gene on chromosomal regions 8q24.3. Wang K, Pugh EW, Griffen S, et al. *Am J Hum Genet* 2001; 68: 1055–70.

Identification of *SLC39A4*, a gene involved in acrodermatitis enteropathica. Küry S, Dréno B, Bézieau S, et al. *Nature Genet* 2002; 31: 239–40.

Overview of inherited zinc deficiency in infants and children. Kambe T, Fukue K, Ishida R, et al. *J Nutr Sci Vitaminol* 2015; 61 Suppl: S44–6.

Genetic causes and gene-nutrient interactions in mammalian zinc deficiencies: acrodermatitis enteropathica and transient neonatal zinc deficiency as examples. Kasana S, Din J, Maret W. *J Trace Elem Med Biol* 2015; 29: 47–62.

First-Line Therapy

- Oral zinc supplementation

A

In most cases, oral supplementation with two to three times the recommended daily allowance of zinc salts in doses of 30–55 mg of elemental Zn^{2+} will be sufficient to restore normal zinc status within days to a few weeks, depending on the degree of depletion. The dose of elemental zinc must be determined by the patient's blood or plasma zinc levels and by body weight. In AE, zinc replacement should begin at 2–3 mg/kg/day of elemental zinc. Serum or plasma zinc should be checked every 3–6 months, adjusting the zinc dosage accordingly. In patients with acquired or dietary zinc deficiency, treatment should begin at 0.5–1 mg/kg/day. Available forms of zinc supplementation include zinc sulfate, zinc acetate, zinc gluconate, and zinc propionate. *Dosage must be based on the amount of elemental zinc present in the preparation, which varies between compounds. For example, a standard 125-mg effervescent tablet of a commercial zinc preparation contains approximately 45 mg Zn^{2+} , which is an adequate daily dose for deficient individuals. A commonly used preparation is Solvazinc, which is zinc sulfate monohydrate.*

A significant side effect of zinc supplementation is gastric irritation with nausea, vomiting, and gastric hemorrhage. Large accidental overdoses of zinc may cause fatal multisystem organ failure.

Zinc deficiency in acrodermatitis enteropathica: multiple dietary intolerance treated with synthetic diet. Barnes PM, Moynahan EJ. Proc Roy Soc Med 1973; 66: 327–9.

In 1973, Barnes and Moynahan were treating children with chronic, unresponsive AE-type acral dermatoses and having poor results. They then tried different medications, one of which was oral zinc. To their surprise, the patients receiving the zinc supplements cleared rapidly and completely.

The role of the Slc39a family of zinc transporters in zinc homeostasis in skin. Bin BH, Hojyo S, Seo J, et al. Nutrients 2018; 10(2): 219. doi: 10.3390/nu10020219.

An excellent review of AE and other zinc deficiency disorders.

Zinc therapy in dermatology: a review. Gupta M, Mahajan VK, Mehta KS, et al. Dermatol Res Pract 2014; 2014: 709152.

A detailed review of the use of zinc in over 20 dermatologic conditions.

Actinic keratosis

Sherrif F. Ibrahim, Marc D. Brown

Actinic keratoses (AKs) are ill-defined, pink to skin-colored, scaly lesions found on chronically sun-exposed areas in light-skinned individuals. They most frequently appear on the face, ears, balding scalp, extensor forearms, and dorsal hands. AKs are a strong predictor for the development of squamous cell carcinoma (SCC) and, to a lesser extent, basal cell carcinoma. Australians have the highest reported prevalence, which approaches 60%, and in the US, AKs are the second most common reason for visits to the dermatologist.

MANAGEMENT STRATEGY

AKs are common dysplastic intraepidermal lesions that are considered to be precursors to SCC. Reports have varied as to the rates of progression to invasive SCC, from 0.025% to over 25% per year, and AKs are commonly located adjacent to SCC histologically. For these reasons, most practitioners advocate the treatment of AKs, as considerable morbidity and potential mortality can be associated with invasive disease. In 2018, Weinstock and colleagues were the first to perform a randomized trial showing that topical treatment for AKs led to a significantly reduced need for surgery for SCC.

The diagnosis of AK is primarily clinical, and because of their superficial nature, a variety of effective management approaches exist. Biopsy of suspected AKs is typically not warranted; however, in patients with a history of multiple skin cancers, immunosuppressed patients, and lesions in high-risk areas such as the lip or ear, clinicians should have a low threshold for biopsy to rule out invasive SCC. Indications for biopsy include tenderness, rapid growth or thickening of lesions, bleeding, hyperkeratosis, and failure to respond to treatment.

Prevention of AKs through sun avoidance and diligent use of broad-spectrum sunscreens and blocking agents is an important aspect of management. This has been shown to prevent the development of new AKs and reduce the incidence of non-melanoma skin cancers.

With cumulative sun exposure and advancing age, rates of AK development increase, necessitating either *ablative* or field treatment. *Cryotherapy* with liquid nitrogen is by far the most commonly employed therapeutic modality for discrete lesions because it can be performed quickly and effectively in the office setting. However, given the common appearance of AKs on a background of diffuse actinic damage, individual lesions may be poorly defined and involve large, contiguous areas requiring field treatment with topical agents such as 5-fluorouracil (5-FU) or *imiquimod*, or with photodynamic therapy. The advantages of field approaches are that they are non-invasive, carry little risk, and can be used for anatomically difficult or cosmetically sensitive areas. Furthermore, they address both clinically apparent as well as subclinical areas of skin in contiguous fashion. Most of these agents must be used for weeks to months, result in some degree of erythema, inflammation, and discomfort, and require adequate patient compliance.

Photodynamic therapy (PDT) with aminolevulinic acid (ALA) or methyl aminolevulinate (MAL) has continued to become more widespread, given its proven therapeutic results and excellent cosmetic outcome. PDT offers a physician-administered approach to field treatment with shorter periods of inflammation and erythema than several topical agents and, thus, higher patient satisfaction. Variations in the light dose, light source, sensitizing agent and its application time, and frequency of treatments may improve efficacy. Most recently, PDT using natural daylight to excite the chemical sensitizer has gained popularity.

Head-to-head trials of different treatment approaches are difficult to perform, as variations in treatment protocols make direct comparisons challenging. Several well-designed trials have suggested topical 5-fluorouracil as the most effective stand-alone topical agent to treat AKs. Recently, there has been a growing trend towards *combination therapy*, such as topical agents either before or after cryotherapy, or sequential use of multiple field modalities with differing mechanisms of action. Other approaches such as *laser resurfacing*, *chemical peels*, and *dermabrasion* may be considered in certain situations when lesions have failed the above treatments, or if severe photodamage is present. Finally, for recalcitrant or hyperkeratotic lesions, *curettage* or *excision* may be appropriate.

Specific Investigation

- Biopsy

Actinic keratoses and the incidence of occult squamous cell carcinoma: a clinical-histopathologic correlation. Ehrig T, Cockerell C, Piacquadio D, et al. *Dermatol Surg* 2006; 32: 1261–5.

Two hundred and seventy-one clinically diagnosed AKs were biopsied. Clinical diagnosis agreed with histology 91% of the time, with about 1 in 25 lesions revealing invasive SCC.

Clinical recognition of actinic keratoses in a high-risk population: how good are we? Venna SS, Lee D, Stadecker MJ, et al. *Arch Dermatol* 2005; 141: 507–9.

Seventeen of 23 lesions (74%) with classic features of AK in patients with a history of previous skin cancer were confirmed histologically. Five lesions (22%) were shown to be SCC.

Actinic keratoses are typically diagnosed clinically. However, there should be a low threshold to biopsy tender, hyperkeratotic, large, or recalcitrant lesions to exclude malignancy.

First-Line Therapies

• Sunscreens	A
• Cryosurgery	B
• Topical 5-FU	A
• Imiquimod	A
• Photodynamic therapy	A

A randomized controlled trial to assess sunscreen application and beta carotene supplementation in the prevention of solar keratoses. Darlington S, Williams G, Neale R, et al. Arch Dermatol 2003; 139: 451–5.

In this Australian study, 1621 adults were randomized to either daily use of sunscreen or application at their usual discretionary rate. There was a 24% reduction in AKs in the daily use group.

Reduction of solar keratoses by regular sunscreen use. Thompson SC, Jolley D, Marks R. N Engl J Med 1993; 14: 1147–51.

In a 6-month randomized, placebo-controlled trial of 588 patients in Australia, SPF 17 sunscreen applied daily was found to both reduce the development of new AKs and increase the remission of existing AKs in comparison to a vehicle cream.

A prospective study of the use of cryosurgery for the treatment of actinic keratoses. Thai K, Fergin P, Freeman M, et al. Int J Dermatol 2004; 43: 687–92.

In this prospective multicenter study, 90 patients with 421 AKs on the face and scalp were treated with cryotherapy with a single freeze–thaw cycle using different freeze times. The patients were reviewed 3 months later. Overall, the complete response (CR) rate was 67.2%, varying from 39% for freeze times less than 5 s to 83% for times longer than 20 s. The authors also found that hypopigmentation was present in 29% of CR lesions. Patients rated cosmetic outcomes as good to excellent for 94% of CR lesions.

Chemoprevention of basal and squamous cell carcinoma with a single course of fluorouracil, 5%, cream: a randomized clinical trial. Weinstock MA, Thwin SS, Siegel JA, et al. JAMA Dermatol 2018 1; 154: 167–74.

In this randomized trial, 932 patients with a prior history of non-melanoma skin cancer received either 5-FU cream or vehicle twice daily for 2–4 weeks. There was a significantly reduced need for surgery to address SCC in the treatment arm.

Effective treatment of actinic keratosis with 0.5% fluorouracil cream for 1, 2 or 4 weeks. Weiss J, Menter A, Hevia O, et al. Cutis 2002; 70: 22–9.

In this randomized, double-blind, parallel-group vehicle-controlled study, 177 patients with at least five AKs were treated with topical 0.5% 5-FU cream daily for 1, 2, or 4 weeks. In patients who were treated for 4 weeks, complete clearance of lesions was observed in 47.5%, compared with 26% who were treated for 1 week ($p < 0.001$ vs vehicle). Moderate-to-severe irritation of the skin was noted in 90% of these patients.

Imiquimod 5% cream for the treatment of actinic keratosis: results from two phase III, randomized, double-blind,

parallel group, vehicle-controlled trials. Lebwohl M, Dinehart S, Whiting D, et al. J Am Acad Dermatol 2004; 50: 714–21.

In this report of two phase III double-blind, vehicle-controlled studies, 436 subjects at 24 centers in the US were randomized to either 5% imiquimod or vehicle applied once daily, two days per week, for 16 weeks. The complete clearance rate for the treated arm was 45%, as opposed to 3.2% for the vehicle group. The median percent reduction in AK lesions was 83% for the treated group and 0% for the vehicle group, indicating that a reduced frequency of imiquimod application is quite effective.

Imiquimod 2.5% and 3.75% for the treatment of actinic keratoses: results of two placebo-controlled studies of daily application to the face and balding scalp for two 3-week cycles. Hanke CW, Beer KR, Stockfleth E, et al. J Am Acad Dermatol 2010; 62: 573–81.

Imiquimod 2.5% and 3.75% for the treatment of actinic keratoses: results of two placebo-controlled studies of daily application to the face and balding scalp for two 2-week cycles. Swanson N, Abramovits A, Berman B, et al. J Am Acad Dermatol 2010; 62: 582–90.

These two back-to-back reports demonstrate the efficacy and tolerability of lower concentration formulations of imiquimod as well as alternate dosing schedules. Interestingly, the results were essentially identical for two 3-week cycles as they were for two 2-week cycles, with the 3.75% strength imiquimod proving superior to the 2.5% in both studies and slightly less efficacious than previous studies that have investigated 5% imiquimod used twice weekly for 16 weeks.

A randomised study of topical 5% imiquimod vs. topical 5-fluorouracil vs. cryosurgery in immunocompetent patients with actinic keratoses: a comparison of clinical and histological outcomes including 1-year follow-up. Krawtchenko N, Roewert-Huber J, Ulrich M, et al. Br J Dermatol 2007; 157 Suppl 2: 34–40.

This study compared the baseline and 1-year follow-up rates of clinical clearance, histological clearance, and cosmetic outcomes of imiquimod, 5-FU, and cryosurgery for the treatment of AKs. Patients were randomized to one of the three treatment groups. Clinical clearance was achieved in 68% of those treated with cryosurgery, 96% with 5-FU, and 85% with imiquimod. Histological clearance rate was 32% for cryosurgery, 67% for 5-FU, and 73% for imiquimod. The 1-year sustained clearance rate was 28% for cryosurgery, 54% for 5-FU, and 73% for imiquimod. The patients treated with imiquimod were also judged to have superior cosmetic outcomes.

Randomized trial of four treatment approaches for actinic keratosis. Jansen MHE, Kessels JPHM, Nelemans PJ, et al. N Engl J Med 2019; 380: 935–46.

This study included 624 patients with AKs over a 3-year span and randomized them to receive treatment with 5-FU, 5% imiquimod, MAL-PDT, or 0.015% ingenol mebutate. At 12 months after the end of treatment, 5-FU was the most effective monotherapy.

A real world, community-based cohort study comparing the effectiveness of topical fluorouracil versus topical imiquimod for the treatment of actinic keratosis. Neugebauer R, Levandoski KA, Zhu Z, et al. J Am Acad Dermatol. 2018; 78: 710–6.

The authors studied 5700 patients with a diagnosis of AK treated with either 5-FU or imiquimod in 2007 and followed

them for short-term (2-year) and long-term (5-year) incidence of subsequent AK. They concluded that 5-FU was superior to imiquimod in the short term, with no difference in the long-term prevention of future AKs.

Intraindividual, right-left comparison of topical methyl aminolaevulinate-photodynamic therapy and cryotherapy in subjects with actinic keratoses: a multicentre, randomized controlled study. Morton C, Campbell S, Gupta G, et al. *Br J Dermatol* 2006; 155: 1029–36.

In this 24-week study, subjects received one treatment session of PDT to one side of their face and two cycles of freeze-thaw cryosurgery to the other. Of the 1501 lesions treated, PDT resulted in a higher rate of cure (87% vs 76% reduction from baseline). Both subjects and investigators preferred PDT and also felt it had a better cosmetic outcome. Both treatment regimens were deemed safe and well tolerated.

Photodynamic therapy with aminolevulinic acid topical solution and visible blue light in the treatment of multiple actinic keratoses of the face and scalp: investigator-blinded, phase 3, multicenter trials. Piacquadio DJ, Chen DM, Farber HF, et al. *Arch Dermatol* 2004; 140: 41–6.

In this randomized, placebo-controlled study, 243 patients were randomized to receive vehicle or aminolevulinic acid (ALA) followed by PDT within 14–18 hours. Clinical response rate was based on complete clearing of 75% of lesions measured at weeks 8 and 12. Of the PDT-treated group, 77% had a complete response by week 8 and 89% by week 12. This compared to 18% and 13% for the placebo group. Most patients experienced erythema and edema at the treated sites, which improved within 4 weeks of therapy. Stinging, burning, or pain occurred during the treatments, but resolved within 24 hours.

A randomized pilot comparative study of topical methyl aminolevulinate photodynamic therapy versus imiquimod 5% versus sequential application of both therapies in immunocompetent patients with actinic keratosis: clinical and histologic outcomes. Serra-Guillen C, Nagore E, Hueso L, et al. *J Am Acad Dermatol* 2012; 66: e131–7.

In this study, 105 patients with actinic keratoses were randomized to receive MAL-PDT, 5% imiquimod 3 times/week for 4 weeks, or MAL-PDT followed by imiquimod 1 month later. The clinical and histologic response was high for all three groups with imiquimod providing higher response rates than PDT, but sequential treatment performing better than either monotherapy alone. PDT alone was rated the most satisfactory treatment of the three approaches.

Results of an investigator-initiated single-blind split-face comparison of photodynamic therapy and 5% imiquimod cream for the treatment of actinic keratoses. Hadley J, Tristani-Firouzi P, Hull C, et al. *Dermatol Surg* 2012; 38: 722–7.

In this split-faced trial, 61 patients received 5% imiquimod twice weekly to half the face and two sessions of ALA-PDT to the other side of the face. No significant difference was noted with respect to partial or total clearance rate; however, ALA-PDT was superior when mean lesion reduction rate was evaluated.

Treatment of actinic keratosis: a randomized split-site approach comparison of sequential 5-fluorouracil and 5-aminolevulinic acid photodynamic therapy to 5-aminolevulinic acid photodynamic monotherapy. Pei S, Kaminska ECN, Tsoukas MM. *Dermatol Surg* 2017; 43: 1170–5.

These patients received sequential 5-FU and PDT on one side of the face vs PDT alone on the other. The sequentially treated side had a highly significantly improved result in AK clearance at both 6- and 12-months post treatment.

Second-Line Therapies

• Topical adapalene	A
• Topical diclofenac	A
• Topical ingenol mebutate	A

Assessment of adapalene gel for the treatment of actinic keratoses and lentigenes: a randomized trial. Kang S, Goldfarb MT, Weiss JS, et al. *J Am Acad Dermatol* 2003; 49: 83–90.

In this prospective randomized, vehicle-controlled study, 90 patients received either 0.1% adapalene gel, 0.3% adapalene gel, or vehicle gel, initially daily for 4 weeks, then twice daily for up to 9 months. Overall, 62% ($p < 0.01$) of those who received 0.1% adapalene gel and 66% ($p < 0.01$) of those who received 0.3% adapalene gel showed at least a moderate improvement of their AKs, compared with 34% of patients receiving a vehicle cream. Adapalene gel recipients reported a higher level of mild erythema, peeling, and dryness in comparison to control groups.

Three percent diclofenac in 2.5% hyaluronan gel in the treatment of actinic keratoses: a meta-analysis of the recent studies. Pirard D, Vereecken P, Mélot C, et al. *Arch Dermatol Res* 2005; 297: 185–9.

This meta-analysis pooled 364 patients from three studies that compared diclofenac to hyaluronan vehicle gel. Overall, patients treated with diclofenac had a significantly higher rate of complete clearance of lesions. They concluded that complete response rates were 39% with a mean treatment duration of 75 ± 21 days. Mild-to-moderate skin irritation was the major side effect of the treatment group.

Diclofenac sodium 3% gel in the treatment of actinic keratoses postcryosurgery. Berlin JM, Rigel DS. *J Drugs Dermatol* 2008; 7: 669–73.

This prospective, double-arm, multicenter, open-label, phase 4 study aimed to determine the efficacy of sequential therapy of AKs with cryosurgery followed by diclofenac for 90 days. Forty-six percent of subjects who underwent combination treatment achieved 100% lesion clearance, compared to 21% in the cryosurgery-alone arm. This is a good example of newly emerging strategies involving combinations of established treatment modalities.

Phase IV open-label assessment of the treatment of actinic keratosis with 3.0% diclofenac sodium topical gel (Solaraze). Nelson C, Rigel D, Smith S, et al. *J Drugs Dermatol* 2004; 3: 401–7.

This study evaluated the treatment and efficacy of diclofenac applied twice daily for 90 days with a 30-day follow-up. Of the 67 patients who completed the study, 78% had $\geq 75\%$ clearance of AKs, which improved to 85% by the 30-day follow-up. Dry skin and rash at the application site were the most common side effects of treatment.

Diclofenac sodium 3% gel for the management of actinic keratosis: 10+ years of cumulative evidence of efficacy and safety. Martin GM, Stockfleth E. *J Drugs Dermatol* 2012; 11: 600–8.

This comprehensive review draws from 17 publications beyond the initial phase 3 clinical trials that led to the approval of diclofenac sodium for the treatment of AKs. It discusses the data regarding treatment efficacy, tolerability, and performance in comparison to other topical field agents, as well as its use in combination treatment strategies.

Long-term clinical outcomes of imiquimod 5% cream vs. diclofenac 3% gel for actinic keratosis on the face or scalp: a pooled analysis of two randomized control trials. Gollnick H, Dirschka T, Ostendorf R, et al. *J Eur Acad Dermatol Venereol* 2020; 34: 82–9.

In this paper, 479 patients with 5–10 AKs treated with either imiquimod or diclofenac were followed for 3 years after treatment. The imiquimod group had lower high grade AKs, invasive SCCs, and recurrence of AKs.

Ingenol mebutate gel for actinic keratosis. Lebwohl M, Swanson N, Anderson LL, et al. *N Engl J Med* 2012; 366: 1010–9.

This multicenter, randomized, double-blind report investigated the use of 0.015% ingenol mebutate used once daily for 3 consecutive days for AKs on the face and scalp, as well as 0.05% IM used once daily for 2 consecutive days for AKs on the trunk and extremities. All analyses were conducted at day 57. The rate of complete clearance was 42% for the face/scalp group and 34% for the trunk/extremities group. Local skin reactions peaked between days 3–8 and were mild to moderate in nature. Hypertrophic or hyperkeratotic lesions were excluded from the study.

Randomized, double-blind, double-dummy, vehicle-controlled study of ingenol mebutate gel 0.025% and 0.05% for actinic keratosis. Anderson L, Schmieder GJ, Werschler WP, et al. *J Am Acad Dermatol* 2009; 60: 934–43.

Two hundred and twenty-two patients from 22 US centers with non-facial AKs were randomized to receive vehicle for 3 days, 0.025% ingenol mebutate (IM) gel for 3 days, vehicle for 1 day followed by 0.05% IM gel for 2 days, or 0.05% IM gel for 3 days. Partial clearance rate (>75% reduction in baseline AKs) as well as complete clearance rate was statistically significantly higher in all three treatment groups over baseline and these results were dose dependent. Partial and complete clearance rates were 28%/20% for the 0.025% × 3 days group, 34%/24% for the 0.05% × 2 days group, and 43%/31% for the 0.05% × 3 days cohort. The most common local skin responses seen in all groups included erythema, scaling, crusting, swelling, erosion/ulceration, vesiculation, and pigmentary changes, and were largely resolved by day 15. Patient satisfaction was high.

Efficacy and safety of ingenol mebutate gel in field treatment of actinic keratosis on full face, balding scalp, or approximately 250 cm² on the chest: a phase 3 randomized controlled trial. Hanke CW, Albrecht L, Skov T, et al. *J Am Acad Dermatol* 2020; 82: 642–50.

For this trial, patients with 5–20 AKs received 3 days of IM treatment vs vehicle. There were higher rates of complete clearance, 75% clearance, and sustained clearance in the treatment arm vs vehicle alone.

Third-Line Therapies

• Curettage	E
• Excision	E
• Ablative lasers	B
• Chemical peels	D
• Dermabrasion	D

Guidelines for the management of actinic keratoses. de Berker D, McGregor JM, et al. *Br J Dermatol* 2007; 156: 222–30.

Recalcitrant treatment-resistant AKs may be treated with curettage or surgical excision. Both techniques enable tissue to be obtained for the purposes of histological analysis. Curettage can be used alone or in conjunction with electrosurgery, cryotherapy, or chemical applications. Surgical excision is particularly useful in lesions suspected of being SCC because this technique enables the clinician to treat the lesion and establish the diagnosis.

Widespread, extensive AKs may benefit from field treatments of a physically destructive nature. These include ablative laser resurfacing, dermabrasion, and chemical peels.

Full face laser resurfacing: therapy and prophylaxis for actinic keratoses and non-melanoma skin cancer. Iyer S, Friedli A, Bowes L, et al. *Lasers Surg Med* 2004; 34: 114–9.

In this retrospective study of 24 patients with over 30 AKs on the face treated with full-face UltraPulse CO₂ laser or erbium Er:YAG laser resurfacing, the authors found that 21 patients remained lesion free for at least 1 year.

Recurrence rates and long-term follow-up after laser resurfacing as a treatment for widespread actinic keratoses on the face and scalp. Ostertag JU, Quaedvlieg PJ, Neumann MH, et al. *Dermatol Surg* 2006; 32: 261–7.

A retrospective case-control study of 25 patients who underwent laser resurfacing for widespread AKs on the scalp and/or face. Forty-four percent had no recurrences in an average follow-up period of 39 months (range 7–70 months).

Laser-assisted photodynamic therapy for actinic keratosis: a systematic review and meta-analysis. Steeb T, Schlager JG, Kohl C, et al. *J Am Acad Dermatol*. 2019; 80: 947–56.

For this analysis, seven randomized controlled trials were reviewed to conclude that laser-assisted PDT showed significantly higher clearance rates than PDT monotherapy.

Single ablative fractional resurfacing laser treatment for forearm actinic keratosis: 6-month follow-up data from an inpatient comparison between treated and untreated sites. Chen R, Wargo JJ, Williams A, et al. *Lasers Surg Med* 2020; 52: 84–7.

In this study, 30 subjects with AKs on both arms underwent a single fractionally ablative laser treatment to one forearm and AKs were recorded at several time points. There was a 62% reduction in AKs in the treated arm at 6 months after treatment.

This result makes us question results as seen in the prior study listed – does ablative laser treatment make PDT more efficient, or is it acting to directly reduce the number of AKs?

Randomized controlled trial comparing 35% trichloroacetic acid peel and 5-aminolaevulinic acid photodynamic therapy for treating multiple actinic keratosis. Holzer G, Pinkowicz A, Radakovic S, et al. *Br J Dermatol* 2017; 176: 1155–61.

In this study, 28 patients were treated with trichloroacetic acid (TCA) in one area and photodynamic therapy (PDT) on another and assessed by a blinded investigator at several time points after treatment. ALA-PDT provided significantly better clinical results than TCA.

Nonablative fractional photothermolysis for facial actinic keratoses: 6-month follow-up with histologic evaluation. Katz TM, Goldberg LH, Marquez D, et al. *J Am Acad Dermatol* 2011; 65: 349–56.

In this study, 14 patients underwent five treatments of non-ablative fractional resurfacing with 32–40% surface area coverage at 2–4-week intervals. Clinical images and biopsies were evaluated. Although clinical images had a reduced number of AKs, virtually all histologic specimens were positive for features of AK and/or SCC. It was concluded that fractional non-ablative resurfacing was not adequate therapy for AKs.

A clinical comparison and long-term follow-up of topical 5-fluorouracil versus laser resurfacing in the treatment of widespread actinic keratoses. Ostertag JU, Quaedvlieg PJ, van der Geer S, et al. *Lasers Surg Med* 2006; 38: 731–9.

A prospective randomized trial of 55 patients comparing 5-FU with Er:YAG laser resurfacing. At 3, 6, and 12 months there were significantly fewer recurrences in the laser group than in the 5-FU group. Side effects were more common in the group treated with laser resurfacing. Side effects included erythema and hypopigmentation.

Long-term efficacy and safety of Jessner's solution and 35% trichloroacetic acid vs 5% fluorouracil in the treatment of

widespread facial actinic keratoses. Witheiler DD, Lawrence N, Cox SE, et al. *Dermatol Surg* 1997; 23: 191–6.

In this prospective study, 15 patients with severe facial AKs were treated on one side of the face with a single application of Jessner's solution – a medium-depth chemical peel – and the other side with twice-daily applications of topical 5-FU 5% for 3 weeks. The authors found that both treatments resulted in a similar reduction of AKs at 12 months, with an increase in the number of AKs in both groups from 12 to 32 months. The authors concluded that both treatments were similarly efficacious in the treatment of AK, and that retreatment for recurrences might be necessary after 12 months.

Dermabrasion for prophylaxis and treatment of actinic keratoses. Coleman WP 3rd, Yarborough JM, Mandy SH. *Dermatol Surg* 1996; 22: 17–21.

In this retrospective study, 23 patients who had undergone dermabrasion for facial AKs were followed for 2–5 years. The authors found that the benefits of dermabrasion diminished with time: 1-year postdermabrasion, 22 patients remained clear of AKs. Of 13 patients who were followed up for 5 years, seven remained clear. The authors concluded that dermabrasion provided long-term clearance of AKs in some patients.

Actinic prurigo

Marianne de Brito, Ian H. Coulson, Tsui Chin Ling

(Synonyms: hereditary polymorphic light eruption of American Indians, Hutchinson summer prurigo, photodermatitis in North American Indians)

Actinic prurigo (AP) is a distinct photodermatosis, diagnosed on the basis of characteristic clinical features and supported by phototest results and human leukocyte antigen (HLA) typing. It has a perennial nature, although it tends to be worse in the sunnier months in countries with seasonal variation in sunlight exposure. Morphologically, it presents as a papular or mixed papulovesicular eruption during acute flares, persistent eczematized nodules, and/or dermatitic patches, scarring, dorsal nose involvement, cheilitis, and conjunctivitis. Exposed skin tends to be more severely affected than unexposed skin, but it is not unusual for covered areas, such as the buttocks, to be involved. Abnormal photosensitivity (to ultraviolet A [UVA], ultraviolet B [UVB]) is frequently severe, but when onset has been in childhood, the condition generally gradually improves, probably largely by patients learning to adapt to their photosensitivity.

MANAGEMENT STRATEGY

Diagnosing AP requires a high index of suspicion for the general dermatologist. Differential diagnoses include severe polymorphic light eruption and photoaggravated atopic dermatitis. Although differences between European and Amerindian forms of AP have been described, these are either closely related conditions or the same disease with some differences affected by population and environment. Full phototesting and HLA typing is needed to confirm the diagnosis and establish the severity of the photosensitivity. Photopatch testing may reveal coexisting sunscreen allergies and help guide the choice of suitable sunscreens.

Once the diagnosis is established, initial management consists of advice on *photoprotective* measures (behavioral, clothing, and sunscreen use) and the use of potent or very potent *topical*

corticosteroids for acute flares. *Topical tacrolimus* can also be considered, especially if prolonged treatment to the face is required. This approach alone is often insufficient. Some patients may benefit from the addition of a springtime course of narrowband (TL-01) UVB or psoralen-ultraviolet A (PUVA) phototherapy to enable skin hardening. When *phototherapy* is administered for this indication, only normally photoexposed sites need be treated. It is helpful to apply a potent topical steroid to the treated areas immediately after each exposure to reduce the risk of AP flares.

In the UK, systemic treatment is sometimes required. *Thalidomide* is usually effective, but its value is restricted by teratogenicity and the risk of irreversible peripheral neuropathy; *antimalarials* and *β -carotene* are of doubtful value. *Pentoxifylline* has anti-tumor necrosis factor (TNF)- α effects and, although listed as a third-line therapy here, may sometimes be worth considering before thalidomide because of its more attractive safety profile. Elevated serum immunoglobulin E (IgE) levels have been associated with moderate-to-severe clinical AP, suggesting involvement of the Th2-mediated inflammatory pathway. This was successfully targeted by dupilumab in a case report of a pediatric patient and raises the possibility of treatment with biologics for refractory cases in the future.

Specific Investigations

- Phototesting
- HLA typing
- IgE levels

Phototesting may reveal reduced erythmal thresholds on monochromator testing. Typical lesions are sometimes provoked with UVA or solar simulator. Up to 60% of white Caucasian AP patients may carry the HLA-DRB1*0407 subtype, but this may be negative in 40% and diagnosis may need to be supported by clinical and other phototest findings.

Actinic prurigo—a specific photodermatosis? Addo HA, Frair-Bell W. *Photodermatology* 1984; 1: 119–28.

This study showed that almost 60% of AP patients have abnormal delayed erythema on monochromator phototesting.

Phototest abnormalities tend to be more severe in AP than in polymorphic light eruption.

Actinic prurigo among the Chimila Indians in Colombia: HLA studies. Bernal JE, Duran de Rueda MM, Ordóñez CP, et al. *J Am Acad Dermatol* 1990; 22: 1049–51.

In this population, the HLA class I antigen Cw4 was more frequent in AP patients than in controls.

HLA-DR4 may determine expression of actinic prurigo in British patients. Menage H du P, Vaughan RW, et al. *J Invest Dermatol* 1996; 106: 362–7.

Actinic prurigo and HLA-DR4. Dawe RS, Collins P, O'Sullivan A, et al. *J Invest Dermatol* 1997; 108: 233–4.

An even stronger association with the HLA class II antigen HLA-DR4 was shown and, more specifically, with HLA-DRB1*0407.

Association of HLA subtype DRB1*0407 in Colombian patients with actinic prurigo. Suárez A, Valbuena MC, Rey M, et al. *Photodermatol Photoimmunol Photomed* 2006; 22: 55–8.

These associations are not a feature of polymorphic light eruption. The absence of HLA-DR4 can help to rule out the diagnosis of AP, whereas the presence of HLA-DRB1*0407 helps to rule in the diagnosis.

Actinic prurigo: clinical features and HLA associations in a Canadian Inuit population. Wiseman MC, Orr PH, MacDonald SM, et al. *J Am Acad Dermatol* 2001; 44: 952–6.

No statistically significant association of AP with HLA-DR4 (frequent in the studied population) or HLA-DRB1*0407 was detected, and another HLA type (DRB1*14) was found more commonly than expected, although it was only present in 19 of 37 AP subjects. The authors acknowledge the possibility that they were studying a different condition from AP in other populations.

Actinic prurigo in Singaporean Chinese: a positive association with HLA-DRB1*03:01. Chen Q, Shen M, Heng YK, et al. *Photochem Photobiol* 2016; 92: 355–9.

In this population the strongest association was with HLA-DRB1*03:01, although it should be noted that although a strong association was compared with controls, only six of these 14 Chinese Singaporean patients diagnosed with AP had this HLA allele.

These findings suggest we should be cautious in attempting to use HLA typing as a diagnostic test, especially in populations in which strong HLA associations have not been confirmed. The diagnosis should still be based on the characteristic constellation of clinical features.

Actinic prurigo of the lower lip – review of the literature and report of five cases. Mounsdon T, Kratochvil F, Auclair P, et al. *Oral Surg Oral Med Oral Pathol* 1988; 65: 327–32.

Follicular cheilitis – a distinctive histopathologic finding in actinic prurigo. Herrera-Geopfert R, Magana M. *Am J Dermatopathol* 1995; 17: 357–61.

Actinic prurigo cheilitis: clinicopathologic analysis and therapeutic results in 116 cases. Vega-Memije ME, Mosqueda-Taylor A, Irigoyen-Camacho ME, et al. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 2002; 94: 83–91.

A ‘follicular cheilitis’ has been reported to be characteristic of AP. Thirty-two of 116 patients attending a dermatology clinic in Mexico City had cheilitis as their sole manifestation of disease.

Lip histopathology may be helpful diagnostically, especially in patients presenting with cheilitis without cutaneous features at presentation. Where other typical features (skin, eyes) are present, it is arguable how much lip histopathology will contribute to diagnosis.

Correlation of serum IgE levels and clinical manifestations in patients with actinic prurigo. Cuevas-Gonzalez JC, Lievanos-Estrada Z, Vega-Memije ME, et al. *An Bras Dermatol* 2016; 91: 1–23.

A case-control study of 21 patients with a clinical and histopathological diagnosis of AP and 21 controls showed elevated levels in 11 of 21 patients (compared with no controls). Those with elevated levels were more likely to have moderate-to-severe clinical lesions.

Raised serum IgE levels may correlate with AP severity, which may be of limited use diagnostically; this raises the possibility of a Th2-inflammatory pathway targeted biologic agents.

Topical photoprotection for hereditary polymorphic light eruption of American Indians. Fusaro RM, Johnson JA. *J Am Acad Dermatol* 1991; 24: 744–6.

The authors of this open study found 18 of 30 patients with hereditary polymorphic light eruption of American Indians (with described features indistinguishable from AP) to show ‘good to excellent results’ with use of a broad-spectrum sunscreen.

Although broad-spectrum sunscreens are useful, advice on other sunlight avoidance measures, including appropriate clothing and behavioral avoidance, is equally important.

Actinic prurigo deterioration due to degradation of Derma-Gard window film. Kerr AC, Ferguson J. *Br J Dermatol* 2007; 157: 619–20.

Window films that reduce the transmission of UV rays can be used as a method of environmental photoprotection. This case report describes an exacerbation of AP explained by increased transmission through such a window film as it aged. Because the technology of such window films has matured, such degradation now might be less likely, but the possibility of it should be considered.

Treatment of actinic prurigo with intermittent short-course topical 0.05% clobetasol 17-propionate: a preliminary report. Lane PR, Moreland AA, Hogan DJ. *Arch Dermatol* 1990; 126: 1211–3.

Seven out of eight patients treated with intermittent 3- to 14-day courses of topical 0.05% clobetasol 17-propionate cream or ointment cleared or markedly improved. All had previously found less potent topical steroids ineffective.

Narrow-band UVB (TL-01) phototherapy: an effective preventative treatment for the photodermatoses. Collins P, Ferguson J. *Br J Dermatol* 1995; 132: 956–63.

Six patients with AP were included in this open study. All reported at least a sixfold increase in tolerable duration of sunlight exposure, which was sustained 4 months after treatment. In one patient whose phototesting (severely abnormal before treatment) was repeated after treatment, the test results normalized.

Actinic prurigo: treatment with tacrolimus. Favorable response in two pediatric patients. Vivoda JL, Mantero N, Jaime LJ, et al. *Rev Arg Derm* 2015; 96: 30–4.

These two girls showed a good response by 10 days of treatment with tacrolimus ointment.

Treatment of actinic prurigo with tacrolimus 0.1%. Gonzalez-Carrascosa Ballesteros M, De la Cueva DP, et al. *Med Cutan Ibero Lat Am* 2006; 34: 233–6.

A 13-year-old boy with only facial involvement with AP was reported to respond rapidly to 0.1% tacrolimus ointment after failure to respond to topical corticosteroids.

Tacrolimus ointment can be helpful in treating facial AP, especially when there are concerns about topical corticosteroid adverse effects.

The quality of life of 790 patients with photodermatoses. Jong CT, Finlay AY, Pearse AD, et al. *Br J Dermatol* 2008; 159: 192–7.

Of the photodermatoses assessed in the British tertiary referral photodermatology centers participating in this study, AP was associated with the greatest health-related quality of life impairment.

First-Line Therapies

• Photoprotective measures – environmental, behavioral, clothing, sunscreen use, window UV films	C
• Potent/very potent topical corticosteroids	C
• Topical tacrolimus	E
• Narrowband (TL-01 lamp) UVB phototherapy	C

Second-Line Therapies

- PUVA photochemotherapy **C**
- Thalidomide **C**

Treatment of actinic prurigo with PUVA: mechanism of action. Farr PM, Diffey BL. *Br J Dermatol* 1989; 120: 411–8.

Five patients were treated in this open study. Clinical improvement was accompanied by an increase of UVA minimal erythral doses to within the normal range on phototesting. Corroboration that PUVA worked through a local effect was provided by before and after phototesting of areas kept covered during treatment. The UVA minimal erythema dose did not increase in these areas.

In the absence of any controlled study comparisons of PUVA and TL-01 phototherapy for this condition, PUVA should generally be reserved for those who fail to benefit from TL-01.

Thalidomide in the treatment of actinic prurigo. Londoño F. *Int J Dermatol* 1973; 12: 326–8.

Thirty-four patients were treated, with a starting dose of 300 mg thalidomide daily, gradually reducing to a minimum of 15 mg; 32 had good results while on the drug but relapsed on stopping.

Thalidomide in actinic prurigo. Lovell CR, Hawk JL, Calnan CD, et al. *Br J Dermatol* 1983; 108: 467–71.

Of 14 British patients treated with thalidomide (adult starting dose 100–200 mg daily), 13 reported improvement. One could not tolerate the drug due to dizziness. This benefit was sustained in 11 patients, of whom eight required maintenance doses of between 50 mg weekly and 100 mg daily.

Includes a review of earlier open studies reporting the use of thalidomide in AP.

Third-Line Therapies

- β -Carotene **C**
- Pentoxifylline **C**
- Tetracycline and vitamin E **C**
- Oral corticosteroids **E**
- Azathioprine **E**
- Chloroquine **E**
- Ciclosporin eye drops **E**
- Ciclosporin A **E**
- Dupilumab **E**

Hereditary polymorphic light eruption in American Indians: photoprotection and prevention of streptococcal pyoderma and glomerulonephritis. Fusaro RM, Johnson JA. *JAMA* 1980; 244: 1456–9.

Seventeen of 54 patients who participated in this open study were reported to have achieved complete photoprotection, and 16 'marked improvement'. The plasma carotene level tended to be higher in those who benefited. The authors also comment on their use of dihydroxyacetone and Lawsone cream, with apparent benefit.

The clinical features of the study patients were not reported, but the authors' introductory description of hereditary polymorphic light eruption suggests that they probably included AP.

Pentoxifylline in the treatment of actinic prurigo: a preliminary report of 10 patients. Torres-Alvarez B, Castanedo-Cazares JP, Moncada B. *Dermatology* 2004; 208: 198–201.

Clinical improvement was reported in all 10 participants in this 6-month open-label uncontrolled study.

Treatment of actinic prurigo in Chimila Indians. Duran MM, Ordóñez CP, Prieto JC, et al. *Int J Dermatol* 1996; 35: 413–6.

One group of eight patients was treated with tetracycline (1.5 g daily), and another eight with vitamin E (100 IU daily). On follow-up analysis comparing signs and itch, no difference was found between the groups. Both treatments were considered promising and the possibility of using a tetracycline–vitamin E combination therapy was raised.

These treatments need further investigation but may be worth considering if first-line therapies are inadequate and thalidomide is contraindicated or not tolerated.

The clinical features and management of actinic prurigo: a retrospective study. Lestarini D, Khoo LS, Goh CL. *Photodermatol Photoimmunol Photomed* 1999; 15: 183–7.

This is a review of the features and clinical course of 11 patients. Of three treated with systemic corticosteroids, one improved slightly. Intralesional steroids helped one. Three patients were treated with azathioprine: two appeared to benefit.

Topical cyclosporine in the treatment of ocular actinic prurigo. Ortiz-Castillo JV, Boto-de-los-Bueis A, De-Lucas-Laguna R, et al. *Arch Soc Esp Oftalmol* 2006; 81: 661–4.

In these two case reports, topical 2% ciclosporin eye drops were associated with improvement in chronic AP conjunctivitis.

Lymphocyte subtypes and adhesion molecules in actinic prurigo: observations with cyclosporin A. Umaña A, Gómez A, Durán MM, et al. *Int J Dermatol* 2002; 41; 3: 139–45.

Eighteen of 19 patients reported to have significant clinical improvement in lesions and pruritis after 2 months of treatment with ciclosporin A, sustained 6 months after cessation.

Actinic prurigo in Scandinavian adolescent successfully treated with cyclosporine A. Sitek JC. *Dermatol Reports* 2017; 9; 1: 7050.

A case report of an 11-year-old girl with typical lesions and HLA-DRB1*0407 allele refractory to photoprotection, potent steroids, and tetracyclines whose skin became clear after 4 months of ciclosporin A.

Clearance of pediatric actinic prurigo with dupilumab. Eickstaedt JB, Starke S, Krakora D, et al. *Pediatr Dermatol* 2020; 37; 6: 1176–1178.

Case report of successful treatment with dupilumab of a pediatric patient with AP with cheilitis, refractory to topical steroids and methotrexate (although with response to ciclosporin). Skin almost cleared at 8 weeks, sustained response at 7 months.

Dupilumab, an anti-IL-4 receptor antagonist, targets Th2-mediated inflammation and could be a way to avoid systemic side effects of thalidomide and ciclosporin if topical treatments are ineffective, as in this pediatric case.

Actinomycosis

Jonathan E. Blume, Daniel Caplivski

Actinomycosis is an indolent infection that may be difficult to recognize initially and is caused by an anaerobic, Gram-positive rod that is a normal human commensal. Infections are usually the result of introduction of bacteria into a normally sterile space from the oropharynx, gastrointestinal tract, or vaginal tract. The organism may be difficult to recover in the microbiology laboratory because it grows slowly and is ideally cultured under anaerobic conditions. Microscopically, it has a similar appearance to *Nocardia* spp.; however, it does not retain the modified acid-fast stain, and the colonies may have a molar-tooth appearance. Infections of the cervical region are typified by the slow induration of the skin at the angle of the jaw that progresses over several weeks or months. A mass may be palpable and, due to the slow progression and absence of systemic inflammatory symptoms, the infection can often be confused with other conditions such as malignancies. Patients may notice the discharge of small yellow grains known as *sulfur granules*. These are macroscopic colonies of the organism that may be cultured for confirmation, but their absence should not exclude the diagnosis from consideration.

MANAGEMENT STRATEGY

Actinomyces spp. are universally susceptible to *penicillin*. The severity of the illness will dictate whether the patient requires intravenous or oral formulations of the antibiotic, but the general principle is that prolonged treatments for 6 months or more are often required for cure. In patients who are penicillin allergic, the *tetracycline* class of antibiotics is a useful substitute. *Surgical removal* of the abscess may also be required to ensure complete resolution. Treatment failures are rare but may be due to coinfecting organisms from the oropharynx. In order to treat these organisms, the combination of a β -lactam antibiotic with a β -lactamase inhibitor may be sufficient. *Carbapenems* such as *imipenem*, *meropenem*, or *ertapenem* are also effective.

Clinical review: actinomycosis. Wong VK, Turmezei TD, Weston VC. *BMJ* 2011; 343: d6099.

Susceptibility of pathogenic actinomycetes to antimicrobial compounds. Lerner PI. *Antimicrob Agents Chemother* 1974; 5: 302–9.

SPECIFIC INVESTIGATIONS

Diagnostic methods for human actinomycosis. Holmberg K. *Microbiol Sci* 1987; 4: 72–8.

An excellent review of the diagnosis of actinomycosis.

The most accurate way to diagnose actinomycosis is by culture – usually a difficult task – which requires thioglycolate or brain–heart-enriched agar at 37°C under anaerobic or microaerophilic conditions. ‘Molar-tooth’ and ‘breadcrumb’ colonies may take up to 3 weeks to grow. Unfortunately, definitive identification cannot be based on colony morphology and requires the measurement of physiologic and biochemical characteristics (e.g., sensitivity to oxygen, presence of preformed enzymes).

Because cultures of *Actinomyces* spp. are often unsuccessful, observation of ‘sulfur granules’ on a peripheral smear or histology often helps make the diagnosis. The granules are bacterial colonies, which on hematoxylin and eosin staining have a basophilic central area surrounded by a zone of eosinophilic ‘clubs’. Other typical histologic findings include extensive fibrosis, chronic granulation tissue, sinus tracts, and scattered microabscesses.

Immunofluorescent staining of *Actinomyces* spp. is available and can be used on clinical material, granules, and formalin-fixed tissues. The direct immunoperoxidase technique can specifically show *Actinomyces* spp. in formalin-fixed sections via light microscopy. These techniques, as well as gene sequencing (see later), are promising diagnostic modalities given the difficulty of culture and histologic identification.

Cervicofacial actinomycosis: diagnosis and management. Oostman O, Smego RA. *Curr Infect Dis Res* 2005; 7: 170–4.

Culture isolation of *Actinomyces* spp. and microscopic visualization of Gram-positive, non-acid-fast, thin, branching filaments remain the best methods of diagnosing cervicofacial actinomycosis.

Diagnosis of pelvic actinomycosis by 16S ribosomal RNA gene sequencing and its clinical significance. Woo PCY, Fung AMY, Lau SKP, et al. *Diagn Microbiol Infect Dis* 2002; 43: 113–8.

Actinomyces odontolyticus was identified by rRNA gene sequencing. Because the 16S ribosomal RNA gene is conserved within a species, it can be used to identify a specific species of bacteria.

Cervicofacial actinomycosis: CT and MR imaging findings in 7 patients. Park JK, Lee HK, Ha HK, et al. *Am J Neuroradiol* 2003; 24: 331–3.

Findings on computed tomography (CT) and magnetic resonance imaging (MRI) may be helpful in distinguishing cervicofacial actinomycosis from malignant neoplasms, tuberculosis, and fungal infections.

First-Line Therapy

- Penicillin

C

Antimicrobial susceptibility testing of *Actinomyces* species with 12 antimicrobial agents. Smith AJ, Hall V, Thakker B, et al. *J Antimicrob Chemother* 2005; 56: 407–9.

The authors tested the susceptibility of 87 strains of *Actinomyces* to 12 different antimicrobial agents. All isolates were susceptible to penicillin and amoxicillin.

Actinomycosis. Smego RA, Foglia G. Clin Infect Dis 1998; 26: 1255–63.

The authors recommend 2 months of oral penicillin V (2–4 g/day divided every 6 hours) or a tetracycline (e.g., oral doxycycline 100 mg twice daily) for mild cervicofacial disease. For more complicated infections, parenteral penicillin G (10–20 million U/day divided every 6 hours) for 4–6 weeks followed by 6–12 months of oral penicillin V (2–4 g/day divided every 6 hours) is suggested. Tetracycline, erythromycin, clindamycin, or cephalosporins are advocated for patients allergic to penicillin.

Actinomycosis and nocardiosis. A review of basic differences in therapy. Peabody JW, Seabury JH. Am J Med 1960; 28: 99–115.

The authors review the treatment of actinomycosis and state that penicillin is the drug of choice.

Second-Line Therapies

• Amoxicillin	C
• Ceftriaxone	D
• Clindamycin	C
• Doxycycline	D
• Erythromycin	D
• Imipenem	C
• Minocycline	C
• Tetracycline	D

The use of oral amoxicillin for the treatment of actinomycosis: a clinical and invitro study. Martin MV. Br Dent J 1984; 156: 252–4.

Ten patients with cervicofacial actinomycosis were cured in less than 6 weeks with a combination of amoxicillin (500 mg four times daily) and surgery.

Actinomycosis abscess of the thyroid gland. Cevera JJ, Butehorn HF 3rd, Shapiro J, et al. Laryngoscope 2003; 113: 2108–11.

A 39-year-old woman who developed actinomycosis of the thyroid gland after tooth extraction was cured with thyroidectomy and 6 months of ceftriaxone (1 g intravenously every 12 hours).

Successful treatment of thoracic actinomycosis with ceftriaxone. Skoutelis A, Petrochilos J, Bassaris H. Clin Infect Dis 1994; 19: 161–2.

A 38-year-old patient with pulmonary actinomycosis was successfully treated with a 3-week course of daily ceftriaxone (2 g intravenously), followed by 3 months of daily oral ampicillin (no dose listed but typically given 500 mg orally every 6 hours).

Mandibular actinomycosis treated with oral clindamycin. Badgett JT, Adams G. Pediatr Infect Dis J 1987; 6: 221–2.

Clindamycin in the treatment of cervicofacial actinomycosis. de Vries J. Int J Clin Pharmacol 1974; 9: 46–8.

A 60-year-old man with cervicofacial actinomycosis that was resistant to penicillin and tetracycline responded fully to a 1-month course of clindamycin (150 mg four times a day).

Clindamycin in the treatment of serious anaerobic infections. Fass RJ, Scholand JE, Hodges GR, et al. Ann Intern Med 1973; 78: 853–9.

Four patients with cervicofacial actinomycosis and one with thoracic actinomycosis were successfully treated with a combination of intravenous (1.8–2.7 g/day) and oral (0.9–1.2 g/day) clindamycin.

Primary actinomycosis of the hand: a case report and literature review. Mert A, Bilir M, Bahar H, et al. Int J Infect Dis 2001; 5: 112–4.

A 35-year-old man with primary actinomycosis of the hand was cured with 1 month of intravenous ampicillin (12 g/day), followed by 11 months of oral doxycycline (200 mg/day).

Actinomycosis of the prostate. de Souza E, Katz DA, Dworzack DL, et al. J Urol 1985; 133: 290–1.

A case of acute prostatitis due to *Actinomyces* spp. was cured with long-term erythromycin (500 mg intravenously every 6 hours followed by 500 mg orally every 6 hours), chosen because of its excellent penetration into prostatic secretions.

Actinomycosis of the temporomandibular joint. Bradley P. Br J Oral Surg 1971; 9: 54–6.

A 58-year-old man with actinomycosis of the temporomandibular joint was cured with a 12-week course of erythromycin (500 mg six times a day).

Use of imipenem in the treatment of thoracic actinomycosis. Yew WW, Wong PC, Wong CE, et al. Clin Infect Dis 1994; 19: 983–4.

Report of eight cases of pulmonary actinomycosis and their treatment with imipenem–cilastatin. Yew WW, Wong PC, Lee J, et al. Arch Chest Dis 1994; 54: 126–9.

Seven of eight patients with pulmonary actinomycosis were successfully treated with a 4-week course of parenteral imipenem–cilastatin (500 mg intravenously every 8 hours).

Cutaneous disseminated actinomycosis in a patient with acute lymphocytic leukemia. Takeda H, Mitsunashi Y, Kondo S. J Dermatol 1998; 25: 37–40.

A patient with primary cutaneous disseminated actinomycosis was cured with a 3-month course of intravenous minocycline (2 mg/kg/day).

Antibiotic treatment of cervicofacial actinomycosis for patients allergic to penicillin: a clinical and in vitro study. Martin MV. Br J Oral Maxillofac Surg 1985; 23: 428–34.

Six patients with cervicofacial actinomycosis were cured with 8–16 weeks of oral minocycline (250 mg four times a day). There were no recurrences after 1 year.

Primary actinomycosis of the quadriceps. Langlosh JT, Lauerman WC. J Pediatr Orthop 1987; 7: 222–3.

Surgical drainage followed by a 6-week course of oral tetracycline (500 mg orally every 6 hours) cured a case of actinomycosis of the quadriceps.

Comparative in vitro susceptibilities of 396 unusual anaerobic strains to tigecycline and eight other antimicrobial agents. Goldstein EJ, Citron DM, Merriam CV, et al. Antimicrob Agents Chemother 2006; 50: 3507–13.

Tigecycline (50 mg intravenously every 12 hours, with a 100-mg loading dose) had good in vitro activity against isolates of *Actinomyces* spp.

Resistance patterns in clinical isolates of pathogenic *Actinomyces* species. Steninger C, Willinger B. J Antimicrob Chemother 2016; 71: 422–7.

β-lactam antibiotics are effective; however, rates of resistance to metronidazole suggest that alternatives should be considered in case of β-lactam allergy.

Third-Line Therapies	
• Ciprofloxacin	E
• Levofloxacin	E
• Rifampicin	E

Treatment of recalcitrant actinomycosis with ciprofloxacin. Macfarlane DJ, Tucker LG, Kemp RJ. J Infect 1993; 27: 177–80.

Treatment of pulmonary actinomycosis with levofloxacin. Ferreira D de F, Amado J, Neves S, et al. J Bras Pneumol 2008; 34: 245–8.

Treatment of pulmonary actinomycosis with rifampin. Morone N, De Castro Pereira CA, Saito M, et al. G Ital Chemioter 1982; 29: 121–4.

Pulmonary actinomycosis. Rapid improvement with isoniazid and rifampin. King JW, White MC. Arch Intern Med 1981; 141: 1234–5.

A series of single case reports responding to other antibiotic options.

Acute generalized exanthematous pustulosis

Sidra S. Khan, Ian H. Coulson

Acute generalized exanthematous pustulosis (AGEP) is characterized by the acute onset of numerous small, non-follicular, sterile pustules arising on a diffuse erythematous base in a febrile patient with an accompanying blood neutrophilia. Most cases occur in the context of drug ingestion (commonly within 24 hours). Rapid resolution after drug withdrawal is the usual outcome.

MANAGEMENT STRATEGY

Treatment of AGEP involves establishing the correct diagnosis coupled with the *withdrawal of any implicated medication* (Table 8.1). Pustular psoriasis is its main differential diagnosis. A comprehensive drug history and a personal or family history of psoriasis are therefore required.

Intraepidermal or subcorneal pustules in conjunction with a leukocytoclastic vasculitis, focal necrosis of keratinocytes, marked edema of the papillary dermis, and an infiltrate of eosinophils are histologic features that help distinguish AGEP from pustular psoriasis; biopsy is thus an integral facet of management.

Differentiation of AGEP from other inflammatory, toxic, or infectious conditions, such as Sneddon–Wilkinson disease (subcorneal pustular dermatosis) or, in severe cases, toxic epidermal necrolysis, is often readily apparent both clinically and histologically. The clinician should, however, be aware that erythema multiform-like targetoid lesions, mucous membrane involvement, facial edema, purpura, and vesicubullous lesions have all been documented in the context of AGEP.

Antibiotics (primarily penicillin or macrolide based) are the most frequently implicated medications. Numerous case reports have cited various other causative agents, including calcium channel blockers, non-steroidal antiinflammatory drugs (NSAIDs),

angiotensin-converting enzyme (ACE) inhibitors, and anticonvulsants (Table 8.1). Acute enterovirus infection, mycoplasma pneumonia, cytomegalovirus, parvovirus B19, spider bites, Chinese herbal compounds (ginkgo biloba), contrast media, and mercury exposure have also been reported as possible causes.

There is no specific therapy for AGEP. A skin swab establishes the sterile nature of the pustules, and drug withdrawal, if feasible, results in rapid spontaneous resolution. *Supportive therapy* is all that is required. A superficial desquamation often occurs during this time and may be treated with *simple emollients*. Several case reports cite the use of patch testing to confirm the causative medication. Recalcitrant cases have benefited from *oral prednisolone*, *ciclosporin*, and *secukinumab*.

Specific Investigations

- Detailed history
- Hematology
- Skin swab of pustule
- Microscopy, culture, Gram stain
- Skin biopsy

First-Line Therapy

- Drug withdrawal

E

Risk factors for acute generalized exanthematous pustulosis (AGEP) – results of a multinational case-control study (EuroSCAR).

Sidoroff A, Dunant A, Viboud C. Br J Dermatol 2007; 157: 6. A multinational case-control study (97 cases of AGEP and 1009 controls) that assessed the risk for different drugs causing severe cutaneous adverse reactions.

The most frequently implicated drugs were pristinamycin (a macrolide marketed in France), ampicillin/amoxicillin, quinolones, (hydroxy) chloroquine, anti-infective sulfonamides, terbinafine, and diltiazem. Infections and a personal or family history of psoriasis were not deemed to be significant risk factors for developing AGEP. Of note, the median treatment duration was 1 day for antibiotics and 11 days for all other associated drugs.

Acute generalized exanthematous pustulosis. Analysis of 63 cases.

Roujeau JC, Bioulac-Sage P, Bourseau C, et al. Arch Dermatol 1991; 127: 1333–8. A retrospective review of cases of AGEP. Almost 90% of cases were attributable to drugs, with 50% of reactions occurring within 24 hours of ingestion.

Acute generalized exanthematous pustulosis.

Manders SM, Heymann WR. Cutis 1994; 54: 194–6. Two of the three cases reported in this series were attributable to penicillin. This succinct overview of AGEP also provides the reader with useful clinicopathologic features that may help distinguish AGEP from pustular psoriasis.

Generalized pustular psoriasis or drug-induced toxic pustuloderma? The use of patch testing.

Whittam LR, Wakelin SH, Barker JNWN. Clin Exp Dermatol 2000; 25: 122–4. Patch testing to a 1% and 5% amoxicillin preparation confirmed a type 4 hypersensitivity reaction in a patient with long-standing plaque psoriasis who developed a generalized pustular eruption when treated with amoxicillin for an episode of epididymo-orchitis.

Table 8.1 Drugs and other substances reported to have caused AGEF**Drugs****Antibiotics**

Penicillins: amoxicillin, ampicillin, bacampicillin, piperidic acid, piperacillin, propicillin, tazobactam, meropenem
 Macrolides: azithromycin, erythromycin
 Quinolones: ciprofloxacin, norfloxacin, ofloxacin
 Tetracyclines: doxycycline, minocycline
 Cephalosporins: cefaclor, cefazolin, cefuroxime, cephalexin, cephadrine
 Aminoglycosides: gentamicin, isepamicin sulfate, streptomycin
 Other antibiotics
 Chloramphenicol, clindamycin, cotrimoxazole, imipenem/cilastatin, lincomycin, metronidazole, nifuroxazide, sulfamethoxazole, teicoplanin, vancomycin, daptomycin, telavancin

NSAIDs

Celecoxib, etoricoxib, ibuprofen, naproxen, nimesulide, valdecoxib
 ACE inhibitors
 Captopril, enalapril
 Calcium channel blockers
 Nifedipine, nimodipine, diltiazem

Anticonvulsants

Carbamazepine, phenobarbital, phenytoin
 Analgesia (opioid/non-opioid)
 Acetaminophen, paracetamol, morphine, codeine, dextropropoxyphene

Antiplatelets

Aspirin, ticlopidine, clopidogrel

Benzodiazepines

Clobazam, nitrazepam, tetrazepam

Antimalarials

Chloroquine, hydroxychloroquine, proguanil, pyrimethamine

Antipsychotics

Clozapine, chlorpromazine

Antifungals

Amphotericin, fluconazole, itraconazole, nystatin, terbinafine

Antivirals

Lamivudine, lopinavir, ritonavir, zidovudine

Antituberculosis drugs

Isoniazid, rifampicin

Proton pump inhibitors

Lansoprazole, omeprazole

Immunosuppressants

Azathioprine

Antidepressants

Amoxapine, sertraline

Antihistamines

Clemastine, hydroxyzine

Beta agonists and antagonists

Buphenine, fenoterol, nadolol

H₂-receptor antagonists

Cimetidine, famotidine, ranitidine

Table 8.1 Drugs and other substances reported to have caused AGEF—cont'd**Cholesterol-lowering medications**

Simvastatin, pitavastatin, fenofibrate

Corticosteroids

Dexamethasone, methylprednisolone, prednisolone

Diuretics

Furosemide, hydrochlorothiazide

Antineoplastic drugs

Gefitinib, imatinib, vemurafenib

Other drugs

Acetazolamide, allopurinol, bamifylline, bleomycin, bupropion hydrochloride, cadralazine, carbimazole, carbutamide, cytarabine, dalteparin, disulfiram, eperisone hydrochloride, eprazinone, fludione, icodextrin, interferon, metamizole, pentoxifylline, piperazine, propafenone, alprostadil, progestogens, pseudoephedrine, psoralen + UVA, quinidine, ranolazine, sulbutamine, senna, sulfasalazine, terazosin, thalidomide

Other substances

Chromium picolinate
 Diphenyl sulfone
 Contrast agents iohexol and iopamidol
 Mercury
 Pneumococcal vaccine
 Essential oil
Andrographis paniculata

A systemic reaction to patch testing for the evaluation of acute generalized exanthematous pustulosis. Mashiah J, Brenner S. Arch Dermatol 2003; 139: 1181–3.

The authors report a generalized AGEF-like reaction caused by patch tests carried out to determine the drug eliciting AGEF. Interestingly, negative results were obtained with the drug in question.

Second-Line Therapies

• Corticosteroids	E
• Ciclosporin	E

Acute generalized exanthematous pustulosis: clinical characteristics, etiologic associations, treatments, and outcomes in a series of 28 patients at Mayo Clinic, 1996–2013. Alniemi DT, Wetter DA, Bridges AG, et al. Int J Dermatol 2017; 56: 405–14.

A retrospective review of 28 patients with AGEF. Ten of the 28 were treated with oral corticosteroids and demonstrated complete resolution. Three patients went on to develop non-AGEF skin eruptions a few months after resolution of their AGEF.

Successful treatment of hydroxychloroquine-induced recalcitrant acute generalized exanthematous pustulosis with ciclosporin: case report and literature review. Yalçın B, Çakmak S, Yidirim B. Ann Dermatol. 2015; 27: 431–4.

A case report of a 67-year-old rheumatoid arthritis patient with recalcitrant AGEF secondary to hydroxychloroquine responding successfully to ciclosporin 4 mg/kg/day tapered over 2 months.

Third-Line Therapy

- Secukinumab

E

Interleukin 17 as a therapeutic target of acute generalized exanthematous pustulosis (AGEP). Gualtieri B, Solimani F, Hertl M, et al. J Allergy Clin Immunol Pract 2020; 8; 6: 2081-4.

A case report of a 63-year-old patient with terbinafine-induced AGEP that was unresponsive to prednisolone. A rapid clinical improvement was observed following a single 300 mg dose of secukinumab.

Allergic contact dermatitis and photoallergy

Rosemary L. Nixon, Claire Felmingham

Allergic contact dermatitis (ACD) is a delayed or type IV hypersensitivity reaction. It consists of a primary sensitization phase followed by secondary elicitation by haptens, leading to activation of T lymphocytes.

ACD usually appears 24–48 hours after contact with an allergen. Typically, the rash is localized to the site of contact. It may later spread to other areas. Spreading is characteristic of ACD and can help differentiate the diagnosis from that of irritant contact dermatitis. The spread of the rash can occur from transfer of the allergen (e.g., from hands to face), or as a result of an id reaction (also known as autoeczematization). Other possible routes of exposure to contact allergens include systemic, airborne, and proxy exposures.

The rash of ACD is typically pruritic and eczematous, with papules and vesicles on an erythematous base.

The location on the body at which the rash originated can assist in determining the causative allergen. For example, if the hands are affected, the causative allergen could be rubber glove accelerators. If the rash begins at the scalp and neck, perhaps paraphenylenediamine from hair dye is the culprit. ACD to nickel might occur at the left wrist from a watch, at the ears or neck from jewelry, or at the navel from a belt buckle.

Factors that increase the likelihood of sensitization include chemical factors (such as chemical size and concentration); skin factors (such as integrity of the skin exposed to the chemical); and factors pertaining to the conditions of contact (such as the duration of contact).

Photoallergens additionally require activation by UV light to cause photoallergic contact dermatitis (PACD). Organic UV absorbers and topical non-steroidal antiinflammatory agents are the two most common photoallergens. Other potential photoallergens include fragrances, antibacterials, plants, and insecticides.

MANAGEMENT STRATEGY

Identification and avoidance of offending allergens and potential cross-reacting agents is the principal management strategy for ACD. Patch testing is the gold standard for diagnosing ACD and identifying allergens. Following this, patient education regarding the diagnosis, the relevant allergen(s), and how to avoid them, is essential.

Government legislation can reduce ACD rates significantly. The European Union has introduced legislation to limit the concentration of the preservative methylisothiazolinone (MI) in personal products, to restrict nickel content in jewelry, and to reduce available chromate in cement by adding ferrous sulfate. These measures have resulted in reduced sensitization rates and a reduced number of cases of ACD to MI, nickel, and chromate, respectively.

The workplace also plays an important role in minimizing exposure to allergens, thereby reducing rates of sensitization and ACD. This can be done by modifying work environments; for example, by improving ventilation to reduce exposure to airborne substances, by substituting common allergens, and by providing and ensuring the use of appropriate personal protective equipment (PPE).

Glove use is an important component of ACD prevention and management. Glove choice will depend on the activity being performed and on the chemicals being handled. When working in a hot environment, sweating and leaching of chemicals from gloves can occur. Cotton gloves can be worn underneath rubber or leather gloves to prevent sensitization to rubber accelerators and chromate.

The initial management of ACD follows the general principles of eczema therapy. This includes avoiding skin irritants (such as water, soap, friction, and heat), using emollients or moisturizing creams, and applying topical corticosteroids to affected areas. Barrier creams have had limited success in preventing dermatitis. Topical tacrolimus and pimecrolimus have been shown to be effective. In severe cases, oral corticosteroids may be required. These are usually short courses of prednisolone 25–50 mg daily for 1 week.

If secondary infection is suspected, oral antibiotics (cephalosporins, erythromycin, or flucloxacillin) or topical antibiotics (mupirocin or fusidic acid) may be required.

ACD will usually resolve with this initial treatment, provided that the responsible allergen has been identified and avoided. However, patients may experience ongoing issues if they are inadvertently exposed to the allergen or if they develop persistent postoccupational dermatitis, a dermatitis that recurs despite absence of exposure to causative agents.

If ACD is chronic or refractory to first-line treatments, ultraviolet light therapy with narrowband ultraviolet B (UVB) or psoralen plus ultraviolet A (PUVA) can be used. Systemic immunosuppression with ciclosporin, azathioprine, and methotrexate may be considered. Acitretin may be helpful in some cases, particularly if there is hyperkeratotic palmar involvement. Alitretinoin is helpful in cases of chronic hand eczema; however, more evidence is required to determine its usefulness in treating ACD specifically.

Small case series and a retrospective chart review have suggested that dupilumab is effective in treating ACD. A phase 4 clinical trial is underway to investigate the effects of dupilumab on ACD in 20 patients.

Recent evidence suggests that there is an association between contact dermatitis and smoking. There is no strong evidence available to show that smoking cessation leads to improvement of ACD. However, smoking cessation could be a worthwhile action, especially when considering health cobenefits.

For PACD, identification and avoidance of the photoallergen is again the major treatment goal. Sun protection, with sunscreen and protective clothing, is also important. If the photoallergen is an ingredient in sunscreen, avoidance and substitution of that ingredient is recommended. Physical UV blockers such as zinc oxide or titanium dioxide are not known to cause allergic or PACD and may be useful substitutes to chemical sunscreens.

Specific Investigations

- Patch testing to appropriately diluted allergens
- Photopatch testing if PACD is suspected – duplicate sets of allergens are applied, and after 48 hours one set is exposed to 5 J/cm² UVA; results are read after a further 48 hours
- Repeat open application test (ROAT) to determine whether a reaction is significant in individuals who develop weak (1+) positive reactions to an allergen

First-Line Therapies

Allergic contact dermatitis

• Allergen avoidance and substitution	C
• Skin care education	B
• PPE	D
• Topical corticosteroids	B
• Emollients and soap substitutes	C
• Barrier creams	B
• Calcineurin inhibitors (tacrolimus, pimecrolimus)	B
• Prednisolone	D
• Antibiotics – topical and systemic	D
• Alitretinoin	A

Photoallergy

• Allergen avoidance and substitution	C
• Photoprotection	C
• Sunscreens – physical UV blockers	E

Skin care education and individual counseling versus treatment as usual in healthcare workers with hand eczema: randomised clinical trial. Ibler KS, Jemec GBE, Diepgen TL, et al. *BMJ* 2012; 345: e7822.

Two hundred and fifty-five healthcare workers with hand eczema were randomized to an intervention or control group. The intervention comprised education in skin care, individual counseling based on patch and prick testing, and assessment of occupational and domestic exposures. At the 5-month follow-up, hand eczema was significantly improved in the intervention group compared with the control group as measured both objectively and subjectively.

Determinants of epoxy allergy in the construction industry: a case-control study. Spee T, Timmerman JG, Rühl R, et al. *Contact Dermatitis* 2016; 74: 259–66.

A case-control study compared 179 German epoxy workers with diagnosed ACD to epoxy (cases) with 151 epoxy workers without such an allergy (controls). ACD to epoxies was found to be associated with unusually high levels of exposure to the chemicals (OR 2.13) and with poor compliance with personal protection, including wearing short sleeves and trousers (OR 2.38), and incorrect glove use (OR 2.12).

Effectiveness of skin protection measures in prevention of occupational hand eczema: results of a prospective randomized controlled trial over a follow-up period of 1 year. Kütting B, Baumeister T, Weistenhöfer W, et al. *Br J Dermatol* 2010; 162: 362–70.

A total of 1020 metalworkers were randomized to one of four arms: skin care (use of moisturizer), skin protection (application of protection creams before or during work), both combined, and a control group. Eight hundred subjects were retained in the study after 12 months, with a compliance range of 73.7–88.7%. Hands were examined using a quantitative skin score. The group following the regime of both skin care and skin protection demonstrated the greatest improvement.

Tacrolimus 0.1% vs. mometasone furoate topical treatment in allergic contact hand eczema: a prospective randomized clinical study. Katsarou A, Makris M, Papagiannaki K, et al. *Eur J Dermatol* 2012; 22: 192–6.

Thirty adults with chronic hand eczema and positive patch test reactions were randomized to either tacrolimus 0.1% ointment or mometasone furoate 0.1%. A significant difference was observed in both groups in all parameters between baseline and day 90 results. The results suggest tacrolimus is a favorable alternative therapy to topical corticosteroids with similar outcomes.

A phase 3, randomized, double-blind, placebo-controlled study evaluating the efficacy and safety of alitretinoin (BAL4079) in the treatment of severe chronic hand eczema refractory to potent topical corticosteroid therapy. Fowler JF, Graff O, Hamedani AG. *J Drugs Dermatol* 2014; 13: 1198–204.

Five hundred and ninety-six participants were randomized to receive either treatment with 30 mg of alitretinoin, or placebo, for 24 weeks. A greater proportion of alitretinoin-treated patients achieved a physician global assessment of 'cleared' or 'almost cleared' of eczema at the end of the trial. Alitretinoin was shown to significantly improve severe chronic hand eczema.

New sunscreens confer improved protection for photosensitive patients in the blue light region. Moseley H, Cameron H, Macleod T, et al. *Br J Dermatol* 2001; 145: 789–94.

Seven patients with known photosensitivity extending into the visible (blue) region at 430 ± 30 nm were tested with new reflectant sunscreens, which use larger particle size zinc oxide and titanium dioxide as active ingredients. The mean photo protection factors at this wavelength were determined. The new sunscreens were found to provide protection for patients with sensitivity to visible light (blue light region); for example, those with chronic actinic dermatitis, compared with sunscreens using chemical UV absorbers and microfine particles, which scatter radiation.

Second-Line Therapies

Allergic contact dermatitis

• Ultraviolet light (PUVA, UVB)	B
• Azathioprine	C
• Cyclosporin	D
• Methotrexate	D
• Acitretin	E
• Low-nickel diet for nickel dermatitis	C
• Grenz ray therapy	C

Chronic eczematous dermatitis of the hands. A comparison of PUVA and UVB treatment. Rosén K, Mobacken H, Swanbeck G. *Acta Derm Venereol* 1987; 67(1): 48–54.

Thirty-five patients with chronic hand dermatitis were randomly allocated to PUVA or UVB treatment. Twenty-two of the patients had ACD. One hand was exposed to treatment; the other served as an untreated control. The treated hand cleared in all participants receiving PUVA. There was also statistically significant clinical improvement in the group treated with UVB.

Azathioprine versus betamethasone for the treatment of parthenium dermatitis: a randomized controlled study. Verma KK, Mahesh R, Srivastava P, et al. *Indian J Dermatol Venereol Leprol* 2008; 74: 453–7.

Fifty-five patients with contact dermatitis caused by airborne *Parthenium* were randomly assigned to azathioprine 100 mg daily or betamethasone 2 mg daily for 6 months in a double-blinded manner. Treatment effects appeared equal in each group; however, the group randomized to betamethasone appeared to have more adverse effects.

Oral cyclosporine inhibits the expression of contact hypersensitivity in man. Higgins EM, McLelland J, Friedmann PS, et al. *J Dermatol Sci* 1991; 2: 79–83.

Six patients with chronic contact dermatitis were treated with ciclosporin 5 mg/kg/day. Quantitative patch test reactions were diminished in all six, and responses were reduced over the whole range of allergen concentrations. In addition, the clinical manifestations of ACD resolved completely within 2–3 weeks of ciclosporin therapy.

Methotrexate use in allergic contact dermatitis: a retrospective study. Patel A, Burns E, Burkemper NM. *Contact Dermatitis* 2018; 78: 194–8.

In a retrospective chart review of 32 patients with ACD, 78% of patients showed either a partial or complete response to treatment with methotrexate (dose range: 15–30 g per week).

Open-label exploratory study of acitretin for the treatment of severe chronic hand dermatitis. Tan J, Maari C, Nigen S, et al. *J Dermatolog Treat* 2015; 26: 373–5.

In a pilot study, nine participants with severe chronic hand dermatitis were treated with 10–30 mg of acitretin daily for up to 24 weeks. Three patients withdrew from the study. In the remaining patients 33.3% achieved clear or almost clear on physician global assessment.

A double-blind study of Grenz ray therapy in chronic eczema of the hands. Lindelöf B, Wrangsjö K, Lidén S. *Br J Dermatol* 1987; 117: 77–80.

Twenty-four patients with chronic hand eczema received Grenz ray therapy (at 3 Gy) to one hand, and a simulated therapy to the other, on six occasions at 1-week intervals. A significantly better response was observed in the hands receiving Grenz ray therapy.

Third-Line Therapies

Allergic contact dermatitis

• Disulfiram	C
• Pentoxifylline	E
• Dupilumab	E

Disulfiram and low nickel diet in the management of hand eczema: a clinical study. Sharma AD. *Indian J Dermatol Venereol Leprol* 2006; 72: 113–8.

In this single-blinded controlled trial, 21 patients with chronic hand eczema and nickel sensitivity were randomly divided into a treatment group, with a low nickel diet and 4 weeks of oral disulfiram, and a control group, with a regular diet and oral placebo. Hand eczema cleared completely in 10 of 11 participants in the treatment group, and in 1 of 10 participants in the control group.

The effect of the topical application of different pentoxifylline concentrations on the patch test results of nickel-sensitive patients. Saricaoglu H, Başkan EB, Tunalı S. *Int J Dermatol* 2004; 43: 315–6.

Twenty-two volunteers with nickel-induced contact dermatitis were pretreated with three concentrations of pentoxifylline and then patch tested to nickel. Though there was some evidence of suppressed patch test results, the decrease in patch test reactions was statistically insignificant.

Effect of tobacco smoking and alcohol consumption on the prevalence of nickel sensitization and contact sensitization. Thyssen JP, Johansen JD, Menné T, et al. *Acta Derm Venereol* 2010; 90: 27–33.

In this cross-sectional study, 3460 adults underwent patch testing and answered a questionnaire on smoking status. Using an adjusted model, a statistically significant trend ($p < 0.05$) was found between smoking status and nickel sensitization.

Dupilumab treatment in two patients with severe allergic contact dermatitis caused by sesquiterpene lactones. Ruge IF, Skov L, Zachariae C, et al. *Contact Dermatitis* 2020; 83: 2: 137–9.

Two cases of recalcitrant, severe ACD to sesquiterpene lactones demonstrated an adequate response to dupilumab.

Alopecia areata

Brittany Craiglow, Danielle Peterson, Brett King

Photo courtesy of Dr Craiglow.

Alopecia areata (AA) is a common autoimmune disease characterized by non-scarring hair loss. Extent or severity of disease ranges from one or more patches of alopecia (involving the scalp and/or other hair-bearing sites) to complete scalp hair loss (referred to as alopecia totalis [AT]) or complete body hair loss (referred to as alopecia universalis [AU]). Patients with AA often experience a negative impact on quality of life and have increased rates of depression and anxiety.

MANAGEMENT STRATEGY

There are presently no FDA-approved treatments for AA. Approach to management depends on a variety of factors, including patient age, extent and duration of hair loss, and impact on quality of life. Traditional therapeutic options include topical, intralesional and systemic corticosteroids, topical immunotherapy, and systemic immunomodulatory medications. While mild patchy disease often improves with topicals and/or intralesional corticosteroids, more severe AA is less likely to respond to these treatments. Janus kinase (JAK) inhibitors have recently emerged as an effective treatment for AA, and large clinical trials are presently underway.

Intralesional corticosteroids, most commonly triamcinolone acetate, are considered first-line therapy for adult patients with limited, patchy AA. There is evidence that 2.5 mg/mL has similar efficacy to 5 mg/mL and 10 mg/mL concentrations. Injections are typically performed at 4–6-week intervals, with up to 40 mg administered per session. Side effects include skin atrophy, which is usually transient.

For patients who are unable to tolerate intralesional therapy, *topical corticosteroids* may provide some benefit. Superpotent topical corticosteroids such as clobetasol propionate are applied

twice daily to affected areas and may be followed by an eventual taper once there has been regrowth.

Topical immunotherapy with contact sensitizers, including *squaric acid dibutyl ester (SADBE)* and *diphenylcyclopropenone (DPCP)*, also called diphenylprone, induces allergic contact dermatitis, which likely works by changing the immune milieu of the hair follicle. DPCP is a more stable compound than SADBE and more widely utilized. Patients are first sensitized with 2% DPCP to a localized area (e.g., 2 cm² area on the buttock or hip) followed by weekly applications of increasing concentrations typically ranging from 0.001% to 0.1% until the patient develops mild erythema and pruritus, which is then maintained with repeated application of the same concentration solution. Side effects include generalized dermatitis and lymphadenopathy.

Janus kinase (JAK) inhibitors are an emerging treatment for patients with AA, with efficacy now described in numerous case reports, retrospective series, and open-label clinical trials. These small molecules, which variably target the JAK family of enzymes, disrupt signaling of IFN- γ and IL-15, which appear to be integral cytokines to AA pathogenesis. *Tofacitinib* and *ruxolitinib* have been most commonly used, with larger studies reporting that 50%–75% of patients experienced >50% scalp hair regrowth and 20%–66% patients experienced near-complete or complete regrowth. In adult patients, we typically start with tofacitinib 5 mg twice daily and consider increasing to 10 mg twice daily if there is not at least 25% scalp hair regrowth by 3–6 months. While JAK inhibitors are generally well tolerated, potential adverse events include serious infection, malignancy, and blood clots and therefore a thorough discussion of potential risks is important prior to initiating treatment. Large, placebo-controlled clinical trials investigating a variety of JAK inhibitors are now underway. While there have been reports of successful use of topical JAK inhibitors for AA, clinical trials have failed to show efficacy. Compounded topical preparations of tofacitinib or ruxolitinib in 1%–2% concentrations may be considered for the treatment of limited areas, such as the eyebrow regions or small areas on the scalp, or for patients in whom avoidance of systemic therapy is desired or appropriate.

Systemic corticosteroids are sometimes effective for the treatment of AA; however, there are significant risks associated with long-term treatment and relapse is common after discontinuation, and so routine use is not recommended. Pulsed therapy may be associated with less morbidity and may be useful for some patients experiencing rapidly progressive hair loss. Monthly doses of prednisone 5 mg/kg (maximum 300 mg) for 4–6 months may be considered; however, patients need to be counseled that hair growth may not be sustained.

Oral minoxidil monotherapy has been shown to lead to significant scalp hair regrowth in 18% of patients and may be synergistic with oral JAK inhibitors, and we use it commonly in the treatment of our patients, both as monotherapy and in combination with other treatments. The minoxidil dose we typically use is 2.5–5 mg once or twice daily. *Topical minoxidil* 5% is unlikely to yield improvement in AA when used as monotherapy, but it may be useful as an adjunctive therapy, such as with intralesional or topical corticosteroids or topical JAK inhibitors.

Specific Investigations

- Complete review of systems, with laboratory investigations reserved for patients with findings suggestive of comorbid disease, such as thyroid dysfunction
- Scalp biopsy is rarely needed given the characteristic clinical presentation but may be useful in cases of diffuse alopecia areata or to differentiate from scarring alopecias

First-Line Therapies

• Intralesional corticosteroids	A
• Topical corticosteroids	A
• Topical immunotherapy	B
• Oral JAK inhibitors	B

Benefit of different concentrations of triamcinolone acetonide in alopecia areata: an intrasubject pilot study. Chu TW, Aljasser M, Albarbi A, et al. *J Am Acad Dermatol* 2015; 73: 338–40.

Four patients each received six injections of saline and triamcinolone acetonide 2.5 mg/mL, 5 mg/mL, and 10 mg/mL at 6-week intervals. All three concentrations yielded similar responses and were superior to placebo.

Clobetasol propionate 0.05% under occlusion in the treatment of alopecia totalis/universalis. Tosti A, Piraccini B, Pazzaglia M, et al. *J Am Acad Dermatol* 2003; 49: 96–8.

A refractory group of 28 patients with AT/AU of 3–12 years' duration who had not responded to immunotherapy were treated on half of their scalp with 2.5 g of clobetasol propionate ointment under plastic film 6 nights per week for 6 months. Regrowth started at 6–14 weeks, and eight patients (28.5%) achieved >75% regrowth. Eleven patients developed painful folliculitis, including five of the six who withdrew from the study. At 6 months, follow-up, 18% of the 28 patients maintained complete regrowth.

Randomized double-blind placebo-controlled trial in the treatment of alopecia areata with 0.25% desoximetasone cream. Charuwichitratana S, Wattanakrai P, Tanrattanakorn S. *Arch Dermatol* 2000; 136: 1276–7.

This double-blind, controlled trial randomized 70 patients with patchy AA to either topical 0.25% desoximetasone cream or placebo twice daily for 12 weeks. At the end of 12 weeks, any patient without complete regrowth was offered intralesional triamcinolone acetonide (10 mg/mL). Complete hair regrowth was seen in 15 (57.7%) of the treatment arm compared with 11 (39.3%) in the placebo group but this was not statically significant ($p=0.28$). Among those with incomplete regrowth, 14 elected for intralesional steroid injection with 13 (92.9%) achieving complete regrowth after 1–3 monthly injections. Among those with complete regrowth, 66% had no recurrence at 6 months, follow-up.

Diphencyprone in the treatment of alopecia areata. Happle R, Hausen BM, Weisner-Menzel L. *Acta Derm Venereol* 1983; 63: 49–52.

This study demonstrated the unilateral response observed when one side of the scalp is treated with DPCP. A total of 27 patients (5 with mild alopecia, 22 with totalis) were sensitized with 2% solution of DPCP and titrated to an effective concentration (0.0001–2%). Among those, 18 (66.6%) demonstrated continuous response, five (18.5%) had initial response, and four (14.8%) had no response. Interestingly, among the five patients who demonstrated an initial response, four responded to a lower concentration of DPCP.

Topical immunotherapy with diphenylcyclopropenone in the treatment of chronic extensive alopecia areata. Sotiriadis D, Patsatsi A, Lazaridou E, et al. *Clin Exp Dermatol* 2007; 32: 48–51.

This prospective, open clinical trial included 17 patients with AT/AU and 24 with severe AA (>50% scalp involvement). After sensitization with DPCP 2% in acetone, progressively higher concentrations (from 0.001% to 0.1%) were applied once weekly for a period of 6–12 months. Significant hair regrowth was observed

in five patients with AT/AU (31.25%) and 10 patients with AA (45.4%). These results were sustained in 66.6% of patients for a 12-month follow-up period.

Topical immunotherapy with diphenylcyclopropenone of patients with alopecia areata – a large retrospective study on 142 patients with a self-controlled design. Ohlmeier MC, Traupe H, Luger TA, et al. *J Eur Acad Dermatol Venereol* 2012; 26: 503–7.

This large, retrospective review evaluated 142 patients (70% female), the majority of whom (60%) had multifocal AA. After sensitization with 2% DPCP in acetone, weekly challenges with increased concentrations (0.00001–2%) were used. Complete response (>90% hair regrowth) was seen in 51 (37.8%) patients and 20 (14.8%) patients had partial regrowth (50%–90%). Hair regrowth was inversely related to severity of disease (severe AA less responsive to DPCP) and 45.1% of patients with complete response relapsed within 3 years.

Oral ruxolitinib induces hair regrowth in patients with moderate-to-severe alopecia areata. Mackay-Wiggan J, Jabbari A, Nguyen N, et al. *JCI Insight* 2016; 1: e89790.

This open-label study evaluated 12 patients with moderate-to-severe AA receiving ruxolitinib 20 mg twice daily for 3–6 months with a 3-month follow-up after cessation of therapy. Nine patients (75%) demonstrated >50% regrowth. Responders experienced shedding at the cessation of therapy.

Safety and efficacy of the JAK inhibitor tofacitinib citrate in patients with alopecia areata. Crispin MK, Ko JM, Craiglow BG, et al. *JCI Insight* 2016; 1: e89776.

This multicenter, open-label, single arm trial evaluated tofacitinib 5 mg twice daily in 66 patients with severe AA (>50% scalp loss) for 3 months. A majority of patients had AU (71.2%). Twenty-one patients (32%) were significant responders (>50% change in Severity of Alopecia Tool [SALT] score), 21 patients (32%) were intermediate responders (5–50% change) and 24 patients (36%) were non-responders (<5% change) at 3 months. AA and ophiasis subtypes were more responsive than AT/AU. Duration of current episode was negatively correlated with percentage change in SALT score.

Tofacitinib for the treatment of severe alopecia areata and variants: a study of 90 patients. Liu LY, Craiglow BG, Dai F, et al. *J Am Acad Dermatol* 2017; 76: 22–8.

This retrospective study evaluated 90 patients with severe AA (>40% scalp loss) treated with tofacitinib. Of these, 75 patients (83.3%) had AU, 2 patients (2.2%) had AT, and 13 patients (14.4%) had AA. All patients started on tofacitinib 5 mg twice daily. Adjuvant therapy (300 mg prednisone monthly for 3 doses) or tofacitinib dose was increased (10 mg twice daily) if the patient had no response or the response plateaued. Clinical response (>50% SALT reduction) was seen in 77%, complete response was seen in 13 patients (20%), and moderate response (51%–90%) was seen in 25 patients (38.4%). AA subtype was more responsive than AT/AU.

Tofacitinib for the treatment of alopecia areata and variants in adolescents. Craiglow BG, Liu LY, King BA. *J Am Acad Dermatol* 2017; 76(1): 29–32.

This retrospective study evaluated 13 adolescent patients treated with tofacitinib 5 mg twice daily for median duration of 5 months. Six patients (46%) had AA, one patient (8%) had AT and six patients (46%) had AU. Nine patients (69%) experienced regrowth. The mean duration of current episode was similar

between responders and non-responders (2 years), except for one non-responder who had AU for 12 years.

Second-Line Therapies

• Oral minoxidil	B
• Topical minoxidil	B
• Anthralin	B

Evaluation of oral minoxidil in the treatment of alopecia areata. Fiedler-Weiss VC, Rumsfield J, Buys CM, et al. Arch Dermatol 1987; 123: 1488–90.

Sixty-five patients were treated with oral minoxidil 5 mg twice daily. Forty-four patients (68%) had 75%–100% hair loss, 19 patients (29%) had 25%–74% of hair loss, and two patients (3%) had 0%–24% loss. Fifty-two patients (80%) had some response to oral minoxidil. Cosmetic response was reported in 18% of patients, with the majority of responders (66.7%) having mild-to-moderate disease (<75% loss at baseline). The drug was generally well tolerated; higher sodium intake increased the risk of fluid retention.

Combination tofacitinib and oral minoxidil treatment for severe alopecia areata. Wambier CG, Craiglow BG, King BA. J Am Acad Dermatol 2019; S0190-9622(19)32688-X.

This retrospective review examined 12 patients with severe AA treated with combination tofacitinib 5–10 mg twice daily and oral minoxidil 2.5 mg dosed daily for female patients and twice daily for male patients (to minimize hirsutism in female patients). Seven patients (58%) achieved at least 75% improvement in baseline SALT score over 4–6 months of treatment with tofacitinib 5 mg twice daily in combination with oral minoxidil.

Topical minoxidil solution (1% and 5%) in the treatment of alopecia areata. Fiedler-Weiss VC. J Am Acad Dermatol 1987; 16: 745–8.

Sixty-six patients applied minoxidil 1% or 5% solution twice daily at night under white petrolatum occlusion. In the minoxidil 5% solution group, 4 of 11 patients (37%) with 25%–74% scalp hair loss at baseline and 2 of 26 patients (6%) with 75%–100% scalp hair loss were 'cosmetic responders'.

Treatment of alopecia areata by anthralin-induced dermatitis. Plewig G, Braun-Falco O. Arch Dermatol 1979; 115: 1254–5.

In this study using 0.5% and 1.0% concentrations of anthralin, the mean time to response was 11 weeks and the mean time to cosmetic response was 23 weeks (range 8–60 weeks). Cosmetic response was achieved in 29% (11/38) of patients with <75% scalp hair loss and in 20% (6/30) of patients with >75% scalp hair loss. Approximately 75% of responders maintained adequate hair growth with continued treatment.

Third-Line Therapies

• Systemic corticosteroids	B
• Ciclosporin	A
• Intralesional autologous platelet-rich plasma	C
• Sulfasalazine	C
• Methotrexate	C
• Azathioprine	C
• Excimer laser	C
• Combination treatment of simvastatin and ezetimibe	C
• Topical/compounded JAK inhibitors	A

High-dose pulse corticosteroid therapy in the treatment of severe alopecia areata. Seiter S, Ugurel S, Tilgen W, et al. Dermatology 2001; 202: 230–4.

In this prospective open study 30 patients with >30% hair loss were treated with three courses of IV methylprednisolone (8 mg/kg) on 3 consecutive days at 4-week intervals. Twelve of 18 AA patients achieved >50% regrowth. None of the four patients with AT, five with AU, or three with ophiasic AA responded. Ten patients who responded retained the growth at 10 months.

Placebo-controlled oral pulse prednisolone therapy in alopecia areata. Kar BR, Handa S, Dogra S, et al. J Am Acad Dermatol 2005; 53: 1100–1.

Forty-three patients were randomized to receive oral prednisolone 200 mg weekly (23) or placebo (20) for 3 months. All patients had more than 40% scalp hair loss, or more than 10 patches of AA, for more than 9 months. Eight of 23 in the treatment group showed more than 30% regrowth, compared with none in the placebo group. More than 60% regrowth occurred in only two patients, both within the treatment group. Side effects occurred in 55% of the treatment group, compared with 11% in the placebo group, although all were temporary.

Pulse methylprednisolone therapy for severe alopecia areata: an open prospective study of 45 patients. Friedli A, Labarthe MP, Engelhardt E, et al. J Am Acad Dermatol 1998; 39: 597–602.

This open prospective study evaluated intravenous pulsed methylprednisolone in 45 severe AA patients (> 30% hair loss) with less than 1 year's duration of recent AA episode. Twenty patients had multifocal disease, 10 had ophiasic, and 15 had AT/AU. A pulse dose of IV methylprednisolone 250 mg twice daily for 3 consecutive days was administered at 1, 3, 6, and 12 months. Patients were treated concomitantly with oral ranitidine 2 days prior to the pulse and continued a week afterwards. Among the 28 patients with regrowth, 11 patients (24%) had 100% regrowth after 6 months and 7 patients (15.5%) had 80%–90% regrowth. A majority of complete responders had patchy multifocal AA, with AT/AU and ophiasic patterns being less responsive.

Cyclosporine for moderate-to-severe alopecia areata: a double-blind, randomized, placebo-controlled clinical trial of efficacy and safety. Lai VWY, Chen G, Gin D, et al. J Am Acad Dermatol 2019; 81(3):694–701.

This double-blind, placebo-controlled trial randomized 32 patients with moderate-to-severe AA to ciclosporin 4 mg/kg daily or placebo for 12 weeks. The average duration of current episode of AA was 6.5 years. Five patients (31.3%) achieved a 50% reduction in SALT score at 3 months in the treatment arm compared to the one patient (6.3%) in the placebo, but this was not statistically significant.

A randomized, double-blind, placebo- and active-controlled, half-head study to evaluate the effects of platelet-rich plasma on alopecia areata. Trink A, Sorbellini E, Bezzola P, et al. Br J Dermatol 2013; 169: 690–4.

Forty-five subjects were randomized to platelet-rich plasma (PRP), triamcinolone acetonide 2.5 mg/mL, or placebo injected intralesionally on three occasions at monthly intervals. Both triamcinolone and PRP led to hair regrowth in AA lesions compared with placebo and compared with the untreated side of the scalp at 2, 6, and 12 months.

Treatment of persistent alopecia areata with sulfasalazine. Rashidi T, Mahd AA. Int J Dermatol 2008; 47: 850–2.

An uncontrolled prospective trial of sulfasalazine 1–3 g daily in 39 patients with AA (SALT scores not provided in the article) demonstrated regrowth of more than 60% in 25.6% of patients and a moderate response in 30.7% of patients. Of those with more than 60% response, two patients demonstrated relapse, and among moderate responders three patients relapsed.

Low-dose systemic methotrexate therapy for recalcitrant alopecia areata. Lim SK, Lim CA, Kwon IS, et al. *Ann Dermatol*. 2017; 29(3): 263–7.

This retrospective review evaluated 29 patients with AA treated with methotrexate monotherapy. At the start of the trial, 23 patients (79.3%) had 25%–49% loss, 4 patients (13.8%) had 50%–74% loss, 1 patient (3.4%) had 75%–99% loss, and 1 patient (3.4%) had AT. Patients were treated with an initial dose of methotrexate of 10 mg weekly, which was increased by 2.5 mg every 2 weeks with a maximum dose of 17.5 mg weekly for a mean duration of 28.1 weeks (range 12–74 weeks). Complete regrowth (100%) was seen in 14 patients (48.3%) and with 75%–99% regrowth in 12 patients (41.4%). Patients with a disease duration (>24 months) demonstrated no response to methotrexate.

Long-term follow-up of the efficacy of methotrexate alone or in combination with low doses of oral corticosteroids in the treatment of alopecia areata totalis or universalis. Chartaux E, Joly P. *Ann Dermatol Venereol* 2010; 137: 507–13.

In 33 patients with AT or AU, complete regrowth was achieved in 8 of 14 patients (57%) who took methotrexate 15–25 mg once weekly and in 12 of 19 patients (63%) who took methotrexate in combination with prednisone 10–20 mg daily. Recurrence of AA occurred in 57% of responders after a decrease in the methotrexate dose or after stopping treatment.

Efficacy and tolerability of methotrexate in severe childhood alopecia areata. Royer M, Bodemer C, Vabres P, et al. *Br J Dermatol* 2011; 165: 407–10.

In this retrospective study of 14 children aged 8–18 with AA, five experienced a clinically relevant therapeutic response. The treatment was administered once weekly with a mean maximal dose of 18.9 mg weekly (0.38 mg/kg) and a mean duration of treatment of 14.2 months.

The authors have subsequently reported that response was maintained in two of the five responders at 6 and 4.3 years after treatment.

Could azathioprine be considered as a therapeutic alternative in the treatment of alopecia areata? A pilot study. Farshi S, Mansouri P, Safar F, et al. *Int J Dermatol* 2010; 49: 1188–93.

A total of 20 patients with minimum 6 months' history of AA were included in this pilot study. Azathioprine was taken at a dose of 2 mg/kg of body weight. The mean regrowth was 52.3% and the mean hair loss before treatment was 72.7%, compared with 33.5% after 6 months of treatment.

Treatment of alopecia areata with simvastatin/ezetimibe. Latouf C, Jimenez JJ, Tosti A, et al. *J Am Acad Dermatol* 2015; 72: 359–61.

A series of 29 patients with AA were treated with simvastatin 40 mg and ezetimibe 10 mg daily. Nineteen completed 24 weeks treatment, and 14 of these were considered responders (20% hair regrowth). Five out of seven responders who discontinued the treatment relapsed, whereas five out of seven who continued for a further 24 weeks maintained the response.

Alopecia areata (AA) and treatment with simvastatin/ezetimibe: experience of 20 patients. Loi C, Starace M, Piracini BM. *J Am Acad Dermatol* 2016; 74: e99–100.

No convincing response was observed in this study, which seems to have sampled a more severely affected population.

Unsuccessful treatment of alopecia areata with simvastatin/ezetimibe: experience in 12 patient. Freitas Gouveia M, Trüeb RM. *Skin Appendage Disord* 2017; 3(3): 156–60.

This prospective observational study evaluated 12 patients (75% female) taking simvastatin/ezetimibe 40/10 mg daily in addition to their ongoing therapy for AA over the course of 6 months. No response was seen in eight (67%) patients, two (24%) had transient regrowth, and two (24%) had <20% regrowth.

Ruxolitinib cream for the treatment of patients with alopecia areata: a 2-part, double-blind, randomized, vehicle-controlled phase 2 study. Olsen EA, Kornacki D, Sun K, et al. *J Am Acad Dermatol* 2020; 82(2): 412–9.

In this 24-week study of ruxolitinib 1.5% cream (applied twice daily) in patients with 25%–100% scalp loss there was no significant difference (defined as 50% SALT score reduction) between the ruxolitinib 1.5% cream and vehicle treatment groups.

11

Amyloidosis

William Y.-M. Tang, Loi-Yuen Chan

Amyloid is an altered, insoluble protein folded in β -pleated sheets, which is deposited extracellularly. Amyloid can accumulate in one or many organs, thereby causing dysfunction. The common amyloid entities are AL (amyloid light chain), AA (amyloid associate), ATTR (transthyretin), and β_2 -microglobulin.

Systemic amyloidosis consists of primary systemic amyloidosis (AL amyloidosis), secondary systemic amyloidosis (AA amyloidosis), dialysis-associated amyloidosis (β_2 -microglobulin), and senile systemic amyloidosis. Skin changes such as petechiae, ecchymoses, waxy papules and plaques, nail dystrophy, and, rarely, blisters may occur. Management of systemic amyloidosis is complex. Treatment of any skin lesions depends on treating the underlying systemic amyloidosis and is beyond the scope of this chapter.

Cutaneous amyloidosis may be primary or secondary. The latter refers to deposition of amyloid within skin tumors such as seborrheic keratosis, porokeratosis, pilomatricoma, and basal cell carcinoma. Primary localized cutaneous amyloidosis is characterized by the deposition of amyloid in the skin without involving any internal organ. It occurs more commonly in Southeast Asian, Chinese, Middle Eastern, and South American people. There are three types of primary localized cutaneous amyloidosis: lichen amyloidosis; macular amyloidosis (keratinic amyloid in both types, derived from degenerated keratinocytes); and nodular amyloidosis (AL amyloid, derived from immunoglobulin light chains). *Biphasic amyloidosis* refers to co-occurrence of macular and lichen amyloidosis in a patient. Approximately 10% of cases of primary localized cutaneous amyloidosis appear to be familial with autosomal inheritance. Mutation in oncostatin M receptor (OSMR) and interleukin-31 receptor A (IL31RA) genes have been reported.

Lichen amyloidosis is a persistent eruption of multiple red-brown hyperkeratotic papules often affecting extensor aspects of extremities, especially the pretibial surfaces. The male-to-female ratio varies among studies from 2:1 and 1:2. Pruritus is present in 60–90% of primary localized cutaneous amyloidosis lesions and the intensity can be quite severe. Small-fiber neuropathy and increased IL-31 receptor expression might play a role in pruritus.

Macular amyloidosis is characterized by an eruption consisting of small, dusky-brown or grayish pigmented macules distributed symmetrically over the upper back and upper arm. It has a reticulated or rippled pattern. Itch is variable, and patients seek medical advice for aesthetic issues.

Nodular amyloidosis is the rarest subtype of primary localized cutaneous amyloidosis. It is characterized by single or multiple waxy, firm, brown or pink nodules involving the legs, head, trunk, arms, and genitalia. It is usually asymptomatic.

Both lichen and macular amyloidosis run a benign course. However, for primary localized nodular amyloidosis, an estimated 7% risk of progression to systemic amyloidosis has been reported. Further, a case of primary localized nodular amyloidosis associated with CREST and Sjögren syndrome was also reported.

MANAGEMENT STRATEGY

Pruritus and unsightly presentation are common in localized cutaneous amyloidosis. Currently, effective treatment of cutaneous amyloidosis is lacking. *Antihistamines* and *topical corticosteroids* are commonly prescribed.

Phototherapy (ultraviolet B or PUVA [psoralen and ultraviolet A]) has been used to treat lichen amyloidosis successfully for relief of pruritus. Oral retinoid (*acitretin* or *alitretinoin*) either used alone or in combination with phototherapy is an effective treatment. Laser treatments reported to be successful in treating cutaneous amyloidosis include carbon dioxide laser, pulsed-dye laser (PDL), and neodymium:yttrium aluminum garnet (Nd:YAG) laser.

Dermabrasion has been successful in treating lichen and nodular amyloidosis. This improves cosmesis and alleviates pruritus but brings accompanying procedural pain and possible skin atrophy. There is an anecdotal report that dermabrasion of lichen amyloidosis under tumescent anesthesia reduced procedural pain.

Other treatment choices include tacrolimus, transcutaneous electrical nerve stimulation (TENS), capsaicin, tocotrienate, *amitriptyline*, and *methotrexate*.

Specific Investigations

- Skin biopsy
- Dermoscopy

All forms of amyloidosis have similar histological findings. On light microscopy, amyloid is characteristically a pink, amorphous material. Special stains, such as Congo red and crystal violet, can highlight the amyloid deposit. Amyloid can be metachromatically stained red by crystal violet staining of an aqueous mount of the specimen. Congo red staining of amyloid shows apple-green birefringence under polarized light microscopy. There are two major dermoscopic patterns characteristic of primary localized cutaneous amyloidosis. The most common dermoscopic finding is a central hub, either white or brown, surrounded by various configurations of pigmentation. For cases of lichen amyloidosis with prominent hyperkeratosis, the central hub is replaced by a scar-like morphology.

First-Line Therapies

- Sedating antihistamines **E**
- Topical high-potency corticosteroids **E**

Although there are no specific studies evaluating the efficacy of antihistamines and topical corticosteroids for treating cutaneous amyloidosis, they are considered first-line therapies. Sedating antihistamines and high-potency steroids help in the relief of pruritus and thinning of lesions.

Second-Line Therapies

- Phototherapy/photochemotherapy **D**
- Oral retinoids **D**
- Laser **D**
- Tacrolimus **E**
- TENS **D**

Successful treatment of lichen amyloidosis with combined bath PUVA photochemotherapy and oral acitretin. Grimmer J, Weiss T, Weber L, et al. Clin Exp Dermatol 2007; 32: 39–42.

Two male patients with lichen amyloidosis over the extensor surfaces of the lower legs were treated with bath PUVA three to four times per week for 11 weeks, plus oral administration of acitretin 0.5 mg/kg/day for 7 months. There was almost complete resolution of skin lesions in both patients. No relapse was observed for 8 months after discontinuation of treatment.

An alternative treatment model: the combination therapy of narrow band ultraviolet B phototherapy and tacrolimus ointment 0.1% in biphasic amyloidosis. Kalkan G, Markoç F, Bas Y. J Pak Med Assoc 2014; 64(5): 579–82.

A 26-year-old woman with biphasic amyloidosis received tacrolimus 0.1% plus narrow band ultraviolet B treatment. Significant improvement was seen at the end of 8 weeks, with remission of pruritus and flattening of papules.

Successful treatment of lichen amyloidosis with oral alitretinoin. Tietze JK, Heppt MV, Flaig MJ, et al. J Eur Acad Dermatol Venereol 2016; 30(5): 884–5.

A 66-year-old patient with biopsy-confirmed lichen amyloidosis, who failed treatments with topical steroids, tacrolimus ointment, emollients, PUVA therapy, and dimethyl sulfoxide (DMSO), was treated with oral alitretinoin 30 mg QD. The pruritus improved and hyperkeratotic papules flattened within 1 month of therapy. The treatment continued for a further 6 months but was then stopped by the patient. The skin condition remained stable over the next 4 months but then deteriorated. Re-implementation of alitretinoin improved the pruritus and the skin lesions. The effect of alitretinoin was attributed to its strong antiinflammatory and immune-modulatory effects.

Alitretinoin treatment of lichen amyloidosis. Koh WS, Oh EH, Kim JE, et al. Dermatol Ther 2017; 30(6).

A 49-year-old woman with atopic dermatitis and biopsy-proven lichen amyloidosis had been treated by oral ciclosporin, antihistamine, and topical steroids without response. A 6-month course of alitretinoin 30 mg daily produced marked improvement in thickness and color of the papules without aggravation of her dermatitis. It was proposed that alitretinoin increases the production of IL-4, thereby exerting an inhibitory effect on growth

of mast cells, and consequently decreasing pruritogenic IL-31, accounting for its antipruritic effect.

Lichen amyloidosis improved by 0.1% topical tacrolimus. Castaneda-Cazares JP, Lepe V, Moncada B. Dermatology 2002; 205: 420–1.

One patient with lichen amyloidosis was treated with tacrolimus 0.1% ointment twice daily. Resolution of pruritus was noted after 2 weeks of therapy and marked improvement of plaque thickness was observed after 2 months.

Transcutaneous electrical nerve stimulation for reduction of pruritus in macular amyloidosis and lichen simplex. Yüsek J, Sezer E, Aksu M, et al. J Dermatol 2011; 38: 546–52.

Eight patients with macular amyloidosis and eight with lichen simplex were treated with high-frequency TENS thrice weekly for 4 weeks, 30 minutes' duration, to areas with most intense itching. All patients with macular amyloidosis and six (75%) with lichen simplex had relief of their pruritus.

Efficacy of different modes of fractional CO₂ laser in the treatment of primary cutaneous amyloidosis: a randomized clinical trial. Esmat SM, Fawzi MM, Gawdat HI, et al. Lasers Surg Med 2015; 47: 388–95.

Twenty-five patients with primary cutaneous amyloidosis (16 macular amyloidosis and nine lichen amyloidosis) were treated by fractional CO₂ laser using superficial ablation and deep rejuvenation to equal areas of randomly assigned lesions after the application of a topical anesthetic cream. Each patient received four sessions with 4 weeks intervals. Both modes yielded significant reduction of pigmentation, thickness, itching, and amyloid deposit. The superficial ablation was better tolerated by patients.

Successful treatment of lichen amyloidosis using a CO₂ surgical laser. Norisugi O, Yamakoshi T, Shimizu T. Dermatol Ther 2014; 27: 71–3.

Two male patients with lichen amyloidosis on their legs unresponsive to topical corticosteroids were treated with CO₂ laser twice a month, using a setting of 10–15 W with a 0.12-second pulse duration, 0.36-second rest duration, and a 5-mm laser spot size. The papules gradually flattened and there was marked reduction of the itching as assessed by the visual analog score (VAS). No complications of the treatment were noted.

Pulsed dye laser for the treatment of macular amyloidosis: a case report. Barsky M, Buka RL. Cutis 2014; 93(4): 189–92.

A 57-year-old man with recalcitrant macular amyloidosis was treated with three treatment sessions of 595-nm PDL (7.5 J/cm², 30/10 millisecond epidermal cooling, 6-mm spot size) at 2-week intervals. Improvement of lesions was noted with each treatment.

532-nm and 1064-nm Q-switched Nd:YAG laser therapy for reduction of pigmentation in macular amyloidosis patches. Ostovari N, Mohtasham N, Oadras MS, et al. J Eur Acad Dermatol Venereol 2008; 22: 442–6.

Twenty patients with histologically confirmed macular amyloidosis were treated with Q-switched Nd:YAG laser with 532 nm in a part of their plaques and with 1064 nm in another part of their plaques. Assessment of efficacy was done by colorimetric scores and digital photographs before laser therapy and 8 weeks after treatment. Both lasers were effective in reducing pigmentation, with the 532 nm more effective; 90% of cases treated by 532 nm had a good or very good response. For the 1064-nm-treated patches, 60% of cases had a good or very good response.

Third-Line Therapies

- Capsaicin
- Tocoretinate
- Amitriptyline
- Methotrexate

E
D
E
E

Successful treatment of lichen amyloidosis using capsaicin 8% patch. Zeidler C, Metze D, Ständer S. *J Eur Acad Dermatol Venereol* 2016; 30(7): 1236–8.

Two male patients with longstanding lichen amyloidosis not responding to topical corticosteroid and systemic antihistamine were treated with an 8% capsaicin patch applied once directly over the itchy area for 60 minutes. Pruritus subsided totally the next day and the improvement lasted for at least 2–3 months. The mechanism of action is due to capsaicin inducing regrowth of anatomically normal nerves and restoring normal neuronal function over the treated areas.

Clinical effect of tocoretinate on lichen and macular amyloidosis. Terao M, Nishida K, Murota H, et al. *J Dermatol* 2011; 38(2): 179–84.

Tocoretinate is a synthetic esterified compound of retinoic acid and tocopherol that is used for treating skin ulcers and improving skin manifestations of scleroderma, morphea, and hypertrophic scars. Ten patients (seven men and three women) with lichen amyloidosis and macular amyloidosis were treated with once-daily topical tocoretinate ointment. The outcome was very good for four, good for two, moderate for two, and poor for two. Normalization of epidermal differentiation via decreased expression

of involucrin and keratins 1 and 10 shown in vivo was thought to be beneficial in the treatment of amyloidosis.

Itch in familial lichen amyloidosis: effective treatment with amitriptyline in two cases. Yew YW, Tey HL. *Dermatol Ther* 2014; 27: 12–5.

Two Chinese male patients with lichen amyloidosis had extensive, pruritic, and hyperkeratotic papules affecting the shins. In both patients, the pruritus was not improved with potent topical steroids and oral antihistamines. Amitriptyline was started at a dose of 10 mg every other night, resulting in significant reduction of itch score and Dermatology Life Quality Index score assessed 3 weeks after commencement of treatment. Itch was well controlled at 8 months and 6 months, respectively. Side effects were minimal. However, the lesions of lichen amyloidosis remained unchanged. The action of amitriptyline may be related to inhibition of the reuptake of 5-HT and noradrenaline in the brainstem and spinal cord and the inhibition of voltage-dependent sodium and potassium channels in peripheral nerves.

Methotrexate for the treatment of recalcitrant primary localized cutaneous amyloidosis: a case series. Stull CM, Tey HL, Yosipovitch G. *Acta Derm Venereol* 2018; 98(9): 900–1.

Two Chinese males (57 years old and 71 years old) with 30 years' history of primary localized cutaneous amyloidosis failing to respond to multiple prior treatments. Significant reduction of itch and resolution of lesions were seen after methotrexate treatment (15 mg weekly for 4 weeks and 10 mg weekly for 8 weeks, respectively). The authors proposed methotrexate as a viable treatment option for longstanding refractory primary localized cutaneous amyloidosis that failed to respond to other treatment modalities.

Androgenetic alopecia

Rodney Sinclair, Wei-Liang Koh

In androgenetic alopecia (AGA), genetically predisposed scalp hair follicles miniaturize in response to androgens. AGA manifests clinically as male pattern hair loss (MPHL) in men and female pattern hair loss (FPHL) in women. Men develop bitemporal recession, diffuse thinning over the frontal scalp, and vertex balding. In women, especially those with long hair, the first symptoms are recurrent episodes of increased hair shedding and a reduction in ponytail volume. These symptoms may precede the visible diffuse thinning over the mid-frontal scalp by many years. The main hormone implicated is dihydrotestosterone (DHT), which is derived from testosterone after activation by 5 α -reductase type II sited at the hair follicle outer root sheath (ORS). In females, factors other than androgens (e.g., estrogens imbalance) may also play a role.

The severity of MPHL is most commonly graded by the Hamilton–Norwood scale. Men who experience early onset hair loss tend to progress more rapidly. In these men, early treatment is likely to have the greatest impact on hair growth. The severity of FPHL is most commonly scored using the Sinclair scale, a validated five-point photographic grading system based on part width.

The diagnosis is usually established clinically, through history and physical examination, including trichoscopy. Differential diagnoses include acute and chronic telogen effluvium, diffuse alopecia areata, and cicatricial alopecia (in particular frontal fibrosing alopecia). Blood tests may be indicated to exclude potential contributory cofactors such as thyroid dysfunction, iron deficiency anemia, or polycystic ovary syndrome. AGA may be associated with metabolic syndrome. Scalp biopsy is only required when a clinical diagnosis cannot be made confidently. In AGA, trichoscopy shows an increased proportion of single hair follicular units, miniaturized vellus-like hairs, and variable hair shaft diameters.

The goals of treatment are to identify and manage any possible triggering factors or comorbidities; reduce hair shedding; arrest progression of the hair loss; and where possible regrow scalp hair.

Specific Investigations

- Full blood count
- Ferritin
- Thyroid function test
- Female androgen screen:
 - Free serum testosterone
 - Sex hormone-binding globulin
 - Dehydroepiandrosterone sulfate (DHEA-S)
 - Prolactin
 - Luteinizing hormone/follicle-stimulating hormone
- Consider metabolic syndrome screening (fasting glucose/lipids)
- Trichoscopy
- Serial photographic documentation
- Scalp biopsy (only if diagnosis is in doubt)

Towards a consensus on how to diagnose and quantify female pattern hair loss – The ‘Female Pattern Hair Loss Severity Index (FPHL-SI)’. Harries M, Tosti A, Bergfeld W, et al. *Eur Acad of Dermatol and Venereol* 2016; 30: 667–76.

This scale looks at three components (Sinclair hair shedding scale, Sinclair hair density scale, and trichoscopy findings) and assigns points for a score range of 0–20 points. Calculation of the severity index can be performed rapidly in an office setting to establish a baseline and to monitor a patient’s progress. Early FPHL can be detected even before the patient developed Ludwig stage I hair loss, and treatment can then be instituted.

MANAGEMENT STRATEGY

A multimodality treatment approach is most likely to increase the chances of treatment success.

Male Pattern Hair Loss

There are two medications currently approved by the US Food and Drug Administration (FDA) for the treatment of MPHL: topical *minoxidil* (2% solution, 5% solution, and 5% foam formulations), and *finasteride* 1 mg once daily. Low-level laser light therapy medical devices also have FDA 510(k) clearance for the treatment of AGA. All other medical treatment options discussed below are used off-label. Treatments need to be continued indefinitely for continued effect.

Topical minoxidil is an effective therapy for AGA, with minimal side effects (e.g., irritant contact dermatitis, which is more likely with solution compared to foam). Minoxidil is converted by sulfotransferase in the ORS of hair follicles into its active metabolite, minoxidil sulfate. Minoxidil prolongs anagen duration, shortens telogen duration, and reverses hair follicle miniaturization. Inter-individual differences in the percutaneous absorption and sulfotransferase levels account for the variable clinical response. For men, the recommended dose of minoxidil 5% solution (50 mg/mL) is 1 mL twice daily. Peak hair growth is seen between 26 and 52 weeks. Some clinical improvement is noted after 2 years of continuous use in 40%–60% of patients. The vertex responds better than the frontal scalp. Continued use is necessary for sustained efficacy, and patients may experience a significant hair shedding

2–3 months after stopping treatment. For topical minoxidil 5% foam, the recommended usage is half a capful twice daily.

Minoxidil has also been used orally off-label. It has a higher patient treatment adherence rate compared to topical application. It is particularly useful for patients who develop contact dermatitis to topical minoxidil. Doses of 0.25–5 mg once daily have been evaluated in various studies for both MPHL and FPHL and found to be useful. Potential side effects are dose-related and include postural dizziness, palpitations, fluid retention, and hypertrichosis. Finasteride is a 5 α -reductase type II isoenzyme competitive inhibitor that is FDA-approved for the treatment of MPHL. Finasteride 1 mg daily reduces serum DHT by 71.4% and scalp DHT by 64.1% after 6 weeks in one study, while serum DHT is reduced by 68.4% after 52 weeks in another. On the other hand, finasteride 5 mg daily reduces serum DHT by 72.2% and scalp DHT by 69.4% after 6 weeks in one study, while serum DHT is reduced by 73% and scalp DHT by 41% after 24 weeks in another. Its actions include reversal of hair follicle miniaturization and prolonging anagen duration. Continuous use for 2 years arrests hair loss in over 95% of men, with 66% achieving moderate hair regrowth and 5% marked hair regrowth. Following discontinuation of finasteride, patients' hair counts return to baseline within 1 year. Finasteride is generally well tolerated. Sexual side effects such as decreased libido, erectile dysfunction, and decreased seminal fluid volume have been reported in 1.5% of men while on treatment, which usually reverse within 3 months of treatment cessation. Other less common side effects include gynecomastia and depression. Dutasteride has also been used off-label to treat MPHL. Dutasteride is a type I and type II 5 α -reductase isoenzyme inhibitor with greater suppression of DHT production than finasteride. Serum DHT is reduced by 92% and scalp DHT by 51% with dutasteride 0.5 mg daily for 24 weeks. In a meta-analysis, dutasteride has been shown to be more effective than finasteride in MPHL treatment. Dutasteride also produces greater adverse sexual side effects than finasteride.

Female Pattern Hair Loss

Topical minoxidil is the FDA-approved treatment for FPHL. Women may use the 2% solution twice daily, or 5% foam or solution once daily. Clinical improvement is seen in up to 80% of patients. Topical minoxidil is well tolerated. Potential side effects include facial hypertrichosis, scalp pruritus, palpitations, postural dizziness, or headaches in women with low blood pressure. While oral minoxidil has been used to treat pre-eclampsia in pregnancy in doses up to 100 mg daily, use of topical minoxidil to treat hair loss is generally not recommended for women while pregnant. Oral minoxidil has also been used off-label to treat FPHL in doses of 0.25–5 mg daily. It is particularly useful for women who develop scalp irritation with topical minoxidil and for women with long hair who find it difficult to adhere to topical therapy.

A number of oral antiandrogens have also been used off-label to treat FPHL. These agents appear to be more effective in women with hyperandrogenism. Androgen receptor antagonists used include spironolactone, cyproterone, flutamide, and bicalutamide. The 5 α -reductase inhibitors finasteride and dutasteride have also been used to treat FPHL; however, they appear to be less effective than androgen receptor antagonist agents. Antiandrogens and 5 α -reductase inhibitors could potentially feminize an unborn male fetus and caution is required when using in women with childbearing potential. Spironolactone has been shown to arrest progression of FPHL in over 90% of women, with approximately 30% having hair regrowth. This can be given at

a dose of 100–200 mg once daily. Potential side effects include breast tenderness, menstrual irregularities, headaches, decreased libido, polyuria, and hyperkalemia. There is no need for routine monitoring of serum potassium levels in a healthy female with no kidney disease. Cyproterone acetate has been used at a dose of 50–100 mg once daily for the first 10 days of the menstrual cycle in premenopausal women and continuously or for 3 weeks per month in postmenopausal women. Potential side effects include weight gain, breast tenderness, and decreased libido. Flutamide is a potent antiandrogen that can be used at doses of 50–250 mg for the treatment of FPHL not responding to other medical treatment modalities. Rare but severe cases of hepatotoxicity have been reported; hence, regular monitoring of liver function tests is mandatory. Other potential side effects include diarrhea and hot flushes. Bicalutamide is an antiandrogen in the same family as flutamide but is less likely to cause hepatotoxicity and has fewer other side effects. Effective doses used include 10–50 mg once daily.

Finasteride has been used off-label in the treatment of FPHL. Studies in premenopausal and postmenopausal women have reported effective dosing between 1.25 mg and 5 mg once daily. Potential side effects include decreased libido and risk of teratogenicity.

Hair restoration surgery is effective in patients who do not respond satisfactorily to medical therapy and in whom the hair loss is advanced. Skilled hair transplant surgeons can create a natural hair line and achieve a cosmetically significant increase in hair density. The technique requires substantial additional training and there is significant doctor to doctor variation in the quality of the outcome.

Other possible adjunctive treatments include *platelet-rich plasma* (PRP) treatment, *low-level laser light therapy*, *microneedling*, *fractional lasers*, *topical prostaglandin analogs*, and *Stemoxidine*. Further research is required to understand the true potential of these modalities. Keratin fiber camouflage powders, hairpieces, and wigs are also helpful for camouflage.

First-Line Therapies for MPHL

• Topical minoxidil	A
• Finasteride	A
• Oral minoxidil	C

Second-Line Therapy for MPHL

• Dutasteride	A

First-Line Therapies for FPHL

• Topical minoxidil	A
• Oral minoxidil	B
• Spironolactone	B
• Cyproterone acetate	B
• Flutamide	B
• Bicalutamide	C
• Finasteride	B

The effectiveness of treatments for androgenetic alopecia: a systematic review and meta-analysis. Adil A, Godwin M. J Am Acad Dermatol 2017; 77: 136–141.e5.

Meta-analysis showed a mean difference of +12.41 hairs/cm² in the topical minoxidil 2% twice-daily group compared with placebo treatment in women. The treatments that showed a

mean difference in hair count for men are finasteride 1 mg daily (+18.37 hairs/cm²), low-level laser light therapy (+17.66 hairs/cm²), topical minoxidil 5% twice daily (+14.94 hairs/cm²), and topical minoxidil 2% twice daily (+8.11 hairs/cm²). All these treatments were superior to placebo ($p < .00001$).

Effectiveness and safety of low-dose oral minoxidil in male androgenetic alopecia. Jimenez-Cauhe J, Saceda-Corralo D, Rodrigues-Barata R, et al. *J Am Acad Dermatol* 2019; 81: 648–9.

In this retrospective review of 41 males with AGA who received oral minoxidil at 2.5–5 mg daily (16 patients received as monotherapy) over a minimum of 6 months, 90.2% of patients had clinical improvement (26.8% with marked improvement) while the remaining 9.8% showed stabilization. For the oral minoxidil monotherapy subgroup, six out of 16 patients had marked improvement. Mild and well-tolerated side effects include hypertrichosis in 10 patients, lower limb edema in two patients, and shedding in one patient.

Minoxidil 1mg oral versus minoxidil 5% topical solution for the treatment of female-pattern hair loss: a randomized clinical trial. Ramos PM, Sinclair RD, Kasprzak M, et al. *J Am Acad Dermatol* 2020; 82: 252–3.

In this first study of its kind, females between 18 and 65 years of age with FPHL were randomized to receive oral minoxidil 1 mg or topical minoxidil 5% once daily for 24 weeks. The primary end point was change in total hair density in parietal area from baseline to week 24. The increase was by 12% in the oral minoxidil group versus 7.2% in the topical minoxidil group, with an overlap in their 95% confidence intervals. For the oral minoxidil group, 4% had pretibial edema and 27% had hypertrichosis. For the topical minoxidil group, 19% had scalp pruritus and 4% had hypertrichosis. Cases of hypertrichosis were mild and well tolerated. There was no hypotension-related event. Oral minoxidil can be considered if a patient cannot tolerate, or is poorly compliant to, topical minoxidil.

Female pattern hair loss: a pilot study investigating combination therapy with low-dose oral minoxidil and spironolactone. Sinclair RD. *Int J Dermatol* 2018; 57: 104–9.

This is an observational pilot study of 100 women with FPHL treated with combination minoxidil 0.25 mg and spironolactone 25 mg oral capsule once daily, followed prospectively for 12 months. Mean reduction in hair loss severity score by Sinclair staging was 0.85 at 6 months and 1.3 at 12 months. Mean reduction in hair shedding score using a six-point visual analog scale was 2.3 at 6 months and 2.6 at 12 months. Mild side effects were seen in eight patients and included postural hypotension, hypertrichosis, and urticaria. This combination treatment appears to be safe and effective for the treatment of FPHL.

The efficacy and safety of dutasteride compared with finasteride in treating men with androgenetic alopecia: a systematic review and meta-analysis. Zhou Z, Song S, Gao Z, et al. *Clin Interv Aging* 2019; 14: 399–406.

This systematic review and meta-analysis looked at three randomized, controlled trials (total 576 men), comparing dutasteride with finasteride. The mean change in total hair count, investigator's assessment of global photographs for the vertex and frontal views, panel global photographic assessment for the vertex and frontal views, and subjects' assessment were significantly better for the dutasteride group (0.5–2.5 mg daily) compared to the finasteride group (1–5 mg daily) after 6 months of treatment. With regard to side effects, there was no significant difference between

dutasteride and finasteride in altered libido, erectile dysfunction, and ejaculation disorders. Long-term efficacy and tolerance were not assessed. Selection and publication bias might have affected study results.

The efficacy and use of finasteride in women: a systematic review. Hu AC, Chapman LW, Mesinkovska NA. *Int J Dermatol* 2019; 58: 759–76.

In this systematic review evaluating the use of finasteride in various conditions, with regard to female pattern hair loss treatment, higher doses of finasteride (1.25–5 mg/day) seem to be more effective for improving hair loss. Lower doses of finasteride at 1 mg/day do not seem to be efficacious.

Androgens in women: hormone-modulating therapies for skin disease. Azarchi S, Bienenfeld A, Lo Sicco K, et al. *J Am Acad Dermatol* 2019; 80: 1509–21.

This is a comprehensive review of the current hormone-modulating therapies for the management of androgen-mediated cutaneous disorders, including FPHL. The level of evidence and strength of recommendations for spironolactone, flutamide, finasteride, and dutasteride were presented.

Safety of oral bicalutamide in female pattern hair loss: a retrospective review of 316 patients. Ferial Ismail F, Meah N, de Carvalho LT, et al. *J Am Acad Dermatol* 2020 [Epub ahead of print].

This retrospective study included 316 females, with a mean age of 48.96 years (range 15–85 years), receiving bicalutamide 10–50 mg once daily for a mean duration of 6.216 months (range 2–69 months) as monotherapy (8 patients) or associated with oral minoxidil (308 patients) and spironolactone (172 patients). Based on photographs, comparison by three independent dermatologists, the mean Sinclair stage at baseline was 2.77. The mean reduction in Sinclair stage was 0.18 at 3 months, 0.47 at 6 months, 0.56 at 9 months, 0.68 at 12 months, and 0.80 at 2 years. The most common adverse effect was mild elevation of liver transaminases in nine (2.85%) patients.

Second-Line Therapies for FPHL/Third-Line Therapies for MPHL

• Hair transplant surgery	A
• Low-level laser light therapy	A
• Platelet-rich plasma	A
• Microneedling	B
• Fractional laser	B
• Topical prostaglandin analogs	A
• Topical Stemoxydine	B

Old friend or new ally: a comparison of follicular unit transplantation and follicular unit excision methods in hair transplantation. Gupta AK, Love RP, Harris JA. *Dermatol Surg* 2020 [Epub ahead of print].

This article gives a good overview with regard to follicular unit excision and follicular unit transplantation, comparing the pros and cons between the two techniques and when to choose one over the other.

Platelet-rich plasma as a treatment for androgenetic alopecia. Gupta AK, Cole J, Deutsch DP, et al. *Dermatol Surg* 2019; 45:1262–73.

The authors performed a meta-analysis to evaluate the effectiveness of PRP as treatment for AGA. The standardized mean difference (SMD) in hair density in patients treated with PRP injections was 0.58 (medium effect) in favor of PRP treatment when compared with baseline (10 studies, pooled $n=165$, $p < .00001$). The SMD was 0.51 (medium effect) in favor of PRP treatment when compared with placebo treatment (6 studies, pooled $n=99$, $p < .0004$). The authors conclude that PRP is beneficial in AGA treatment and recommended that three monthly sessions of PRP be used followed by a 3–6-month maintenance period.

Comparative effectiveness of low-level laser therapy for adult androgenic alopecia: a system review and meta-analysis of randomized controlled trials. Liu KH, Liu D, Chen YT, et al. *Lasers Med Sci* 2019; 34: 1063–69.

In this meta-analysis, quantitative analysis showed a significant increase in hair density for those treated with low-level laser therapy (LLLT) vs. sham group (standardized mean difference (SMD) 1.316, 95% CI 0.993–1.639). Subgroup analysis showed LLLT increases hair growth in both genders, in both comb- and helmet-type devices and in short- (<20 weeks) and long-term (>20 weeks) treatment course. Paradoxically, the subgroup analysis also revealed a more significant increase in hair growth for LLLT versus sham in the low-frequency treatment group (<60 minutes per week) than in the high-frequency group (>60 minutes per week). The explanation remains unclear. The authors conclude that LLLT represents a potentially effective treatment for both MPHL and FPHL, and that the type of LLLT device and LLLT treatment course duration did not affect hair growth effectiveness.

Microneedling for the treatment of hair loss? Fertig RM, Gamret AC, Cervantes J, et al. *J Eur Acad Dermatol Venereol* 2018; 32: 564–9.

This review article summarizes the current literature on microneedling and its role in treatment of hair loss. For AGA, there are a total of five studies (case series to controlled studies) involving microneedling, but mainly in conjunction with other therapies. Microneedling as adjunctive therapy may have a beneficial effect in improving hair density, although further studies are required to refine a standard treatment protocol. Microneedling may help hair regrowth by triggering neovascularization and stimulating the release of growth factors and expression of Wnt proteins. In addition, microneedling can help facilitate penetration of topically applied medications.

Laser-assisted hair regrowth: fractional laser modalities for the treatment of androgenic alopecia. Dabek RJ, Austen WG Jr, Bojovic B. *Plast Reconstr Surg Glob Open* 2019; 7: e2157.

The authors evaluated nine original studies looking at the effect of fractional lasers on hair growth in AGA. Four different types of lasers were identified (fractional ablative CO₂ laser, fractional ablative erbium:YAG laser, fractional non-ablative Er glass laser, fractional non-ablative thulium laser). Only the non-ablative Er glass and thulium lasers have been shown to be effective for hair growth as monotherapy. The fractional ablative CO₂ laser has been shown to be effective in one human study, in conjunction with the use of topical growth factors. Common side effects were mild transient pain and pruritus. In the studies reviewed, the number of treatment sessions ranged from 5 to 15, with a frequency of once weekly to 30-day intervals. The ideal treatment frequency and duration are yet to be determined. Mechanisms of action leading to hair regrowth are likely similar to the effects of microneedling.

A randomized double-blind placebo-controlled pilot study to assess the efficacy of a 24-week topical treatment by latanoprost 0.1% on hair growth and pigmentation in healthy volunteers with androgenetic alopecia. Blume-Peytavi U, Lönnfors S, Hillmann K, et al. *J Am Acad Dermatol* 2012; 66: 794–800.

In this randomized, double-blind, placebo-controlled study, 16 men with mild AGA (Hamilton II–III) were included. Latanoprost 0.1% and placebo were applied daily for 24 weeks on two comparable minizones on the frontotemporal scalp. Measurements on hair growth, density, diameter, pigmentation, and anagen/telogen ratio were performed at intervals. At 24 weeks, an increased hair density (+22% in the entire study population) on the latanoprost-treated site was observed and this was significantly higher compared with baseline and placebo.

Oral presentation: Stemoxydine, a hair kenogen phase shortener, leading to increased hair density. Reygagne P. *Int J Trichology* 2014; 6(3): 113–39.

Stemoxydine, a prolyl-4-hydroxylase competitive inhibitor, has been found in three double-blind, vehicle-controlled, randomized trials involving healthy males aged 18–55 with AGA Grade III to IV (two intraindividual studies on 16 and 23 males, respectively, with 5 days a week application, and one interindividual study on 100 men with daily application) to significantly increase hair density after a 3-month treatment period (additional 4% increase compared to control). Additionally, a significant decrease in the percentage of hairs in kenogen phase was found in one study. Kenogen is a subphase within telogen and may lead to empty follicles. No skin intolerance was recorded in all three studies. The author suggested that Stemoxydine could act as a kenogen phase shortener in AGA, leading to an increase in visible scalp hair density.

Angiolymphoid hyperplasia with eosinophilia

William Y.-M. Tang, Loi-Yuen Chan

Angiolymphoid hyperplasia with eosinophilia (ALHE), also known as epithelioid hemangioma, is an uncommon disease. ALHE is a benign vascular proliferation of unknown etiology with a characteristic component of epithelioid endothelial cells.

Recent literature review shows that ALHE usually affects patients in their third to fourth decade with approximately an equal male to female ratio. Cutaneous lesions present as single or multiple cutaneous papules or subcutaneous nodules, sometimes with inflammatory features. The ear and periauricular area, face, and scalp are most commonly affected. Peripheral blood eosinophilia is noted in 10%–20%. Regional lymphadenopathy is observed in 5%–10%. Although considered benign in nature, the etiology of ALHE is unknown. Neoplastic proliferation of vascular tissue, arteriovenous shunting, or reactive hyperplasia of vascular tissue secondary to trauma (such as ear piercing), infection (human T-lymphotropic virus [HTLV] or herpes virus 8), renin, or hyperestrogenic states have all been proposed as causal factors. ALHE may cause symptoms such as cosmetic disfigurement, bleeding, itch, and pain. It has been associated with various lymphoproliferative conditions, supporting the contention that it may represent a monoclonal T-cell process.

The differential diagnoses of ALHE include Kimura disease, pyogenic granuloma, lymphocytoma cutis, insect bite, sarcoidosis, Kaposi sarcoma, and angiosarcoma. ALHE and Kimura

disease are generally regarded as separate clinicopathological entities. Kimura disease is a chronic inflammatory condition of unknown etiology often affecting young Asian men, and typically presenting as cervical lymphadenopathy and subcutaneous nodules in the head and neck region. However, coexistence of ALHE and Kimura disease in the same patient has been reported.

MANAGEMENT STRATEGY

Spontaneous remission is rare in ALHE. *Complete surgical excision* is preferred for persistent lesions. Recurrence may occur if excision is incomplete. *Laser therapy and radiofrequency ablation* are alternative surgical options. *Cryotherapy*, inexpensive and easily available, is a conventional treatment although reports on its efficacy are lacking. Other treatments reported effective include *topical and intralesional corticosteroids*, *propranolol*, *topical imiquimod*, *topical tacrolimus*, *isotretinoin*, *methotrexate*, *suplatast tosilate*, *intralesional interferon- α_{2b}* , *thalidomide*, and *photodynamic therapy*. Whatever treatment method, recurrence and incomplete resolution remain frequent. Although treatment failure is lowest with excision, it is still noted in about 40.8%.

Specific Investigations

- Histopathology
- Dermoscopy
- Imaging

Histopathological features of ALHE are characterized by a proliferation of blood vessels of varying sizes lined by plump endothelial cells. These histiocytoid endothelial cells show abundant eosinophilic or clear cytoplasm and large vesicular nuclei. The cells are mostly cuboidal with occasional 'hobnailing', which is related to the presence of cytoplasmic vacuoles in these cells, causing cytoplasmic protrusion into lumina. There is also an accompanying perivascular lymphocytic and eosinophilic infiltrate.

Dermoscopy may help to differentiate ALHE from other vascular tumors such as angiosarcoma or Kaposi sarcoma. Under polarized light, ALHE shows polymorphous vascular pattern composed of dotted and linear vessels with a regular distribution over a pale-reddish to light-pink background.

The location and extent of underlying vascular anomalies may be assessed by angiography, angio-computed tomography, and angio-magnetic resonance imaging.

First-Line Therapies

• Surgery	D
• Laser therapy	D
• Corticosteroid, topical or intralesional	E

Epidemiology and treatment of angiolymphoid hyperplasia with eosinophilia (ALHE): a systematic review. Adler BL, Krausz AE, Minuti A, et al. *J Am Acad Dermatol* 2016; 74: 506–12.

After reviewing 416 studies detailing 908 patients, the authors concluded that surgical excision was the best option, albeit suboptimal, with a treatment failure rate of 40.8%, defined as incomplete resolution of disease or recurrence after treatment. Pulsed dye lasers, or other lasers, may represent other reasonable therapeutic options. The treatment failure rates for different lasers ranged from 50% to 66.7%.

Facial angiolymphoid hyperplasia with eosinophilia: sustained remission following treatment with carbon dioxide laser. Ali FR, Madan V. Clin Exp Dermatol 2016; 41: 96–8.

A 35-year-old woman presented with biopsy-proven ALHE lesions on her left temple, which had developed during pregnancy 5 years previously. Ablation with CO₂ laser (15W, 4-mm spot, 10600 nm) was undertaken in three sessions over the course of 8 months, with an excellent clinical response. There was no recurrence after 30 months.

Combined pulsed dye and CO₂ lasers in the treatment of angiolymphoid hyperplasia with eosinophilia. Sagi L, Halachmi S, Levi A, et al. Lasers Med Sci 2016; 31(6): 1093–6.

The authors reported combination of pulsed dye laser and CO₂ laser in treating 14 patients with ALHE. All patients exhibited clinical response after a mean of 2.4 ± 0.4 treatment sessions. They did not recommend surgery for risk of recurrence or development of new lesions and that further surgical excision would result in a new scar.

Angiolymphoid hyperplasia with eosinophilia treated with vascular laser. Alcántara González J, Boixeda P, Truchuelo Díez MT, et al. Lasers Med Sci 2011; 26: 285–90.

The sequential laser combines 595-nm pulsed dye laser (PDL) with 1064-nm Nd:YAG targeting structures at different dermal levels using two different wavelengths. Greater effectiveness and lower recurrence rates are possible with the Nd:YAG laser, which allows the destruction of deeper vessels than PDL. Three patients with ALHE were treated with this sequential laser system. Complete resolution was observed in two of them 3 years after their last treatment; the other patient showed a marked improvement.

Second-Line Therapies

• Propranolol	E
• Imiquimod	E
• Tacrolimus	E
• Isotretinoin	E
• Radiofrequency ablation	E

Propranolol: a novel treatment for angiolymphoid hyperplasia with eosinophilia. Horst C, Kapur N. Clin Exp Dermatol 2014; 39: 810–2.

A 32-year-old woman presented with multiple ALHE lesions in the left periauricular area and scalp vertex. She was started on oral propranolol 40 mg daily. Within 6 weeks, several lesions had decreased in size and all were less erythematous. Propranolol was subsequently stopped within a few months of initiating treatment. Propranolol targets the vascular proliferative element of ALHE. It is also effective in decreasing the vasculature of hemangiomas of infancy.

There are a few reports successfully utilizing topical timolol in combination with other therapies for ALHE.

Angiolymphoid hyperplasia with eosinophilia treated successfully with imiquimod. Isohisa T, Masuda K, Nakai N, et al. Int J Dermatol. 2014; 53: e43–4.

A 49-year-old woman with multiple ALHE lesions in her left postauricular area and external auditory canal was treated with 5% imiquimod cream five times per week. The pruritus improved markedly within 2 weeks. By 22 weeks of treatment, the small lesions had almost completely regressed. The authors suggested that topical imiquimod should be considered for treatment of ALHE because of its excellent cosmetic results and safety record, especially for those with multiple lesions. The underlying

mechanism may be related to the immunomodulating and anti-angiogenic effect of imiquimod.

A case of angiolymphoid hyperplasia with eosinophilia successfully treated with tacrolimus ointment. Mashiko M, Yokota K, Yamanaka Y, et al. Br J Dermatol 2006; 154: 803–4.

A 33-year-old Japanese woman with ALHE over her left ear for a year was treated with 0.1% tacrolimus ointment twice daily. The lesions disappeared within 4 months. Continuous application resulted in no recurrence in 9 months. The underlying mechanism may be due to tacrolimus ointment reducing eosinophil counts in tissue and suppressing eosinophil function.

In another recent report,¹ a patient with periauricular ALHE showing only a partial response to topical corticosteroids was treated with topical tacrolimus. Complete resolution of the lesions was achieved.

Angiolymphoid hyperplasia with eosinophilia: efficacy of isotretinoin? El Sayed F, Dhaybi R, Ammouy A, et al. Head Face Med 2006; 2: 32.

The authors report a 32-year-old man with multiple pruritic lesions of ALHE treated with isotretinoin 0.5 mg/kg/day for 1 year with complete resolution of one of the two scalp nodules. Two lesions on the cheeks and two in the preauricular region that decreased in size, but did not totally resolve, were surgically removed. The success of isotretinoin was due to its antiangiogenic properties via a reduction of vascular endothelial growth factor production by keratinocytes.

Angiolymphoid hyperplasia with eosinophilia treated with a novel combination technique of radiofrequency ablation and sclerotherapy. Khunger N, Pahwa M, Jain RK. Dermatol Surg 2010; 36: 422–5.

Three patients with ALHE were treated with radiofrequency ablation (RFA) after intralesional sclerotherapy with 3% polidocanol. Lesions were mostly treated with cutting plus coagulation mode with an intensity of 4U. One to four sessions of treatment were required to achieve complete response. No recurrence was seen after follow-up period of 6 months to 2 years. The synergistic effect is due to sclerosants treating the deeper vascular component while RFA ablates the lesion.

Angiolymphoid hyperplasia of external ear treated with intralesional radiofrequency ablation. Yadav D, Singh S, Bhari N, et al. BMJ Case Rep 2018 Apr 20. doi: 10.1136/bcr-2017-223447.

The authors reported a single setting of intralesional radiofrequency ablation using 18-G intravenous cannula to treat a 21-year-old woman with multiple ALHE lesions in the right concha. There was near complete flattening of the lesion after 2 weeks and no recurrence at 3 months' follow-up.

Third-Line Therapies

• Methotrexate	E
• Suplatast tosilate	E
• Interferon- α_{2b}	E
• Thalidomide	E
• Photodynamic therapy	E

Angiolymphoid hyperplasia with eosinophilia treated with low-dose methotrexate. Alaidarous A, Bouissou X, Mazereeuw-Hautier J, et al. J Am Acad Dermatol 2015; 1(6): 342–4.

A 31-year-old woman with multiple infiltrative ALHE lesions on the right neck regressed with prednisolone 30 mg daily but recurred shortly upon tapering the dose. She then responded to pulsed dye laser and remained symptom free for 6 years. She then relapsed but this time she failed to respond to pulsed dye laser. Methotrexate (MTX) was started at 15 mg per week for 12 months. She showed significant improvement. The MTX dose was then tailed down and stopped after 10 months. No recurrence was seen in the subsequent 4 months' follow-up. The clinical response was attributed to the antiinflammatory and antiangiogenic effect of methotrexate.

In another report,² a 14-year-old Caucasian female with biopsy-confirmed ALHE presented with a left eyelid swelling, which was shown by computed tomography (CT) to be an infiltrative mass in the left superotemporal orbit. The lesion shrank with high-dose prednisolone, but it was not possible to tail down to daily 20 mg. Methotrexate was added to the treatment regime and stepped up to 20 mg weekly. The steroid was successfully tapered off, after which the patient still remained symptom free. CT scan 6 months after cessation of methotrexate showed only small residual disease.

Angiolymphoid hyperplasia with eosinophilia on the leg successfully treated with T-helper cell 2 cytokine inhibitor suplatast tosilate. Bito T, Kabashima R, Sugita K, et al. *J Dermatol* 2011; 38: 300–2.

Suplatast tosilate is a Th2 cytokine inhibitor that inhibits T-helper cell production of IL-4 and IL-5. This results in reduced eosinophil infiltration and suppression of IgE production in B cells. A 63-year-old man with ALHE on the right calf was treated with suplatast tosilate both orally and topically. The lesions dramatically improved after 4-week administration and completely disappeared 4 months after the beginning of the treatment. No recurrence was observed even 15 months later.

An earlier report on a 32-year-old man with ALHE was successfully treated with suplatast tosilate 300 mg/day.³

Angiolymphoid hyperplasia with eosinophilia responding to interferon-alpha 2B. Oguz O, Antonov M, Demirkesen C. *J Eur Acad Dermatol Venereol* 2007; 21: 1277–8.

Interferon- α is a potential treatment in benign angioproliferative disorders. Local intralesional injection of interferon- α_{2b} was reported effective for a 27-year-old female with occipital lesions of ALHE. Recurrence of lesions 9 years later was noted but this time the response to repeated interferon- α_{2b} treatment was poor.

In another report,⁴ intralesional interferon- α_{2a} caused almost complete resolution of lesions in one patient. However, recurrence of lesions was noted about 1 year after the last injection and no response occurred with the second course of injection.

Successful management of refractory angiolymphoid hyperplasia with eosinophilia with thalidomide. Rongioletti F, Cecchi F, Pastorino C, et al. *J Eur Acad Dermatol Venereol* 2016; 30: 527–9.

A 58-year-old woman with multiple ALHE lesions on occipital area unresponsive to oral propranolol, cryotherapy, topical and systemic steroids, and topical tacrolimus was put on thalidomide 50 mg twice a day for 2 months, then three times daily for 4 months, with progressive decolorization, flattening, and regression of the lesions. After 6 months of therapy, the lesions almost resolved; however, she developed neuropathy, necessitating the discontinuation of thalidomide. No new lesions were noted at 3 months' follow-up. The action of thalidomide is considered to be due to its antiangiogenic, antiinflammatory, and antitumor effects.

Angiolymphoid hyperplasia with eosinophilia: good response to photodynamic therapy. Sotiriou E, Apalla Z, Patsatsi A, et al. *Clin Exp Dermatol* 2009; 34: e629–31.

Photodynamic therapy (PDT) causes suppression of tumor growth by damaging endothelial cells in the tumor neovasculature. A 60-year-old woman with multiple ALHE lesions on the forehead was treated with two sessions of aminolevulinic acid (ALA) PDT, with a 2-week interval: 20% 5-ALA cream occluded from light for 4 hours, followed by exposure to red light (570–670 nm, dose 80 J/cm²) from a non-coherent light source.

Marked improvement, though not complete regression, was achieved 8 weeks after treatment and maintained at 4 months posttreatment. The moderate response achieved in this study could be due to poor penetration of the photosensitizer to the deep part of the lesion.

Combination of electrocoagulation and photodynamic therapy for angiolymphoid hyperplasia with eosinophilia in the external ear. Wu L, Li F, Shi W, et al. *Photodiagnosis Photodyn Ther* 2019; 27: 449–51.

The authors used combined electrocoagulation and PDT to treat a 21-year-old woman and a 55-year-old man. Both presented with more than 1-year history of red, itchy papules and nodules in the posterior auricular area and external auditory canal that persisted despite topical or intralesional corticosteroids and laser therapy. Each received one electrocoagulation to remove the superficial lesions followed immediately by PDT. Each patient received three PDT sessions with an interval of 7–10 days. The lesions completely regressed with no recurrence seen after 12 months' follow-up.

Angular cheilitis

Jessica Shiu, Jennifer K. Chen, Janellen Smith

With permission from Mayo Foundation for Medical Education and Research. All rights reserved.

Angular cheilitis is a chronic, reactive, inflammatory condition of the oral commissures characterized by atrophy, fissures, crusting, erythema, and scaling. The etiology is often multifactorial, and causes may be mechanical (intertrigo), infectious, nutritional, hormonal, or inflammatory. Angular cheilitis may be a sign of systemic disease.

MANAGEMENT STRATEGY

Successful therapy is based on identifying and correcting any underlying condition(s). The presence of dentures, palatal erythema, and/or edema may suggest candidiasis and denture stomatitis. A pale, depapillated, atrophic tongue suggests iron deficiency. A tender depapillated tongue suggests folate or vitamin B₁₂ deficiency. An eczematous dermatitis of the lower face suggests a staphylococcal infection (infectious eczematoid dermatitis). A history of allergic contact dermatitis may suggest an allergy.

Unilateral lesions are usually short lived and induced by mechanical factors. This has also been reported to be a manifestation of plasma cell cheilitis. Bilateral lesions tend to be chronic and caused by infection or nutritional deficiency and are more likely to be associated with an underlying disease process.

Maceration of the commissural epithelium and adjacent skin is a common, non-infectious cause of mechanical angular cheilitis. Trauma from dental flossing, habitual lip-licking, and excessive salivation all contribute. Periods of oral hydration and then dryness disrupt epithelial integrity, causing fissuring of the commissures. This provides an ideal environment for low-grade candidiasis and infectious eczematoid dermatitis. Other mechanical factors are ill-fitting dentures, loss of vertical dimension of the jaws, sagging skin folds, xerostomia, and perioral dermatitis.

Infectious and systemic causes must be investigated. Angular cheilitis is frequently present in patients with HIV disease, where 10% may have localized candidiasis. Highly active antiretroviral

therapy (HAART) may decrease this incidence. Both *Candida albicans* and *Staphylococcus aureus* can colonize the fissures. Anemia, nutritional deficiencies, Down syndrome, acrodermatitis enteropathica, pemphigus vulgaris, diabetes mellitus, orofacial granulomatosis, and Crohn disease may be present.

Recurrence of angular cheilitis may be prevented by eliminating offending organisms from their reservoirs. Denture stomatitis, candidiasis, and nasal colonization by staphylococci should be investigated. *Topical imidazole creams* after meals and at bedtime may treat candidiasis, whereas *topical mupirocin* is valuable in treating staphylococcal colonization. Dentures should be removed from the mouth nightly and cleansed well before reinsertion in the morning. *New dentures* may restore facial contours, increasing the vertical dimension of the jaws and face. *Injection of fillers* into the commissures may alleviate causative mechanical factors.

Specific Investigations

- Culture or wet mount to evaluate for candidiasis
- Culture for bacteria
- For refractory or recurrent cases, laboratory evaluation should include a complete blood cell count; iron panel; vitamin B, folate, and zinc levels; glucose; hemoglobin A_{1c}; and HIV testing
- Patch testing

Nickel-induced angular cheilitis due to orthodontic braces. Yesudian PD, Memon A. *Contact Dermatitis* 2003; 48: 287–8.

First-Line Therapies

- Topical miconazole, ketoconazole, or nystatin cream two or three times daily for 2–3 weeks **D**
- Topical polymyxin B or mupirocin ointments, three to four times daily until resolution **D**
- Remove dentures nightly and cleanse overnight with chlorhexidine 2% solution or sodium hypochlorite 0.02% solution. Rinse and air-dry before reinsertion. *Please note that chlorhexidine and nystatin inactivate each other and therefore should not be used together* **D**

Oral candidiasis and angular cheilitis. Sharon V, Fazel N. *Dermatol Ther* 2010; 23: 230–42.

A review of topical and systemic therapy of candidiasis. The authors also recommend prophylaxis with chlorhexidine 0.12% mouthwash in recurrent cases.

Review of recent topical and surgical therapies used in angular cheilitis; most recommendations are based on case reports and case series.

Second-Line Therapies

- Systemic antifungal therapy (fluconazole), 50–100mg daily, 100–200mg three times a week, or 150mg weekly until resolution **E**
- Amphotericin B cream, three to four times daily for 7–14 days **E**

Oral candidiasis and angular cheilitis. Sharon V, Fazel N. Dermatol Ther 2010; 23: 230–42.

Reviews the treatment of candidiasis, especially in the immunocompromised patient.

Third-Line Therapies

- Filler injections **E**
- Prosthodontic evaluation and treatment **E**
- Chewing gum with xylitol or chlorhexidine acetate and xylitol **B**
- Gentian violet 0.5% solution twice daily **E**
- Photodynamic therapy **E**
- Topical ozonized olive oil twice daily **E**

Collagen implant in management of perleche (angular cheilosis). Chernosky ME. J Am Acad Dermatol 1985; 12: 493–6.

Soft tissue augmentation may be used to decrease the depth of the fold at the oral commissures, thus decreasing salivary stasis.

Efficacy of ozonized olive oil in the management of oral lesions and conditions: a clinical trial. Kumar T, Arora N, Puri G, et al. Contemp Clin Dent 2016; 7(1): 51–4.

Clinical trial looking at 50 patients with oral lesions – 10 of those with angular cheilitis reported cure but the study was lacking in adequate controls and clinical and microbiologic details. Patients massaged the oil in affected areas for 1 min twice daily until resolution or for a maximum of 6 months' duration.

Antiphospholipid syndrome

Julia S. Lehman, Mark D.P. Davis

Antiphospholipid syndrome (APS; Hughes syndrome) is associated with recurrent venous and arterial thrombosis in the presence of circulating antibodies against phospholipid-binding proteins. Diagnostic criteria for APS require that patients experience clinical features such as vascular thrombosis (venous or arterial) or pregnancy morbidity (e.g., three or more unexplained consecutive spontaneous abortions before the 10th week of gestation with exclusion of other causes). In addition, patients must harbor at least one serum antiphospholipid (aPL) antibody (i.e., lupus anticoagulant, anticardiolipin, anti- β_2 -glycoprotein 1) on two or more occasions over a 12-week period. Despite the misconception that the presence of circulating aPL antibodies is sufficient for a diagnosis of APS, it is important that patients are not diagnosed with APS based on isolated laboratory test findings, as no laboratory test for APS is entirely specific.

Although cutaneous manifestations of APS are not part of the diagnostic criteria, they may represent the initial presentation of APS. Cutaneous signs result from thrombo-occlusion of the cutaneous vasculature and may include livedo reticularis or racemosa, livedoid vasculopathy (atrophie blanche), anetoderma, superficial thrombophlebitis, or ulceration. Patients with Sneddon syndrome, a condition characterized by cerebrovascular disease in patients with livedo reticularis, may have persistently positive serum aPL. Whether Sneddon syndrome represents a subset of APS is controversial.

MANAGEMENT STRATEGY

While APS may represent a primary condition, it is important to exclude a secondary coagulopathy. Therefore, an investigation into underlying causes or other contributing factors, such as infection, prothrombotic medications (such as oral contraceptives), primary hematologic coagulopathies (e.g., factor V Leiden, prothrombin G20210A gene mutation), and connective tissue diseases (e.g., systemic lupus erythematosus [SLE]), is warranted. Patients should be offered subspecialty referral where available.

Because patients with APS are at increased risk for recurrent thromboembolism, the goal of therapy is thromboprophylaxis. Non-pharmacologic interventions include reduction of other prothrombotic risk factors, such as prolonged immobility and oral contraceptive use. Pharmaceutical interventions should be guided by the patient's age and comorbidities, pregnancy status, presence of correctable prothrombotic factors, and coagulation history. In patients with persistently elevated aPL antibodies but no history of thrombosis (thereby not meeting consensus criteria for APS), aspirin has **not** been shown to be effective in preventing future thromboembolic events. In patients with definitive APS and a history of venous thromboembolism, the mainstay of treatment is long-term warfarin therapy. The optimal duration of warfarin therapy has not been established. Based on limited available data, indefinite treatment with warfarin reduces risk for recurrent thromboembolism without an elevated risk for hemorrhagic complications, compared with treatment discontinuation after 6 months. Decisions regarding termination of warfarin therapy should be individualized. Long-term heparin use is discouraged because of the risk of heparin-induced osteopenia. Early reports of oral direct thrombin inhibitors (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, edoxaban) are inconclusive, and one randomized controlled study indicated significantly more frequent adverse events in patients treated with rivaroxaban compared with warfarin. Additional randomized controlled studies are ongoing.

Placement of an inferior vena cava filter may be required in patients with recurrent venous thromboembolism to prevent pulmonary embolism.

In patients with APS who have experienced arterial thromboembolism or have developed recurrent thrombosis despite achieving target international normalized ratio (INR) on warfarin, other treatment options must be pursued. These modalities, such as rituximab, intravenous immunoglobulin, and plasmapheresis, address circulating pathogenic antibodies directly rather than the resultant coagulopathy.

In patients with SLE and APS, hydroxychloroquine has been shown to reduce aPL antibody levels and to have intrinsic anticoagulative properties. Potential future APS therapies may include mTOR inhibitors, factor Xa inhibitors, oral direct thrombin inhibitors, and statins. Correction of reversible prothrombotic factors, such as oral contraceptive use and smoking, is advisable.

Warfarin is contraindicated in pregnancy, a particularly high-risk state for patients with APS. Women with APS should be treated with aspirin before conception. Low-molecular-weight heparin may be introduced thereafter.

In patients with acute thrombosis, monitored intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin, with or without subsequent initiation of warfarin, is standard therapy. Thrombolytic medications (e.g., streptokinase, tissue plasminogen activator [tPA]) or percutaneous or surgical interventions may be necessary in life- or limb-threatening thrombotic events. Catastrophic antiphospholipid syndrome (CAPS), the rapid

development (<1 week) of widespread thromboses with end-organ damage (involving ≥ 3 organs, systems, or tissues), requires intensive multidisciplinary interventions to halt disease progression and to reverse end-organ damage. *Plasma exchange* may have a role in the treatment of CAPS.

Specific Investigations

- Inquiry into history of thromboembolism, pregnancy morbidity, and medication use
- aPL antibodies (i.e., lupus anticoagulant, anticardiolipin IgG and IgM antibodies, anti- β_2 -glycoprotein 1 antibodies)
- Coagulopathy screen (i.e., INR, partial thromboplastin time [PTT], protein C, protein S, antithrombin III, prothrombin G20210A gene mutation, antiprothrombin antibodies, factor V Leiden, homocysteine level)
- Screen for underlying prothrombotic disease state (hematology, fasting blood glucose, fasting lipid profile, connective tissue serology, HIV testing, hepatitis serology, malignancy evaluation) and other risk factors, as directed by clinical evaluation

International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). Miyakis S, Lockshin MD, Atsumi T, et al. *J Thromb Haemost* 2006; 4: 295–306.

Consensus guidelines require a history of thromboembolism and documentation of elevated aPL antibodies on at least two occasions separated by at least 12 weeks for definitive diagnosis of APS.

Controversies and unresolved issues in antiphospholipid syndrome pathogenesis and management. Baker WF Jr, Bick RL, Fareed J. *Hematol Oncol Clin North Am* 2008; 22: 155–74.

Thorough investigation into underlying (and potentially correctable) conditions is recommended.

First-Line Therapies

• Observation (persistent aPL elevation but no thromboembolic events)	A
• Long-term warfarin, target INR 2.0–3.0	A
• Correction of reversible prothrombotic factors	B
• Long-term warfarin, target INR >3.0 (recurrent or arterial thrombosis)	B
• Low-molecular-weight heparin and low-dose aspirin (pregnancy)	B
• Heparin followed by warfarin (acute thrombosis)	C
• Hydroxychloroquine with low-dose aspirin (SLE)	D
• Thrombolytic therapy or percutaneous/surgical intervention (critical thrombosis)	E
• Reduction of prothrombotic risk factors, such as prolonged immobilization	E

Aspirin for primary thrombosis prevention in the antiphospholipid syndrome. Erkan D, Harrison MJ, Levy R, et al. *Arthritis Rheum* 2007; 56: 2382–91.

A randomized, double-blind, placebo-controlled trial of aspirin versus placebo in asymptomatic patients with persistently positive aPL antibodies found no benefit of aspirin in primary thromboprophylaxis.

A comparison of two intensities of warfarin for the prevention of recurrent thrombosis in patients with the antiphospholipid syndrome. Crowther MA, Ginsberg JS, Julian J, et al. *N Engl J Med* 2003; 349: 113–8.

A randomized clinical trial of high-intensity warfarin vs. conventional antithrombotic therapy for the prevention of recurrent thrombosis in patients with the antiphospholipid syndrome. Finazzi G, Marchioli R, Brancaccio V, et al. *Thromb Haemost* 2005; 3: 848–53.

These two randomized, double-blind trials comparing high-intensity warfarin (target INR 3.0–4.0) and moderate-intensity warfarin (target INR 2.0–3.0) in patients with APS found no significant difference in preventing secondary thrombosis between the two treatment regimens.

A systematic review of secondary thromboprophylaxis in patients with antiphospholipid antibodies. Ruiz-Irastorza G, Hunt BJ, Khamashta MA. *Arthritis Rheum* 2007; 57: 1487–95.

In several cohort studies of patients with APS, INR at the time of recurrent thromboembolism on warfarin was <3.0 in 86%. The authors propose that the target INR should be >3.0 in patients with recurrent or arterial thrombosis.

Treatment of antiphospholipid antibody syndrome (APS) in pregnancy: a randomized pilot trial comparing low-molecular-weight heparin to unfractionated heparin. Stephenson MD, Ballen PJ, Tsang P, et al. *J Obstet Gynaecol Can* 2004; 26: 729–34.

In a randomized trial, 28 women with APS received low-dose aspirin and either low-molecular-weight heparin or unfractionated heparin before conception or early in pregnancy. Pregnancy was successful in nine of 13 (69%) women treated with low-molecular-weight heparin and low-dose aspirin and in four of 13 (31%) women treated with unfractionated heparin and low-dose aspirin.

In addition, the obstetrics literature tends to favor low-molecular-weight over unfractionated heparin because of its superior safety profile.

Second-Line Therapies

• Long-term low-molecular-weight heparin (recurrent thrombosis)	D
• Rituximab (SLE)	D
• Hydroxychloroquine (SLE)	E
• Intravenous immunoglobulin (IVIg) (in pregnancy)	E

Rituximab usage in systemic lupus erythematosus-associated antiphospholipid antibody syndrome: a single-center experience. Wang CR, Liu MF. *Semin Arthritis Rheum* 2016; 46(1): 102–8.

A series of six patients with APS treated with rituximab suffered no relapse of thrombosis with a mean follow-up period of over 3 years.

Evidence-based management of thrombosis in the antiphospholipid antibody syndrome. Petri M. *Curr Rheum Rep* 2003; 5: 370–3.

Hydroxychloroquine appears to reduce aPL antibody titers and the risk for recurrent thrombosis in patients with SLE.

An excellent evidence-based review of APS treatments.

A multicenter, placebo-controlled pilot study of intravenous immune globulin (IVIG) treatment of antiphospholipid syndrome during pregnancy. Branch DW, Peaceman AM, Druzin M, et al. *Gen Obstet Gynecol* 2000; 182: 122–7.

In this pilot study of 16 pregnant women with APS, patients were randomized to receive IVIG or placebo. All patients also received heparin and low-dose aspirin. A trend toward decreased fetal growth restriction was observed in the IVIG group compared with the placebo group, but differences were not statistically significant.

Third-Line Therapies

• Plasma exchange (pregnancy)	D
• Placement of inferior vena cava (IVC) filter (medically refractory, recurrent venous thromboses)	D
• Direct oral anticoagulants	D
• Statins (recurrent venous thromboses)	E
• IVIG (recurrent venous thromboses)	E
• Sirolimus (APS-related arterial vasculopathy)	E

Plasma exchange in the management of high risk pregnant patients with primary antiphospholipid syndrome. A report of 9 cases and a review of the literature. Ruffatti A, Marson P, Pengo V, et al. *Autoimmunity Rev* 2007; 6: 196–202.

Nine patients with APS and triple-positive aPL antibodies were treated with plasma exchange for secondary prophylaxis during pregnancy. The authors found that combined plasma exchange and IVIG therapy contributed to favorable pregnancy outcomes in high-risk patients.

Insertion of inferior vena cava filters in patients with the antiphospholipid syndrome. Zifman E, Rotman-Pikielny P, Berlin T, et al. *Semin Arthritis Rheum* 2009; 38: 472–7.

Ten patients with APS who experienced recurrent thrombosis despite warfarin therapy received IVC filters. One patient had a documented pulmonary embolus (PE) after intervention, and two died suddenly of unknown causes (PE could not be excluded). The authors state that the results were suggestive of a protective effect of IVC filters in refractory APS.

Rivaroxaban versus warfarin to treat patients with thrombotic antiphospholipid syndrome, with or without systemic lupus erythematosus (RAPS): a randomised, controlled, open-label, phase 2/3, non-inferiority trial. Cohen H, Hunt BJ, Efthymiou M, et al. *Lancet Haematol* 2016; 3: e426–36.

This randomized, controlled trial comparing rivaroxaban 20 mg daily with warfarin showed that rivaroxaban was non-inferior. No new thromboses were noted with either treatment.

Incidence of a first thromboembolic event in symptomatic carriers of high-risk antiphospholipid antibody profile: a multicenter prospective study. Pengo V, Ruffatti A, Legnani C, et al. *Blood* 2011; 118: 4714–8.

This randomized controlled trial comparing rivaroxaban 20 mg daily with warfarin showed increased overall events (i.e., thromboses, hemorrhage, death) and arterial events in patients treated with rivaroxaban. No patients experienced venous thromboembolism in the study.

Though some small reports demonstrate benefit of IVIG when used as an additive therapy for secondary prophylaxis, large, well-designed studies are lacking.

The NF- κ B specific inhibitor DHMEQ prevents thrombus formation in a mouse model of antiphospholipid syndrome. Nishimura M, Nii T, Trimova G, et al. *J Nephropathology* 2013; 2: 114–21.

Catastrophic Antiphospholipid Syndrome

• Anticoagulation, systemic corticosteroids, and plasmapheresis or IVIG	D
• Eculizumab	E

Catastrophic antiphospholipid syndrome (CAPS): proposed guidelines for diagnosis and treatment. Asherson RA, Espinosa G, Cervera R, et al. *J Clin Rheumatol* 2002; 8: 157–65.

Based on experience from 130 cumulative cases of CAPS, the authors recommend heparin, systemic corticosteroids, and plasmapheresis in the treatment of CAPS.

Catastrophic antiphospholipid syndrome presenting with multiorgan failure and gangrenous lesions of the skin. Incalzi RA, Gemma A, Moro L, et al. *Angiology* 2008; 59: 517–8.

A 38-year-old woman with CAPS triggered by abrupt withdrawal of systemic corticosteroids recovered completely after treatment with immunosuppressive and antibiotic treatment combined with plasmapheresis.

Brief report: induction of sustained remission in recurrent catastrophic antiphospholipid syndrome via inhibition of terminal complement with eculizumab. Shapira I, Andrade D, Allen SL, et al. *Arthritis Rheum* 2012; 64: 2719–23.

First report of eculizumab's efficacy in CAPS. Larger studies are ongoing.

Aphthous stomatitis

Maryam Liaqat, Justin J. Green

Recurrent aphthous stomatitis (RAS) is the most common cause of oral ulceration, affecting 5–25% of the population. It is characterized by the recurrence of one or more painful, shallow, sharply margined ulcerations with a fibrinous base and surrounding erythematous halo on mobile oral mucosa. Three main types include minor, major, and herpetiform aphthae, which differ in size, duration, number, potential for scarring, and location of ulcerations. The etiology remains unclear; however, genetic predisposition (with at least 40% of patients having a positive family history), nutritional deficiencies, infections, hormonal alterations, immunodeficiency, and environmental agents have been implicated. It is important to differentiate aphthae from other causes of mucosal ulcers. The differential diagnosis would include viral and bacterial infections (herpes simplex virus [HSV], Epstein-Barr virus, cytomegalovirus, varicella zoster virus, Coxsackie virus, syphilis, gonorrhea, tuberculosis), erythema multiforme, lichen planus, autoimmune bullous diseases (pemphigus vulgaris and cicatricial pemphigoid), contact dermatitis, chronic ulcerative stomatitis, and trauma. Malignancy and systemic vasculitis must also be considered in lesions that are not self-resolving.

MANAGEMENT STRATEGY

The therapeutic approach to aphthae is dependent on the frequency of recurrence, duration, and severity of symptoms. In addition, underlying hematologic abnormalities, nutritional deficiencies, and medications should be considered as causative agents, as well as systemic disorders such as Crohn disease, Behçet disease, mouth and genital ulcers with inflamed cartilage (MAGIC) syndrome, cyclic neutropenia, Sweet syndrome, reactive arthritis, HIV infection, and autoinflammatory syndromes such as periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis syndrome (PFAPA syndrome). Stress is also thought to play a role in exacerbation of the disease. Unfortunately, because there is no curative treatment to date, the emphasis of treatment is on measures that may afford symptomatic relief and decrease occurrence, without causing significant adverse effects.

Topical corticosteroids are the mainstay of therapy. For milder disease, corticosteroids such as *fluocinonide* can be used. Superpotent corticosteroids such as *clobetasol* or *halobetasol* are appropriate for more severe episodes. Most practitioners suggest the use of topical therapy after meals. These can be applied in equal parts with an occlusive agent such as *Orabase* for better adherence. Drug delivery can be enhanced by cotton-tip applications for 30 seconds and avoidance of eating and drinking for 30 minutes after application. Initial concentrations of 3–10 mg/mL of *intralesional triamcinolone acetonide* are helpful for major aphthae. Repeat injections over 2- to 4-week intervals are suggested. *Dexamethasone elixir* 0.5 mg/5 mL three times daily used as a mouthwash or *beclomethasone dipropionate* aerosol spray can target ulcers on the soft palate or oropharynx. Elixirs can be combined with *sucralfate* or *Kaopectate* to improve adhesion to ulceration. When used for less than 3 weeks, systemic absorption and hypothalamic-pituitary-adrenal axis suppression are unlikely.

RAS that elicits severe pain may require intermittent *systemic corticosteroid therapy*. Prednisone 1 mg/kg (40–60 mg) daily can be given with a 2-week taper or as 'burst therapy' for shorter periods. Concomitant therapy with topical corticosteroids may be helpful. *Thalidomide* 50–200 mg daily is the most effective steroid-sparing agent. It is also the only Food and Drug Administration (FDA)-approved treatment for major aphthae in HIV-positive patients. *Dapsone* 100 mg daily, *pentoxifylline* 400 mg three times daily, and *clofazimine* 100 mg daily may also lead to suppression of aphthae. Oral *rofecoxib* 50 mg on the first day and 25–50 mg per day on the following days or oral *tinidazole* 1 g per day may have some benefit. *Anti-tumor necrosis factor (TNF)-α* therapies may be effective in recalcitrant cases. The use of oral phosphodiesterase-4 inhibitor apremilast in treatment of recalcitrant RAS has also been proposed. Those patients who require suppressive therapy but cannot tolerate the side effects of systemic agents can try medications such as *topical ciclosporin* rinse 500 mg/5 mL three times daily, or *interferon-α_{2a}* 1200 IU daily as a 1-minute rinse and swallow.

Application of *amlexanox 5% paste* four times daily has been shown to reduce aphthous ulcer healing time, and the application of amlexanox OraDisc four times daily to prodromal areas of the buccal mucosa has shown promise in the prevention of recurrent minor aphthous ulceration.

Lidocaine gel or spray, *dyclonine*, *diphenhydramine* (12.5/5 mL), or *benzocaine* are helpful for pain reduction. Patients must avoid desensitization of the entire oral vault, which may lead to self-induced trauma. A compounded *anesthetic mouthwash* (aluminum hydroxide-magnesium hydroxide, diphenhydramine, and lidocaine) has better mucosal adherence. Systemic *nonsteroidal antiinflammatory drugs (NSAIDs)*, *sucralfate suspension*, 0.2% *chlorhexidine gluconate* mouthwash, *triclosan*, or *tetracycline suspension* (250 mg/5 mL) may provide pain relief and reduce healing time, although these are less effective than potent topical corticosteroids. Bioadhesives, such as *carboxymethylcellulose*, provide a protective film and may reduce healing time. Use of laser therapies, including CO₂ laser, Nd:YAG, and low-level light therapies in RAS, has also been shown to improve symptoms caused by consumption of food, beverages, and brushing of teeth.

Trigger avoidance can be useful. Predisposing factors include food (nuts, chocolate, tomatoes, citrus fruits, and spices), alcohol and carbonated beverages, trauma, menstruation, and stress. A *food diary* may be of value in identifying an offending agent. Certain medications, such as β-blockers, NSAIDs, and antioxidants, as well as sensitivity to sodium lauryl sulfate found in toothpaste, may contribute to the recurrence of aphthae. *Hormonal therapy* may alleviate RAS associated with menstruation. *Reassurance* of

the benignity of this condition is paramount, and *relaxation techniques* or *biofeedback* can be discussed if stress is found to be a significant trigger.

Specific Investigations

- Complete blood count
- Vitamins B₁, B₂, B₆, and B₁₂; folate, zinc, and iron levels
- Culture/polymerase chain reaction of aphthae to exclude HSV
- Consider HIV testing

Aphthous ulcers. Messadi DV, Younai F. *Dermatol Ther* 2010; 23: 281–90.

Review article containing the summary of possible etiologies and clinical presentations of aphthae, differential diagnosis, and treatment options.

Oral mucosal disease: recurrent aphthous stomatitis. Scully C, Porter S. *Br J Oral Maxillofac Surg* 2008; 46: 198–206.

Review article highlighting possible etiologies and differential diagnosis of RAS. This article recommends checking complete blood count, folate, iron studies, and B₁₂, as well as excluding infections or systemic diseases that may include aphthae-like ulcerations, namely Behçet disease and HSV.

Haematological deficiencies in patients with recurrent aphthosis. Compilato D, Carroccio A, Calvino F, et al. *J Eur Acad Dermatol Venereol* 2010; 24: 667–73.

Thirty-two patients with RAS and 29 healthy controls were subjected to hematologic investigations. Deficiencies were noted in 56.2% of RAS patients and in 7% of controls. All patients with a negative family history of RAS showed complete remission after replacement therapy, whereas patients with a family history of RAS showed reduction in frequency and severity. The authors recommended that routine screening for serum iron, folic acid, and vitamin B₁₂ deficiencies should be performed.

First-Line Therapies

• Vitamin and mineral deficiency replacement	A
• Topical corticosteroids	A
• Amlexanox 5% paste	A
• Intralesional corticosteroids	B
• Tetracycline suspension	A
• Antimicrobial mouth rinses	A
• Sucralfate	A
• Hydroxypropyl cellulose/carboxymethylcellulose	C
• Herbal supplements	D

Urban legends: recurrent aphthous stomatitis. Baccaglini L, Lalla RV, Bruce AJ, et al. *Oral Dis* 2011; 17: 755–70.

Review article examining several myths about aphthous ulcerations, with specific emphasis of literature review of treatments in the last 6 years. The authors concluded that low-dose topical tetracyclines and amlexanox showed possible benefit.

Topical corticosteroids in recurrent aphthous stomatitis. Systematic review. Quijano D, Rodriguez M. *Acta Otorrinolaringol Esp* 2008; 59: 298–307.

This is a systematic review of published literature evaluating the effectiveness of topical corticosteroids in treating RAS. The

authors were able to show a trend toward reduced healing times and decreased pain but commented on the lack of high-quality experiments in the literature.

Efficacy and safety of dexamethasone ointment on recurrent aphthous ulceration. Lui C, Zhou Z, Lui G, et al. *Am J Med* 2012; 125: 292–301.

This study is a randomized, double-blind, placebo-controlled, parallel, multicenter clinical trial, which showed that dexamethasone 0.1% ointment three times a day for 5 days safely reduced the size and duration of aphthae compared with placebo.

Amlexanox for the treatment of recurrent aphthous ulcers. Bell J. *Clin Drug Investig* 2005; 25: 555–6.

A review of four double-blind, randomized controlled trials (RCTs) indicating that amlexanox 5% paste up to four times per day significantly reduced ulcer size compared with placebo.

Double-blind trial of tetracycline in recurrent aphthous ulceration. Graykowski EA, Kingman A. *J Oral Pathol* 1978; 7: 376–82.

A suspension of tetracycline 250 mg/5 mL was used four times daily in patients with RAS. The suspension was held in the mouth for 2 minutes and then swallowed. This study found that tetracycline therapy significantly reduced ulcer duration, size, and pain, but did not alter the recurrence rate.

Other studies using tetracycline or its derivatives (topically or orally) have drawn similar conclusions.

Chlorhexidine gluconate mouthwash in the management of minor aphthous ulceration: a double-blind, placebo-controlled cross-over trial. Hunter L, Addy M. *Br Dent J* 1987; 162: 106–10.

This crossover study included 38 patients who used 0.2% chlorhexidine gluconate mouthwash three times daily for 6 weeks. The total number of days with ulcers was significantly reduced, and the interval between successive ulcers was increased.

Gel and mouthwash formulations of 0.1% chlorhexidine have also been efficacious. Chlorhexidine mouthwash can stain teeth.

Effect of an antimicrobial mouth rinse on recurrent aphthous ulcerations. Meiller TF, Kutcher MJ, Overholser CD, et al. *Oral Surg Oral Med Oral Pathol* 1991; 72: 425–9.

A 6-month double-blind study compared Listerine antiseptic and a hydroalcoholic control used as a vigorous mouthwash twice daily. The duration of ulcers and pain severity were significantly reduced in the Listerine group. Both the Listerine group and the control group experienced a reduced incidence of ulcers.

Mouth rinses containing triclosan reduce the incidence of recurrent aphthous ulcers (RAU). Skaare AB, Herlofson BB, Barkvoll P. *J Clin Periodontol* 1996; 23: 778–81.

In a double-blind crossover study, 0.15% triclosan mouthwash caused a significant reduction in the number of ulcers during the experimental period. Compared with the 7.8% ethanol and triclosan formulation, the efficacy of the mouthwashes was reduced when propylene glycol or a higher concentration of ethanol (15.6%) was used as a solubilizing agent.

Sucralfate suspension as a treatment of recurrent aphthous stomatitis. Rattan J, Schneider M, Arber N, et al. *J Intern Med* 1994; 236: 341–3.

Sucralfate applied four times daily to ulcers was found to be superior to antacid (aluminum hydroxide and magnesium

hydroxide) and placebo with regard to duration of pain, reduction in healing time, response to first treatment, and duration of remission. The 2-year prospective, randomized, double-blind, placebo-controlled, crossover trial included 21 patients unresponsive to conventional therapy.

A randomized, placebo-controlled, double-blind study of sucralfate applied four times daily to oral and genital ulcerations of Behçet disease resulted in reduced frequency, healing time, and pain in oral ulcerations, and reduced healing time and pain in genital ulcers.

Performance of a hydroxypropyl cellulose film former in normal and ulcerated mucosa. Rodu B, Russell CM. Oral Surg Oral Med Oral Pathol 1988; 65: 699–703.

Zilactin, which contains hydroxypropyl cellulose, led to pain relief after an acidic challenge followed by rechallenge.

Orabase, which contains carboxymethylcellulose, has been beneficial in trials when combined with topical corticosteroids, possibly due to its adhesive properties.

Topical insulin-liposomal formulation in management of recurrent aphthous ulcers: a randomized placebo-controlled trial. El-Wakeel NM, Dawoud MHS. J Invest Clin Dent 2019; 10: e12437.

Eighty participants with minor aphthous ulcers were randomly divided to receive either topical insulin-liposomal gel or placebo gel (once daily) for 6 days. Test group showed a significant decrease by time in pain score.

Second-Line Therapies

• Oral corticosteroids	A
• Colchicine	A
• Thalidomide	A
• Dapsone	A
• Zinc sulfate	A
• Low-level laser therapy	B
• Omega 3	B
• Apremilast	B

Systemic interventions for recurrent aphthous stomatitis (mouth ulcers). Brocklehurst P, Tickle M, Glenny AM, et al. Cochrane Database Syst Rev 2012; 9: CD005411.

This review article includes a total of 25 trials, 22 of which were placebo controlled and eight made head-to-head comparisons. A total of 21 interventions were assessed. The interventions included immunomodulators such as clofazimine, colchicine, prednisone vs. an uncertain category, which included homeopathy, tetracycline, vitamin B₁₂, and propolis. The main conclusions were that no single treatment was found to be effective; therefore, no recommendations regarding best systemic intervention for RAS were made. The reviewers' primary concern was the methodologic rigor of the trials and the high risk of bias.

Systemic treatment in severe cases of recurrent aphthous stomatitis: an open trial. Mimura MA, Hirota SK, Sugaya NN, et al. Clinics 2009; 64: 193–8.

An open, 4-year clinical trial of 21 patients with RAS treated with thalidomide (100 mg/day), dapsone (100 mg/day), colchicine (1.5 mg/day), and pentoxifylline (400 mg three times a day). Thalidomide was the most efficient and well tolerated. Dapsone and colchicine provided good results; however, dapsone was not well tolerated. Pentoxifylline was mildly effective.

Comparison of colchicine versus prednisolone in recurrent aphthous stomatitis: a double-blind randomized clinical trial. Pakfetrat A, Mansourian A, Momen-Heravi F, et al. Clin Invest Med 2010; 33: E189–95.

In this double-blind RCT, 34 patients with RAS were split into two groups: prednisolone 5 mg daily or colchicine 0.5 mg daily for 3 months. Both medications were equally effective in reducing pain, recurrence, size, and number of aphthae, although colchicine had a higher rate of side effects.

Clinical, historic, and therapeutic features of aphthous stomatitis: literature review and open trial employing steroids. Vincent SD, Lilly GE. Oral Surg Oral Med Oral Pathol 1992; 74: 79–86.

'Burst therapy' with prednisone 40 mg once daily for 5 days, followed by 20 mg every other day for 1 week, in addition to topical triamcinolone acetonide 0.1–0.2% four times daily, led to complete or partial control of aphthae in 12 of 13 patients.

Effects of colchicine treatment on mean platelet volume and the inflammatory markers in recurrent aphthous stomatitis. Seçkin HY, Bütün I, Baş Y, et al. J Dermatolog Treat 2016; 27(4): 389–91.

RAS is associated with increased inflammatory markers. Fifteen male and 45 female RAS patients who were taking colchicine were investigated retrospectively. The whole blood parameters of the patients were observed before starting colchicine treatment and in the third month of colchicine treatment. It was determined that colchicine lowers the levels of neutrophil-lymphocyte ratio, white blood cell count, and red cell distribution width. Furthermore, no changes were seen on mean platelet volume, platelet-lymphocyte ratio, and hemoglobin.

Thalidomide for the treatment of oral aphthous ulcers in patients with human immunodeficiency virus infection. Jacobson JM, Greenspan JS, Spritzler J, et al. National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group. N Engl J Med 1997; 336: 1487–93.

Fifty-seven HIV-positive patients were included in this double-blind, randomized, placebo-controlled study of thalidomide 200 mg daily versus placebo as therapy for oral aphthous ulcers in HIV-infected patients. Sixteen of 29 patients in the thalidomide group (55%) had complete healing of their aphthous ulcers after 4 weeks, compared with only two of 28 patients in the placebo group (7%).

Refractory aphthous ulceration treated with thalidomide: a report of 10 years' clinical experience. Cheng S, Murphy R. Clin Exp Dermatol 2012; 37: 132–5.

Retrospective review of 15 patients treated with thalidomide after failing topical and oral steroids. Out of 15 patients, 14 showed improvement with thalidomide; however, nine patients showed a decline in their nerve conduction study, independent of dose. Despite these findings only three patients stopped the medication, and the patient with the largest decline in nerve conduction (80%) opted to continue thalidomide rather than risk recurrence of the ulcers.

The therapeutic and prophylactic role of oral zinc sulfate in management of recurrent aphthous stomatitis (RAS) in comparison with dapsone. Sharquie KE, Najim RA, Al-Hayani RK, et al. Saudi Med J 2008; 29: 734–8.

In this double-blind, placebo-controlled study of 45 patients with RAS, patients were treated with zinc sulfate 150 mg twice

daily, dapsone 50 mg twice daily, and glucose 250 mg daily as placebo. Results showed that both zinc sulfate and dapsone had significant therapeutic effects in decreasing ulcer size. They concluded that zinc sulfate had much more rapid and sustained action.

Recurrent aphthous stomatitis and pain management with low-level laser therapy: a randomized controlled trial. Albrektson M, Hedström L, Bergh H. *Oral Surg Oral Med Oral Pathol Oral Radiol* 2014; 117: 590–4.

This study is a randomized, single-blinded, placebo-controlled trial conducted with low-level laser therapy (wavelength, 809 nm; power, 60 mW; pulse frequency, 1800 Hz; duration, 80 seconds per treatment; dose, 6.3 J/cm²) in 40 patients with RAS. Improvement was assessed with visual analog scale (VAS) and patients' experience of eating, drinking, and brushing teeth. Compared with placebo there was a statistically significant decrease in VAS score, as well as the other symptoms noted.

Efficacy of omega-3 in treatment of recurrent aphthous stomatitis and improvement of quality of life: a randomized, double-blind, placebo-controlled study. El Khouli AM, El-Gendy EA. *Oral Surg Oral Med Oral Pathol Oral Radiol* 2014; 117: 191–6.

A parallel-design, double-blind, placebo-controlled study was conducted on 50 participants divided into treatment to receive omega-3 (1 g three times daily) and control group for 6 months. Results indicated a significant reduction in the number of ulcer outbreaks, the average level of pain, and the duration of ulcer episodes per month starting in the third month of treatment.

Apremilast in treatment-refractory recurrent aphthous stomatitis. Kolios Antonios GA. *N Engl J Med* 2019; 381: 1975–7.

A retrospective series of five patients with RAS who were treated with apremilast (standard induction followed by a dose of 30 mg twice daily) for 2–24 months (mean, 11.4 months). A complete response (PGA [Physician Global Assessment] score of 0) was observed in four of the five patients, and the fifth patient had a PGA score of 1 (almost clear).

Apremilast is FDA approved for the treatment of the oral ulcers associated with Behçet disease. A multicenter, randomized placebo-controlled trial showed apremilast decreased pain, decreased number of ulcers, and increased proportion of patients with ulcer-free complete response.

Third-Line Therapies

• Pentoxifylline	A
• Clofazimine	B
• Ascorbate (vitamin C)	C
• Vitamin B ₁₂	A
• Topical ciclosporin	D
• Oral interferon- α_{2a}	C
• CO ₂ laser	D
• Penicillin G potassium troches	A
• TNF- α inhibitors	D
• Silver nitrate	B
• Montelukast	A

A randomized, double-blind, placebo-controlled trial of pentoxifylline for the treatment of recurrent aphthous stomatitis. Thornhill MH, Baccaglini L, Theaker E, et al. *Arch Dermatol* 2007; 143: 463–70.

Twenty-six patients were randomized to pentoxifylline 400 mg three times daily or placebo. Patients taking pentoxifylline had less pain, smaller ulcers, fewer ulcers, and more ulcer-free days, but this was not statistically significant. However, smaller median ulcer size in the treatment group was statistically significant. Adverse events were common and included dizziness, headaches, gastrointestinal symptoms, and fatigue.

According to the study, patients taking the active drug stated that if it were shown to be effective in the treatment of aphthous ulcers, they would not want to use it because of the side effects.

Topical cyclosporine for oral mucosal disorders. Eisen D, Ellis CN. *J Am Acad Dermatol* 1990; 23: 1259–64.

Four of eight patients with severe aphthous stomatitis obtained nearly complete suppression of ulcers during an 8-week course of topical ciclosporin 500 mg/5 mL, swish and rinse three times daily.

Chronic recurrent aphthous stomatitis: oral treatment with low-dose interferon alpha. Hutchinson VA, Angenend JL, Mok WL, et al. *Mol Biother* 1990; 2: 160–4.

Oral administration of interferon- α_{2a} (1200 IU daily) resulted in remissions of aphthae within 2 weeks of initiating therapy compared with no improvement in the placebo group. The placebo group was then treated similarly with interferon- α_{2a} leading to complete remission of their aphthae.

Treatment of recurrent aphthous stomatitis with Er,Cr:YSGG laser irradiation: a randomized controlled split mouth clinical study. Yilmaz HG, Albaba MR. *J Photochem Photobiol B* 2017; 170: 1–5.

A randomized, controlled split mouth clinical study aimed to investigate the efficacy of Er,Cr:YSGG laser irradiation on pain reduction and healing rate of RAS. Forty patients were enrolled. In the placebo group, RAS lesions were irradiated with the same device without laser emission. Laser application may be appropriate to reduce pain and also accelerate the healing of RAS.

Managing aphthous ulcers: laser treatment applied. Colvard M, Kuo P. *J Am Dent Assoc* 1991; 122: 51–3.

Pain alleviation was observed in 16 of 18 patients after CO₂ laser therapy of minor aphthae.

Evaluation of penicillin G potassium troches in the treatment of minor recurrent aphthous ulceration in a Chinese cohort: a randomized, double-blinded, placebo and no-treatment-controlled, multicenter clinical trial. Zhou Y, Chen Q, Meng W, et al. *Oral Surg Oral Med Oral Radiol Endod* 2010; 109: 561–6.

A randomized, double-blinded, control trial in 258 non-penicillin-allergic Chinese patients was performed with subjects split between placebo, treatment, and no-treatment groups. Patients treated with penicillin G potassium troches showed significant objective decreased ulcer size and subjective decrease in pain.

Efficacy and safety of TNF- α inhibitors in refractory primary complex aphthosis: a patient series and overview of the literature. Sand FL, Thomsen SF. *J Dermatolog Treat* 2013; 24: 444–6.

In this case series, a total of 18 patients were treated with etanercept, adalimumab, infliximab, or golimumab for frequent recurrent oral and genital aphthae or continuous aphthous stomatitis. Of these patients, 16 had complete or almost complete clearance of the aphthosis, whereas five had adverse reactions.

Treatment of recurrent aphthous stomatitis with clofazimine. de Abruë MA, Hirata CH, Pimentel DR, et al. Oral Surg Oral Med Oral Pathol Radiol Endod 2009; 108: 714–21.

In this randomized, controlled, partially blinded study, clofazimine (100 mg daily for 30 days, then 100 mg every other day) and colchicine (0.5 mg three times a day) were investigated for 6 months in the treatment of RAS. Patients taking clofazimine showed significant improvement to colchicine at the second, third, fifth, and sixth months of therapy.

The effect of ascorbate on minor recurrent aphthous stomatitis. Yasui K, Kurata T, Yashiro M, et al. Acta Paediatr 2010; 99: 442–5.

In this study, 16 patients with minor RAS were given daily vitamin C (2000 mg/m²) for 3 months. Treatment was then discontinued for 3 months and then restarted for another 3 months. Patients experienced a significant decrease in stomatitis during treatment months compared with months without treatment.

Effectiveness of vitamin B₁₂ in treating recurrent aphthous stomatitis: a randomized, double-blind, placebo-controlled trial. Volkov I, Rudoy I, Freud T, et al. J Am Board Fam Med 2009; 22: 9–16.

In this randomized, double-blind, placebo-controlled trial, 58 patients with RAS were split into treatment groups of 1000 mcg of sublingual vitamin B₁₂ and placebo. No patients had baseline B₁₂ levels less than 150 pg/mL. The treatment group had significantly fewer outbreaks than the controls, regardless of baseline B₁₂ level.

Of note, there have also been several studies in the literature negating the benefits of vitamin replacement.

Silver nitrate cautery in aphthous stomatitis: a randomized controlled trial. Alidaee MR, Taheri A, Mansoori P, et al. Br J Dermatol 2005; 153: 521–5.

Ninety-seven patients with painful minor aphthae were randomized to receive one stick application of silver nitrate cautery or placebo. After 1 day, a statistically significant reduction in severity of pain was shown. Silver nitrate did not prolong or shorten healing time examined after 7 days. No side effects were noted.

The authors note that the treatment is simple and cost effective for patients, with few recurrences.

Pilot study on recurrent aphthous stomatitis (RAS): a randomized placebo-controlled trial for the comparative therapeutic effects of systemic prednisone and systemic montelukast in subjects unresponsive to topical therapy. Femiano F, Buonaiuto C, Gombos F, et al. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 2010; 109: 402–7.

In this double-blind, randomized, placebo-controlled trial of 60 patients with minor RAS, patients were split equally into treatment groups of prednisone 25 mg daily tapered over 2 months, 10 mg montelukast daily for 1 month, then every other day for the second month, and cellulose (placebo). Both interventions significantly reduced number of lesions and pain relief compared with placebo; however, prednisone was more effective than montelukast. This suggests montelukast may be a safer alternative to prednisone.

Successful management of refractory pediatric-onset complex aphthosis with lenalidomide. Kalampokis I, Rabinovich CE. J Clin Rheumatol 2014; 20: 221–3.

A severe case of pediatric-onset complex aphthosis treated with lenalidomide for nearly 3 years with significant subjective and clinical improvement and no adverse effects.

Atopic dermatitis

Jennifer Mancuso, Lawrence F. Eichenfield

Atopic dermatitis (AD) is a chronic, relapsing, and intensely pruritic dermatosis that develops most commonly during early infancy and childhood and is, in most cases, associated with a personal or family history of atopy (allergic rhinitis, asthma, or eczema). It is associated with abnormalities in skin barrier function and immune dysregulation. Skin involvement ranges from acute weeping and crusted areas of eczema to papular lesions or lichenified plaques. Management involves education on appropriate skin care and avoidance of triggers, topical therapies, phototherapy, and systemic agents, including newer biologics and small molecules as well as traditional immunosuppressive medications.

MANAGEMENT STRATEGY

Successful AD therapy considers the patient's age and needs, the extent and localization of AD at presentation, and the overall disease course. Other factors to consider include previous response to treatment, disease persistence, frequency of flares, and susceptibility to, and past history of, infection (especially those due to *Staphylococcus aureus* and herpes simplex virus). The goals of management are to educate patients and caregivers about the disease, promote excellent skin care, reduce the degree and frequency of flares, minimize signs and symptoms, monitor medication quality/quantity of use, and, if possible, modify the overall disease course and impact on comorbidities.

Interventional Education

Education concerning chronic disease management is a core part of therapy. Learning modalities beyond in-office disease

education may be useful, including handouts, internet-based written materials, instructional videos, and other media. Comprehensive multispecialty 'eczema clinics' offer intensive education as a component of long-term AD management. This model, with its longer appointments, focused educational curricula, patient support networks, and the ability to elicit patient and family feedback, parallels strategies shown to be effective for managing asthma, diabetes, and other chronic diseases. Shared decision making – where therapeutic options and the rationales for recommending them, along with weighing the risks and benefits, are discussed with patients to arrive at therapeutic strategies – is an evolving method thought to improve patient outcomes (e.g., www.eczemacenter.org; www.nationaleczema.org; www.eczema.org).

Skin Care

Excellent skin care remains a cornerstone of management. Emollients improve the xerosis and skin barrier dysfunction associated with AD and may improve pruritus and spare the use of prescription antiinflammatory medications. With little evidence to recommend the use of one emollient or moisturizer over another, patient and caregiver preference should be considered, with product selection based on the premise that 'an emollient that is applied works better than one that remains on a shelf.' Very occlusive ointments may not be tolerated during the summer months or in humid climates because of interference with the function of eccrine sweat ducts and the induction of folliculitis; in these situations, a cream may be a more practical choice. It is best to avoid preparations that contain topical sensitizers such as fragrance, neomycin, benzocaine, etc. Emollients and moisturizers should be applied after any topical pharmacologic therapies to allow active medications to penetrate the skin with full effect.

The value of bathing and the frequency with which it should be undertaken remain controversial, though most experts believe that daily bathing with application of emollients to follow is well tolerated and may be beneficial. The chief benefits of bathing include cleansing, removing irritants and allergens, debridement of infected eczema, improved penetration of topical therapies, and skin hydration (when post bath emollients are used to 'lock in' moisture). Bathing without use of emollients may dry the skin and disrupt the stratum corneum. Recent data demonstrate twice daily soaking baths followed by immediate application of an occlusive moisturizer (soak-and-seal method) is superior at improving disease severity in moderate-to-severe pediatric AD over twice-weekly soak-and-seal baths.

Loss of function mutations in the filaggrin gene can lead to increased transepidermal water loss and an increased risk of developing AD, as well as asthma, allergies, and herpes simplex virus infections. Data regarding transepidermal water loss suggest that the frequency of application of emollients or moisturizers may be more important than timing the application to coincide strictly with bathing (the traditional 'soak-and-seal' approach); this finding remains to be confirmed in larger, more controlled studies.

Wet wraps with topical corticosteroids are a useful tool in the intensive treatment of severe AD and/or disease that is refractory to standard topical therapies. They may increase skin hydration, serve as an effective mechanical barrier to scratching, and act as an occlusive layer that promotes penetration of topical corticosteroids into the skin, thereby increasing the amount of medication delivered to the most severely affected areas. Temporary systemic

bioactivity of the corticosteroids and potential hypothermia are concerns.

Topical Therapies

Topical corticosteroids remain the first-line therapy for inflammation and pruritus associated with AD that are unresponsive to good skin care and moisturizers. Variations in corticosteroid-prescribing habits (e.g., quantity, frequency, and duration of therapy) are common even among dermatologists. Some clinicians start treatment with higher potency topical corticosteroid preparations in order to induce remission, followed by a relatively quick tapering down of potency as the dermatitis improves. Alternatively, other clinicians use short bursts of higher potency corticosteroids followed by moisturizers alone until relapse occurs. Another treatment regimen advocates more prolonged treatment with less potent steroid preparations. For persistent or frequently flaring eczema, use of moderate-to-higher potency topical corticosteroid (TCS) to induce remission followed by several times a week 'proactive' treatment to recurring areas is commonly utilized. Drug-specific FDA indications and an expanding body of clinical trial data should help guide clinicians when educating and instructing patients on TCS usage.

Non-steroid topicals, including topical calcineurin inhibitors (TCIs) tacrolimus and pimecrolimus, and phosphodiesterase (PDE)-4 inhibitor crisaborole, have the important advantage of not being associated with skin atrophy. Current indications for TCI use are as 'second-line therapy for the short-term and non-continuous chronic treatment' of mild-to-moderate AD (pimecrolimus) or moderate-to-severe AD (tacrolimus) in non-immunocompromised adults and children 'who have failed to respond adequately to other topical prescription treatments for AD, or when those treatments are not advisable.' Patients who are especially likely to benefit include those in whom the clinical course of AD is marked by steroid tachyphylaxis (versus simple non-compliance), disease persistence, and/or frequent flares, which would otherwise result in an almost continuous need for TCS treatment. TCIs may also be specifically indicated in sensitive thin skin areas, such as around the eye, face, neck, and genital area where local safety and systemic absorption are of special concern.

The safety and efficacy of tacrolimus and pimecrolimus have been studied in multiple short (6 weeks) and long-term (longer than 2 years) clinical trials. Data from these trials demonstrate that pimecrolimus reduces the number and severity of flares, extends the period between major flares, and reduces pruritus and other cutaneous signs associated with AD. Prospective studies spanning up to 10 years have investigated the clinical use of TCI in pediatric populations and have suggested that the use of TCI is not associated with systemic immunosuppression or an increased risk of cancer of any type, including skin cancer and lymphoma; nor does it appear to affect the delayed-type hypersensitivity response. In most countries, regulatory agencies do not recommend the use of TCI in patients under 2 years of age. Pimecrolimus cream 1% and tacrolimus ointment 0.03% is indicated for adults and children aged 2–15 years, whereas tacrolimus ointment 0.1% is indicated only for adults.

'Proactive' treatment with intermittent TCS or TCI is recommended for disease maintenance for persistent or frequently flaring disease. Long-term, intermittent maintenance use of tacrolimus ointment in patients with stabilized AD has been shown to significantly increase the period between disease exacerbations and the total number of disease-free days compared with vehicle.

Despite the frequency of use, the incidence of side effects in these studies was generally low and most commonly included transient application-site stinging.

Phosphodiesterase (PDE)-4 inhibitors are a newer class of therapy for AD. Studies have shown the topical agent crisaborole to be an effective therapy for AD and it is indicated in patients 3 months of age and older with mild-to-moderate AD. Similar to the TCIs, studies have demonstrated crisaborole to be safe for long-term use without risk of skin atrophy. The incidence of side effects is low, with application-site pain being the most common but often transient effect.

Careful supervision, combined with appreciation of the risk-benefit profiles of moisturizers, topical corticosteroids, TCIs, and topical PDE-4 inhibitors, allows for individualized and optimized patient care. Treatment should be readily adjusted on an 'as-needed' basis that takes advantage of available therapeutic modalities. For children with severe flares, this may mean using short-term bursts of mid- to high-potency topical steroids – with or without wet wraps – instead of relying on long-term use of less potent agents. Close reexamination of the patient at regular intervals to evaluate the efficacy and tolerability of local and systemic therapies is warranted. Once control of a flare is achieved, topical corticosteroids can be tapered to a lower-potency agent and/or from daily to intermittent (e.g., twice- or thrice-weekly) application. Transition to, or incorporation of, non-steroid agents may also be considered. There is a positive risk-to-benefit ratio of proactive, scheduled (biweekly), topical antiinflammatory agents applied to frequently relapsing areas in preventing AD flares. During quiescent periods, therapy should shift to a less intense regimen with a focus on maintenance and proper skin care at its core. The use of TCIs or topical PDE-4 inhibitor monotherapy to control flare recurrence while limiting patients' extended exposure to corticosteroids is supported by some physicians.

Other Treatment Considerations

Total avoidance of environmental aeroallergens is almost impossible and may not significantly influence AD; however, avoidance of known triggers is a reasonable approach. Food allergy is more common in children with AD than without and, in a subset of individuals, clinically relevant food allergy may exacerbate atopic dermatitis. US national guidelines for food allergy recommend that evaluation for milk, egg, peanut, wheat, and soy food allergies are considered in children less than 5 years old with moderate-to-severe AD if the child has a reliable history of an immediate reaction after ingestion of any of these foods, or the child has persistent AD in spite of optimized management and topical therapy. In addition, recent national guidelines recommend that children in the first year of life with severe AD and/or egg allergy have early evaluation with serum immunoglobulin E (IgE) or skin prick tests and also recommend early feeding of peanuts as a method to decrease development of peanut allergy. Specific serum IgE and skin prick tests have high rates of false positives and poor predictive value for food allergy diagnosis, and severely restrictive diets based on positive tests rather than true allergy can be harmful and may result in nutritional deficiencies. Thus, positive IgE testing should be verified through controlled food trials or other means unless there is a reliable history of an immediate allergic reaction after ingestion of a specific food. Maternal dietary restrictions during pregnancy and lactation are not considered to have a significant role in the development of AD and are generally not recommended.

Although they do not appear to have direct effects on the pruritus associated with AD, sedating systemic antihistamines such as hydroxyzine and diphenhydramine may be useful in improving sleep in flaring patients. This practice has not been evaluated rigorously in large, randomized, double-blind, placebo-controlled trials, and the drowsiness that may be associated with daytime use is a legitimate concern for school-age children. Second-generation, non-sedating antihistamines are less useful in managing AD, but may benefit patients with allergic triggers and, with chronic use, are suggested in some studies to reduce the rate of progression to other atopic disease (the atopic march). It is important to note that topical antihistamines are not recommended because of potential cutaneous sensitization.

Studies have shown reduced nocturnal melatonin secretion associated with sleep disturbance and more severe AD disease. Melatonin is a hormone important in sleep regulation that is secreted by the pineal gland, and supplementation with oral melatonin has been used to treat insomnia and jet lag. A randomized control trial showed that melatonin supplementation was associated with a decrease in sleep-onset latency as well as small improvements of the severity of AD compared to placebo.

Patients may have sudden exacerbations of AD due to overgrowth of *Staphylococcus aureus* – honey-colored crusting, folliculitis, and pyoderma are signs of overt infection. Topical and/or oral antibiotic therapy – typically of short duration to avoid the development of bacterial resistance – may be useful. Skin cultures and sensitivity testing can be considered before initiating treatment, as methicillin-resistant *S. aureus* (MRSA) may be an important pathogen in some patients. Recurrent, deep-seated *S. aureus* infections should raise the possibility of an immunodeficiency syndrome such as hyper-IgE syndrome or dedicator of cytokinesis 8 (DOCK8) deficiency.

The addition of antiseptics to bath water, for example, diluted bleach baths ('like swimming in pool water'), may help reduce the number of local skin infections and the need for systemic antibiotics in AD patients with heavily colonized and/or superinfected skin, although there is controversy about its effectiveness and mechanism of action. A bleach bath can be prepared by mixing one-quarter to one-half a cup of sodium hypochlorite 6% solution (chlorine liquid bleach) in a bathtub full of lukewarm water, or a solution made of one teaspoon of bleach per half gallon of water; the goal is to create a modified Dakin-like solution with a final bleach concentration that approximates 0.005%. Standardly soaking or spraying the mixed solution onto the skin for 5–10 min, with or without a rinse with fresh water, is followed by patting dry and applying topical therapy and/or emollient/moisturizer. For added convenience, newer formulations of bleach-like products are specially formulated and available as body washes, sprays, or gels.

Eczema herpeticum may be easily misdiagnosed as bacterial superinfection and presents a serious risk in patients with widespread AD. Patients can present with multiple vesiculopustular lesions and painful 'punched-out' erosions that fail to respond to oral antibiotics. Document herpes infection before treatment via culture and/or direct fluorescent antibody, and initiate antiviral therapy as soon as possible. Intravenous treatment is indicated in cases of severe disseminated eczema herpeticum. Oral acyclovir (or equivalent dosage of other anti-herpetic medications) may be useful with herpes simplex confined to the skin; for adults 400 mg three times daily for 10 days or 200 mg four times daily for 10 days usually provides a sufficient dosage.

Antifungal therapy may reduce the severity of AD lesions exacerbated by *Pityrosporum* species, particularly in the seborrheic

areas of the skin and scalp. Patients with documented dermatophyte infection or IgE antibodies to *Pityrosporum* may benefit from a trial of topical or systemic antifungal therapy.

Due to the immunologic and microbiologic relationships between the skin, gut, and airways, there has been great interest in probiotics. As the findings to date on their utility in preventing or modifying AD are conflicting, the long-term significance of probiotics in the treatment of atopic dermatitis warrants further investigation.

Although the exact mechanism of action is unknown, phototherapy in AD is thought to suppress proinflammatory cytokines (such as IL-2 and IL-12) and induce T-cell apoptosis. Broadband ultraviolet (UV) B, broadband UVA, narrowband UVB (311 nm), UVA1 (340–400 nm), and combined UVA-B phototherapy have been reported to be useful for widespread or recalcitrant disease. Photochemotherapy with psoralen and UVA light may be indicated in severe cases. Multiple treatments are usually required to be effective, and this can be inconvenient for patients and their families, depending on location and accessibility to a suitable light source. Side effects can include skin pain, erythema, pruritus, and pigment changes. Likewise, UV radiation may increase the long-term risk of premature skin aging and cutaneous malignancies. Shielding and appropriate eye protection may help minimize unnecessary exposure.

Systemic Therapies

There are rapid changes in therapeutic options for systemic treatment of AD with the approval of specific biologic agents and the study of multiple new biologic and other agents.

Systemic corticosteroids are often prescribed for acute AD exacerbations, though there are limited data on efficacy or comparative data with other medications. The temptation to use systemic corticosteroids can be significant, given the dramatic clinical improvement that can occur. The propensity to flare with abrupt discontinuation of treatment and the well-known associated systemic side-effect profile, however, suggest that systemic corticosteroids should be reserved for 'crisis cases' – and, even then, used with the intent to bridge to another systemic agent or phototherapy.

Dupilumab is a fully human IgG4 monoclonal antibody and acts as an antagonist to the IL-4 receptor α , targeting IL-4 and IL-13, and has been shown to be efficacious in treating moderate-to-severe AD. It is currently FDA approved for patients 6 years of age and older with moderate-to-severe AD. It also has received FDA approval for asthma in individuals 12 years and older, chronic rhinosinusitis with nasal polyps in adults 18 years and older, and is in clinical trials for eosinophilic esophagitis. Dupilumab for adults and pediatric patients 60 kg or greater is administered as a loading dose of 600 mg given by subcutaneous injection, followed by a maintenance dose of 300 mg every 2 weeks. The recommended dosing for other pediatric patients is 15 to <30 kg: 600 mg loading dose and 300 mg q4 weeks; 30 to <60 kg: 400 mg loading dose and 200 mg q4 weeks. Dupilumab has been shown to significantly improve clinical and patient-oriented outcomes including EASI (Eczema Area and Severity Index), SCORAD (SCORing Atopic Dermatitis), DLQI (Dermatology Life Quality Index), and itch Numeric Rating Scale scores. Concomitant use of topical steroids with dupilumab provides further benefit and several studies demonstrate the efficacy of combination therapy. One study showed the efficacy of dupilumab with concomitant topical steroid in treating adults with AD with an inadequate response or intolerance to ciclosporin.

The safety profile of dupilumab is superior when compared to the immunosuppressants listed below, and laboratory monitoring is not required. There were no significant serious safety concerns in phase III clinical trials; common adverse effects in clinical trials included rhinosinusitis, upper respiratory tract infections, and skin infections; however, these occurred with similar frequency between treatment and placebo groups. One study showed that dupilumab is associated with a decreased risk of skin infections and eczema herpeticum in adults with moderate-to-severe AD. Most studies have shown higher rates of noninfectious conjunctivitis incidence in dupilumab-treated patients with AD than in placebo groups. This adverse effect may be managed with topical lubricants or in conjunction with Ophthalmology with topical eye-drop corticosteroids, tacrolimus, ciclosporin, or lifitegrast.

Ciclosporin is a calcineurin inhibitor that blocks activation of T lymphocytes and reduces the transcription of cytokines, including IL-2, shown to be involved in the pathogenesis of AD. It may be used as a short-term treatment or as a bridge between other steroid-sparing alternatives. Ciclosporin is typically dosed at 2.5–5 mg/kg/day, and a response may be seen in 2–3 weeks. Alternatively, some experts prefer dosing ciclosporin microemulsion at 3 mg/kg/day in children, or 150 mg (low dose) or 300 mg (high dose) in adults, as the microemulsion offers more predictable absorption. Flares can occur after discontinuation of therapy; therefore, gradual tapering or use of another immunosuppressive for maintenance therapy should be considered. The safety, efficacy, and risks of ciclosporin are well documented in both adults and children, and treatment with this agent is associated with reduced skin disease and an improved quality of life. Hypertension and renal toxicity, as well as concerns about malignancy, are limitations to long-term therapy. Continuous therapy beyond 1 year is not recommended, and it is unknown how many short courses may be given safely. Blood pressure, complete blood cell count, renal and hepatic function tests, magnesium, and uric acid should be monitored.

Methotrexate is a folic acid analog that inhibits dihydrofolate reductase and interferes with DNA synthesis and lymphocyte proliferation leading to antiinflammatory effects; however, its greatest advantage may be that the relatively low doses used for skin disease appear less immunosuppressive than other AD systemic therapies. An open-label, prospective, 24-week trial of adults with AD demonstrated a response plateau at approximately 12 weeks with little additional improvement at doses greater than 15 mg weekly. Alternatively, some experts dose methotrexate at 2.5 mg daily for 4 days per week. A retrospective review of children showed that AD was well controlled with effective dosing of 0.5–0.8 mg/kg/week (either as a single weekly dose or divided 3 or 4 days/week). There is a long history of methotrexate use in pediatric and adult inflammatory disease. Nausea and liver function abnormalities/hepatotoxicity may limit dosing. Pulmonary toxicity may be another potential concern. It is unclear what role folic acid supplementation plays in the treatment of AD with methotrexate.

Azathioprine, a 6-mercaptopurine analog that inhibits purine synthesis and demonstrates cytotoxic and immunosuppressive properties, can be an effective monotherapy for AD. Marrow suppression and liver toxicity are major concerns; blood cell counts and liver function tests should be monitored closely. One in 300 individuals is homozygous for low metabolic activity alleles that correlate with higher risk of bone marrow suppression; azathioprine should be dosed according to thiopurine methyltransferase (TPMT) genotype/levels. Dosing in children and adults is

generally 2.5 mg/kg/day in patients with normal TPMT activity and adjusted to lower doses for carriers of mutant alleles and/or definite intermediate TPMT levels (e.g., 1.0 mg/kg/day). Higher doses, up to 5 mg/kg/day, have been utilized in children. Very low or absent TPMT activity indicating homozygous TPMT mutations may be associated with life-threatening myelotoxicity. Drug hypersensitivity and gastrointestinal disturbances have been reported. An increased risk of malignancy is recognized with long-term use to prevent transplant rejection or manage inflammatory bowel disease.

Mycophenolate mofetil (MMF) has a moderately good safety profile and represents a possible therapeutic alternative for severe, refractory AD. It is an inhibitor of inosine monophosphate dehydrogenase involved in de novo purine synthesis and has been used as an immunosuppressant in organ transplantation. Several adult studies have demonstrated efficacy at doses up to 2 g daily. A retrospective review of MMF as monotherapy in 14 pediatric AD patients showed it to be safe and effective at doses of 40–50 mg/kg/day in younger children (presumably due to increased surface area-to-volume ratios) and 30–40 mg/kg/day in adolescents, with maximal effect after 8–12 weeks of therapy. Patients should be monitored for leukopenia and anemia, and drug levels may be increased in the setting of renal insufficiency. MMF has been loosely linked to herpes retinitis, dose-related bone marrow suppression, and increased infection. Further prospective controlled studies are needed for this promising therapy.

The field of AD therapies has entered a new era in which novel topical and systemic agents are rapidly being developed, including biologics and small molecules that selectively target atopic dermatitis-causing pathways. While dupilumab is the prototype of AD-targeted therapies, many others are emerging in clinical trials. Novel topical therapies include topical Janus kinase (JAK) inhibitors and aryl hydrocarbon agonists, among others. Evolving systemic therapies for AD include oral Janus kinase (JAK) inhibitors, including baricitinib, abrocitinib, upadacitinib, anti-IL-13 biologics including lebrikizumab and tralokinumab, anti-IL-22 monoclonal antibody fezakinumab, and anti-IL-31 biologics including nemolizumab, among others.

Referral, Quality of Life Issues, and Educational Resources

Referral to a pediatric dermatologist or an adult dermatologist/AD specialist may help with comprehensive management of skin care and barrier repair, and consideration of systemic therapies. Allergy testing is not generally a first-line referral recommendation in the routine evaluation and treatment of uncomplicated AD. However, consultation with an allergist can be useful when proper skin care alone is not effective and/or when the clinical picture hints strongly at specific allergic triggers. Referral to immunology or gastroenterology is warranted if underlying systemic infections are frequent or when eosinophilic gastroenteritis/esophagitis becomes a concern in younger children with concomitant failure to thrive. Patch testing may be considered to exclude a coexisting contact allergen to, for example, a steroid or emollient constituent in recalcitrant disease.

Emotional stress can exacerbate AD in some patients who may respond to frustration, anxiety, embarrassment, or other psychologically stressful events with a perceived increase in pruritus and subsequent scratching. This may be particularly important in the adolescent population, where even very mild skin

disease may be considered 'disfiguring.' AD has been shown to be associated with several mental health comorbidities including attention-deficit hyperactivity disorder, anxiety, and depression. Psychosocial evaluation and counseling should be considered in families where emotional triggers appear to function as obstacles to disease management, or where quality of life is clearly affected. Therapeutic education has been shown to be beneficial in managing AD and may be accomplished through extended in-office discussion, written handouts, eczema 'school programs,' and/or web resources, which include video training modules (e.g., www.eczemacenter.org). Families may also benefit from support groups such as the US National Eczema Association (www.nationaleczema.org) and the UK National Eczema Society (www.eczema.org).

Hospitalization

Erythrodermic AD patients, those with suspected widespread superinfection, or those with severe recalcitrant disease may benefit from hospitalization.

Specific Investigations

In selected cases only:

- Skin biopsy: especially in adult onset AD and when cutaneous T-cell lymphoma is being considered as an alternative diagnosis
- Quantification of IgE, IgA, IgM, and IgG levels
- Specific serum IgE assays for food or environment allergens and oral food challenges
- Patch testing for allergic contact dermatitis: allergic contact dermatitis may be both an alternative diagnosis and exacerbator of AD
- Bacterial cultures and sensitivities
- HIV enzyme-linked immunosorbent assay (ELISA) screening

Translating atopic dermatitis management guidelines into practice for primary care providers. Eichenfield LF, Boguniewicz M, Simpson E, et al. *Pediatrics* 2015; 136: 554–65.

This paper presents an overview of the strategy for diagnosis and management of AD in the pediatric population.

Guidelines of care for the management of atopic dermatitis: section 1. Diagnosis and assessment of atopic dermatitis. Eichenfield LF, Tom WL, Chamlin SL, et al. *J Am Acad Dermatol* 2014; 70: 338–51.

Guidelines of care for the management of atopic dermatitis: section 2. Management and treatment of atopic dermatitis with topical therapies. Eichenfield LF, Tom WL, Berger TG, et al. *J Am Acad Dermatol* 2014; 71: 116–32.

Guidelines of care for the management of atopic dermatitis: section 3. Management and treatment with phototherapy and systemic agents. Sidbury R, Davis DM, Cohen DE, et al. *J Am Acad Dermatol* 2014; 71: 327–49.

Guidelines of care for the management of atopic dermatitis: section 4. Prevention of disease flares and use of adjunctive therapies and approaches. Sidbury R, Tom WL, Bergman JN, et al. *J Am Acad Dermatol* 2014; 71: 1218–33.

This comprehensive set of guidelines discusses the management of AD – from diagnosis to treatment and prevention – in both adult and pediatric populations.

Current guidelines for the evaluation and management of atopic dermatitis: a comparison of the Joint Task Force Practice Parameter and American Academy of Dermatology guidelines. Eichenfield LF, Ahluwalia J, Waldman A, et al. *J Allergy Clin Immunol*. 2017; 139(4S): S49–57.

This review highlights the basic principles of AD management and therapies from the distinct perspectives of the allergist and dermatologist.

Guidelines for the diagnosis and management of food allergy in the United States: report of the NIAID-sponsored expert panel. Boyce JA, Assaad A, Burks AW, et al. *J Allergy Clin Immunol* 2010; 126: S1–58.

This includes consensus definition for food allergy and discussion of comorbid conditions and IgE-mediated and non-IgE-mediated reactions to food.

Addendum guidelines for the prevention of peanut allergy in the United States: Report of the National Institute of Allergy and Infectious Diseases-Sponsored Expert Panel. Togias A, Cooper SF, Acebal MLA, et al. *Pediatr Dermatol* 2017; 34: e1–21.

This paper presents guidelines for infants at various risk levels for the development of peanut allergy, including the highest-risk group, and infants with severe AD and/or egg allergy. Topics addressed include the definition of risk categories, appropriate use of testing (specific IgE measurement, skin prick tests, and oral food challenges), and the timing and approaches for introduction of peanut-containing foods.

Head-and-neck dermatitis: diagnostic difficulties and management pearls. Maarouf M, Saberian C, Lio PA, et al. *Pediatr Dermatol* 2018; 35: 748–53.

This article reviews head-and-neck dermatitis, including diagnostic gaps, differential diagnosis, and management techniques.

First-Line Therapies

• Education	A
• Emollients*	A
• Topical corticosteroids	A
• Proactive therapy	A
• Wet wraps	B

*The choice of using an emollient or a barrier cream should be made based on personal preference

Age related, structured educational programmes for the management of atopic dermatitis in children and adolescents: multicentre, randomized controlled trial. Staab D, Diepgen T, Fartasch M, et al. *Br Med J* 2006; 332: 933–8.

A comparison of children with AD whose parents had received 6 weeks of intensive AD education versus those children whose parents received no education. The investigators taught age-appropriate interventions to the parents. Patients in the 'treatment' group demonstrated significantly improved subjective quality-of-life scores and objective measures of eczema severity over the 12-month period.

Psychological and educational interventions for atopic eczema in children. Ersser SJ, Latter S, Sibley A, et al. *Cochrane Database Syst Rev* 2007; 3: CD004054.

Emollients improve treatment results with topical corticosteroids in childhood atopic dermatitis: a randomized comparative study. Szczepanowska J, Reich A, Szepietowski JC. *Pediatr Allergy Immunol* 2008; 19: 614–8.

A randomized study of 52 patients aged 2–12 years found that the use of emollients can significantly improve xerosis and pruritus during corticosteroid treatment of AD and helped maintain clinical improvement after discontinuation of therapy.

Quantitative assessment of combination bathing and moisturizing regimens on skin hydration in atopic dermatitis. Chiang C, Eichenfield LF. *Pediatr Dermatol* 2009; 26: 273–8.

A crossover study in five pediatric patients with AD and five patients with healthy skin in whom objective parameters of cutaneous hydration status were assessed after various combinations of bathing and moisturizing regimens. This study found that bathing without moisturizer may compromise skin hydration. Bathing followed by moisturizer application provides modest hydration benefits, though less than that of simply applying moisturizer alone.

Frequent versus infrequent bathing in pediatric atopic dermatitis: a randomized clinical trial. Cardona ID, Kempe EE, Lary C, et al. *J Allergy Clin Immunol Pract* 2020; 8: 1014–21.

This randomized clinical trial demonstrates that twice-daily soaking baths followed by immediate application of an occlusive moisturizer (soak-and-seal method) is superior at improving disease severity in moderate-to-severe pediatric AD over twice-weekly soak-and-seal baths, with a greater than 30% SCORAD (SCORing Atopic Dermatitis index) improvement.

Scoping systematic review of treatments for eczema. Nankervis H, Thomas KS, Delamere FMC, et al. *NIHR Journals Library* 2016; 4: 1–528.

A systematic review of 287 trials covering 92 different AD interventions.

Topical corticosteroids for atopic eczema: clinical and cost effectiveness of once-daily vs. more frequent use. Green C, Colquitt JL, Kirby J, et al. *Br J Dermatol* 2005; 152: 130–41.

A systematic review found no clear differences in outcomes between once-daily and more frequent application of topical corticosteroids.

Topical agents for the treatment of atopic dermatitis. Eichenfield LF, Luger T, Papp K, et al. *J Drugs Dermatol* 2020; 19: 50–64.

This literature review summarizes the efficacy and safety data of topical AD therapies, and specifically states that the published clinical studies for crisaborole demonstrate its efficacy and safety profile. It also states that comparison among different therapies is difficult due to differing methodologies across clinical trials.

A systematic review of the safety of topical therapies for atopic dermatitis. Callen J, Chamlin S, Eichenfield LF, et al. *Br J Dermatol* 2007; 156: 203–21.

This review of topical therapies for AD found that although some systemic exposure to topical steroids does occur, physiologic changes appear to be uncommon, and systemic complications are rare when medications are used properly.

Efficacy and safety of wet-wrap dressings in children with severe atopic dermatitis: influence of corticosteroid dilution. Wolkerstorfer A, Visser RL, De Waard van der Spek FB, et al. *Br J Dermatol* 2000; 143: 999–1004.

In children with severe refractory AD, 5%, 10%, and 25% dilutions of fluticasone propionate 0.05% cream proved highly efficacious, irrespective of dilution, when applied under wet-wrap dressings. Improvement occurred mainly during the first week, and the only significant adverse effect was folliculitis.

Wet dressing therapy in conjunction with topical corticosteroids is effective for rapid control of severe pediatric atopic dermatitis: experience with 218 patients over 30 years at Mayo Clinic. Dabade TS, Davis DM, Wetter DA, et al. *J Am Acad Dermatol* 2012; 67: 100–6.

Intensive inpatient treatment (with wet dressings and topical corticosteroids) was highly effective in controlling severe and recalcitrant atopic dermatitis.

Second-Line Therapies

• Topical immunomodulators	A
• Against routine antimicrobial use	A
• Against routine antihistamines/anxiolytics use	A
• Avoidance of true IgE-mediated triggers	A
• Topical phosphodiesterase inhibitors	A
• Dupilumab (moderate-to-severe disease)	A

Efficacy and safety of crisaborole ointment, a novel, non-steroidal phosphodiesterase 4 (PDE4) inhibitor for the topical treatment of atopic dermatitis (AD) in children and adults. Paller AS, Tom WL, Lebwohl MG, et al. *J Am Acad Dermatol* 2016; 75: 494–503.e6.

Crisaborole's safety and efficacy were established through two phase III clinical trials. The studies included 1522 randomized patients; 1016 received crisaborole ointment and 506 received vehicle twice daily for 28 days. At the completion of the study, a statistically significant ≥ 2 grade improvement in Investigator's Static Global Assessment (ISGA) score ($p=0.038$ for center 1 and $p<0.001$ for center 2) was noted. Application-site pain was the most common adverse effect, present in 4.4% of crisaborole-treated and 1.2% of vehicle-treated patients. However, 77.6% of patients had resolution of this symptom within 1 day of onset.

Safety and efficacy of pimecrolimus cream in atopic dermatitis: a 5-year randomized trial. Sigurgeirsson B, Boznanski A, Todd G, et al. *Pediatrics* 2015; 135: 597–606.

This is a 5-year-long randomized control trial of pimecrolimus 1% cream compared with TCS. After 5 years, >85% of patients achieved overall and facial treatment success. In addition, safety of this treatment modality was demonstrated.

A meta-analysis of the efficacy and tolerability of proactive treatment with TCS versus TCI. Schmitt J, von Kobyletzki L, Svensson A, et al. *Br J Dermatol* 2011; 164: 415–28.

This meta-analysis suggests that topical fluticasone propionate (relative risk=0.46) may be more efficacious in preventing disease flares than topical tacrolimus (relative risk=0.78).

0.03% Tacrolimus ointment applied once or twice daily is more efficacious than 1% hydrocortisone acetate in children with moderate-to-severe atopic dermatitis: results of a randomized double-blind controlled trial. Reitamo S, Harper J, Bos JD, et al.; European Tacrolimus Ointment Group. *Br J Dermatol* 2004; 150: 554–62.

This study, involving 624 children aged 2–15 years with moderate-to-severe AD, demonstrated that tacrolimus 0.03% ointment applied

once or twice daily resulted in a significantly greater reduction in modified Eczema Area and Severity Index (mEASI) scores than hydrocortisone acetate 1% ointment applied twice daily ($p < 0.001$).

Intermittent therapy for flare prevention and long-term disease control in stabilized atopic dermatitis: a randomized comparison of 3-times-weekly applications of tacrolimus ointment versus vehicle. Breneman D, Fleischer AB Jr, Abramovits W, et al. *J Am Acad Dermatol* 2008; 58: 990–9.

A double-blind study in which 197 clinically clear patients with a history of moderate-to-severe AD were randomized to three-times-weekly topical tacrolimus or vehicle for 40 weeks; tacrolimus ointment was associated with significantly more flare-free days than vehicle and a significantly longer time until relapse.

Topical calcineurin inhibitors and malignancies in AD patients. Legendre L, Barnette T, Mazereeuw-Hautier J. *J Am Acad Dermatol* 2015; 72: 992–1002.

A systematic review of the long-term safety of topical corticosteroids and TCIs in pediatric AD patients.

No evidence of increased cancer incidence in children using topical tacrolimus for atopic dermatitis. Paller AS, Fölster-Holst R, Chen SC, et al. *J Am Acad Dermatol* 2020; 1: S0190-9622 304 98-9.

In this prospective, longitudinal, international observational cohort study of 8000 children with AD treated with tacrolimus ointment, malignancies were observed at the expected rate for the age- and sex-matched general population.

Systematic review of published trials: long-term safety of topical corticosteroids and topical calcineurin inhibitors in pediatric patients with atopic dermatitis. Siegfried EC, Jaworski JC, Kaiser JD, et al. *BMC Pediatr* 2016; 16: 75.

A systematic review of the literature included multiple tacrolimus trials for pediatric AD.

The study included over 5800 patients and did not note any cases of lymphoma.

Long-term efficacy and tolerability of tacrolimus 0.03% ointment in infants: a 2-year open-label study. Mandelin JM, Rubins A, Remitz A, et al. *Int J Dermatol* 2012; 51: 104–10.

Tacrolimus 0.03% ointment was associated with substantial clinical improvement of AD in infants aged <2 years. Treatment tolerability was similar to that seen in older children.

Staphylococcus aureus: colonizing features and influence of an antibacterial treatment in adults with atopic dermatitis. Bath-Hextall FJ, Birnie AJ, Ravenscroft JC, et al. *Br J Dermatol* 2010; 163: 12–26.

Twenty-six studies involving 1229 participants were included. The authors failed to find any evidence that commonly used anti-staphylococcal interventions are clinically helpful in AD that is not clinically infected.

An evidence-based review of the efficacy of antihistamines in relieving pruritus in atopic dermatitis. Klein PA, Clark RA. *Arch Dermatol* 1999; 135: 1522–5.

This review of 16 AD-associated antihistamine trials found that the majority of studies were flawed in terms of sample size or study design.

Managing sleep disturbances in children with atopic dermatitis. Patel D, Levoska M, Shwayder T. *Pediatr Dermatol* 2018; 35: 428–33.

This article reviews the benefits and limitations of therapeutic agents used to manage sleep disturbance in pediatric patients with AD.

An assessment of the use of antihistamines in the management of atopic dermatitis. He A, Feldman SR, Fleischer AB Jr. *J Am Acad Dermatol* 2018; 79: 92–6.

This article suggests that there is no high-level evidence to suggest that non-sedating antihistamines reduce itch in AD or that sedating antihistamines provide benefit in controlling AD symptoms with the exception of sleep and AD comorbidities, including allergic rhinitis.

Melatonin supplementation for children with atopic dermatitis and sleep disturbance: a randomized clinical trial. Chang YS, Lin MH, Lee JH, et al. *JAMA Pediatr* 2016; 170: 35–42.

This double-blind, placebo-controlled crossover study found melatonin supplementation to be a safe and effective way to improve both sleep-onset latency and disease severity in pediatric AD. In 48 children treated with melatonin, the SCORAD index decreased by 9.1 compared with the placebo group ($p < 0.001$) and the sleep-onset latency shortened by 21.4 min after melatonin treatment compared with placebo ($p = 0.02$). No adverse event was reported throughout the study.

Two phase 3 trials of dupilumab versus placebo in AD. Simpson EL, Bieber T, Guttman-Yassky E, et al. *New Eng J Med* 2016; 375: 2335–48.

This two-center, double-blind, randomized, controlled trial compared dupilumab weekly and biweekly with placebo in 671 adults with moderate-to-severe AD not controlled by topical therapies. Dupilumab weekly and biweekly both resulted in an Investigator's Global Assessment (IGA) score reduction of two points or more in 36% of patients versus 10% in the placebo control group. Additionally, there was a significant improvement in AD severity observed in those receiving dupilumab compared with placebo based on a >75% change in EASI score ($p < 0.001$). Dupilumab therapy was also associated with a statistically significant improvement in other clinical end points, including reduction in pruritus, symptoms of anxiety and depression, and improvement in quality of life. Side effects occurring more frequently in the dupilumab therapy groups than in the placebo groups included injection-site reactions (8%–19% versus 6%) and conjunctivitis (3%–5% versus $\leq 1\%$).

Dupilumab treatment in adults with moderate-to-severe atopic dermatitis. Beck LA, Thaçi D, Hamilton JD, et al. *N Engl J Med* 2014; 371: 130–9.

In this study, four separate randomized, double-blind, placebo-controlled trials were performed to assess the safety of dupilumab and found that patients treated with dupilumab had marked and rapid improvement in all evaluated measures of AD disease activity. Adverse events were more frequent in the placebo group and were not dose limiting.

A clinician's guide to the recognition and management of dupilumab-associated conjunctivitis. Agnihotri G, Shi K, Lio PA. *Drugs R D* 2019; 19: 311–8.

This article provides a useful approach on management of conjunctivitis, which is one of the most common side effects of dupilumab. It suggests that mild conjunctivitis may be managed by the dermatologist with warm compresses and eye drops, including artificial tears and antihistamine drops. Moderate-to-severe

conjunctivitis should be managed by an ophthalmologist with topical eye drops with corticosteroids, tacrolimus, ciclosporin, or, potentially, lifitegrast.

Dupilumab with concomitant topical corticosteroid treatment in adults with atopic dermatitis with an inadequate response or intolerance to ciclosporin A or when this treatment is medically inadvisable: a placebo-controlled, randomized phase III clinical trial (LIBERTY AD CAFÉ). de Bruin-Weller M, Thaçi D, Smith CH, et al. *Br J Dermatol* 2018; 178: 1083–101.

In this study of 318 adult patients with inadequate response to, intolerance of, or for whom ciclosporin was contraindicated, dupilumab plus topical corticosteroids significantly improved signs and symptoms of AD and quality of life.

Efficacy and safety of dupilumab in adolescents with uncontrolled moderate to severe atopic dermatitis: a phase 3 randomized clinical trial. Simpson EL, Paller AS, Siegfried EC, et al. *JAMA Dermatol* 2019; 156: 44–56.

This study of 240 adolescents aged 13–17 demonstrated that dupilumab significantly improved AD signs, symptoms, and quality of life, with an acceptable safety profile.

Third-Line Therapies

• Dust mite reduction	A
• Phototherapy	B
• Azathioprine	B
• Ciclosporin	B
• Methotrexate	B
• Mycophenolate mofetil	C
• Systemic corticosteroids	B

Prescribing practices for systemic agents in controlling pediatric AD. Totri CR, Eichenfield LF, Logan K, et al. *J Am Acad Dermatol* 2017; 76: 281–5.

The TREAT survey included 133 dermatologists from the Society for Pediatric Dermatology. Of these participants, 86.5% used systemic treatments for severe pediatric AD. Ciclosporin (45.2%), methotrexate (29.6%), and mycophenolate mofetil (30.4%) were the most frequently preferred initial treatments. Factors that discouraged systemic therapy use included side effect profiles and suspected risks of long-term toxicities.

Double-blind controlled trial of effect of housedust-mite allergen avoidance on atopic dermatitis. Tan BB, Weald D, Strickland I, et al. *Lancet* 1996; 347: 15–8.

Measures to reduce house dust mites using a combination of Gore-Tex bedcovers, benzyl tannate spray, and a high-filtration vacuum cleaner were compared with cotton bedcovers, water spray, and a conventional vacuum cleaner in the households of 48 children and adults with AD. Both active and placebo treatments caused significant reductions in house dust mite antigen concentrations. The severity of eczema decreased in both groups, but the active group showed significantly greater improvement.

Probiotic supplementation for the first 6 months of life fails to reduce the risk of atopic dermatitis and increases the risk of allergen sensitization in high-risk children: a randomized controlled trial. Taylor AL, Dunstan JA, Prescott SL. *J Allergy Clin Immunol* 2007; 119: 184–91.

The role of psoralen photochemotherapy (PUVA) in the treatment of severe atopic eczema in adolescents. Atherton DJ, Carabott F, Glover MT, et al. *Br J Dermatol* 1988; 118: 791–5.

Oral PUVA resulted in initial clearance of eczema in 14 of 15 children, 9 of whom achieved complete remission. This was associated with resumption of normal growth in children who were previously growing poorly.

Phototherapy for atopic eczema with narrow-band UVB. Grundmann-Kollmann M, Behrens S, Podda M, et al. *J Am Acad Dermatol* 1999; 40: 995–7.

Five patients with moderate-to-severe AD were treated with narrowband UVB (NB-UVB) for a cumulative dose of 9.2J/cm² over a mean of 19 treatments. NB-UVB was effective after 3 weeks in all patients.

When does atopic dermatitis warrant systemic therapy? Recommendations from an expert panel of the International Eczema Council. Simpson EL, Bruin-Weller M, Flohr C, et al. *J Am Acad Dermatol* 2017; 77: 623–33.

This article provides recommendations in making the decision to start systemic medications for AD based on the assessment of the severity of the disease, quality of life, the patient's general health status, psychological needs, and personal attitudes toward systemic agents.

Azathioprine in severe adult atopic dermatitis: a double-blind, placebo-controlled, crossover trial. Berth-Jones J, Takwale A, Tan E, et al. *Br J Dermatol* 2002; 147: 324–30.

In this double-blind crossover trial, adult patients with severe AD were treated with azathioprine 2.5 mg/kg daily and placebo for 3 months each. There was a significant difference in favor of azathioprine in the improvement of the six area, six sign atopic dermatitis (SASSAD) score, decreasing by 26% during treatment with azathioprine versus 3% on placebo. Pruritus, sleep disturbance, and disruption of work/daytime activity all improved significantly on active treatment, but the difference in mean improvement between azathioprine and placebo was statistically significant only for disruption of work/daytime activity. The authors suggested that a longer period of treatment might have further improved the eczema.

Efficacy and tolerability at 3 and 6 months following use of azathioprine for recalcitrant atopic dermatitis in children and young adults. Hon KL, Ching GK, Leung TF, et al. *J Dermatolog Treat* 2009; 20: 141–5.

The clinical efficacy of azathioprine, and its hematologic and biochemical effects (serum IgE level, liver, and renal function), were assessed at 3 months and 6 months in 17 patients with recalcitrant AD. Disease severity was evaluated with the scoring atopic dermatitis (SCORAD) score. Azathioprine reduced the severity of AD within 3 months in these children. Better efficacy was observed in females at 6 months. Mild transient elevation of glutamic-pyruvic transaminase was noted in one patient and mild elevation of serum bilirubin in two other patients.

Systemic treatment of pediatric atopic dermatitis with azathioprine and mycophenolate mofetil. Waxweiler WT, Agans R, Morrell DS. *Pediatr Dermatol* 2011; 28: 689–94.

Medical records of 28 pediatric patients with AD treated with either azathioprine (AZ) or mycophenolate mofetil (MM) were analyzed for laboratory values, TPMT levels, symptoms, infections, and other relevant data. Seventeen of 28 (61%) patients treated with AZ and 8 of 12 (66%) treated with MM reported

significant improvement. Lower rates of laboratory abnormalities and side effects were seen with MM compared with AZ; however, similar rates of cutaneous infections were noted.

Oral azathioprine for recalcitrant pediatric atopic dermatitis: clinical response and thiopurine monitoring. Caufield M, Tom WL. *J Am Acad Dermatol* 2012; 68: 29–35.

This prospective study of 12 children with severe, recalcitrant AD who were treated with oral azathioprine showed that azathioprine can be of benefit in the treatment of recalcitrant pediatric AD. In addition, repeat assessment of TPMT activity (not thiopurine metabolite levels) may be helpful for evaluation of non-response or change in response to treatment.

Cyclosporine in the treatment of patients with atopic eczema – a systematic review and meta-analysis. Schmitt J, Schmitt N, Meurer M. *J Eur Acad Dermatol Venereol* 2007; 21: 606–19.

The authors conducted a systematic review of the effectiveness of systemic ciclosporin in patients with severe atopic eczema and included 15 studies comprising a total of 602 patients. In all studies analyzed, ciclosporin consistently decreased the severity of atopic eczema. Data from 12 of the 15 studies were pooled and showed a dose-related response with a mean decrease in disease severity of 22% (95% CI: 8%–36%) under low-dose ciclosporin (3 mg/kg) and 40% (95% CI: 29%–51%) at dosages ≥ 4 mg/kg after 2 weeks of treatment. After 6–8 weeks the relative effectiveness was 55% (95% CI: 48%–62%). Effectiveness of ciclosporin was similar in adults and children, but tolerability may be better in children.

Double-blind, controlled, crossover study of cyclosporine in adults with severe refractory atopic dermatitis. Sowden JM, Berth-Jones J, Ross J, et al. *Lancet* 1991; 338: 137–40.

A multicenter, randomized, double-blind, controlled crossover clinical trial was conducted on 33 patients with severe refractory atopic dermatitis to determine the effects of ciclosporin (5 mg/kg/day) on their health-related quality of life. After treatment with ciclosporin, patients indicated significant improvement in quality of life; however, there was either no correlation or only a very poor correlation between the quality-of-life parameters and clinical measures of extent and activity of eczema. Relapse was noted when ciclosporin was stopped; however, the mean scores for disease activity and extent of disease in these patients were less than their baseline values.

Cyclosporine in atopic dermatitis: time to relapse and effect of intermittent therapy. Granlund H, Erkkö P, Sinisalo M, et al. *Br J Dermatol* 1994; 132: 106–12.

Forty-three patients with severe AD were treated with a 6-week course of ciclosporin 5 mg/kg daily and then re-treated after a follow-up of 6–26 weeks (depending on the time to relapse) with an identical course of ciclosporin. A significant reduction in disease activity was observed after 2 weeks of ciclosporin treatment. After both treatment periods, approximately half of the patients relapsed after 2 weeks; after 6 weeks' follow-up the relapse rates were 71% and 90%, respectively, for the two treatment periods. Notably, after the first treatment period, five patients did not relapse during the 26-week follow-up and, for the second treatment period, two did not relapse. All of these seven patients were still in remission at 1 year.

Cyclosporine in atopic dermatitis: review of the literature and outline of a Belgian consensus. Naeyaert JM, Lachapelle JM, Degreef H, et al. *Dermatology* 1999; 198: 145–52.

This excellent review summarizes all the major trials of ciclosporin for AD and gives practical recommendations for the clinician. These authors recommend that ciclosporin is reserved for adults with severe AD and only used in children with recalcitrant disease for short periods. A starting dosage of 2.5 mg/kg daily can be adjusted up after 2 weeks, depending on response, to a maximum dose of 5 mg/kg daily. Screening for gynecologic or prostate malignancy and skin biopsy to exclude cutaneous T-cell lymphoma, as well as close monitoring of renal function and blood pressure, are recommended.

An open-label, dose-ranging study of methotrexate for moderate-to-severe adult atopic eczema. Weatherhead SC, Wahie S, Reynolds NJ, et al. *Br J Dermatol* 2007; 156: 346–51.

This 24-week, open-label safety and efficacy study evaluated 12 adults with moderate-to-severe AD in a dose-ranging, prospective trial of methotrexate.

A randomized trial of methotrexate versus azathioprine for severe atopic eczema. Schram ME, Roekevisch E, Leeflang MM, et al. *J Allergy Clin Immunol* 2011; 128: 353–9.

Forty-two patients were randomly assigned to receive either methotrexate or azathioprine for 12 weeks. Both treatments were found to be safe in the short term and achieved clinically relevant improvement with a 42% reduction in AD severity seen with methotrexate and 39% with azathioprine.

Treatment of atopic eczema with oral mycophenolate mofetil. Neuber K, Schwartz I, Itschert G, et al. *Br J Dermatol* 2000; 143: 385–91.

Ten patients with severe AD were treated with oral MM at an initial dose of 1 g/day during the first week and then 2 g daily for a further 11 weeks. Median scores for disease severity improved by 68% (100% in one patient, >75% in three patients, and >50% in the remainder).

Mycophenolate mofetil for severe childhood atopic dermatitis: experience in 14 patients. Heller M, Shin HT, Orlow SJ, et al. *Br J Dermatol* 2007; 157: 127–32.

Enteric-coated mycophenolate sodium versus cyclosporin A as long-term treatment in adult patients with severe atopic dermatitis: a randomized controlled trial. Haeck IM, Knol MJ, Ten Berge O, et al. *J Am Acad Dermatol* 2011; 64: 1074–84.

An observer-blinded, randomized controlled trial was conducted comparing enteric-coated mycophenolate sodium (EC-MPS) with cyclosporin A (CsA) as long-term treatment in adult patients with severe AD. This study showed that EC-MPS is as effective as CsA as maintenance therapy in patients with AD. However, clinical improvement with EC-MPS was delayed in comparison with CsA. Remission after stopping EC-MPS lasted longer compared with CsA.

Recombinant interferon gamma therapy for atopic dermatitis. Hanifin JM, Schneider LC, Leung DY, et al. *J Am Acad Dermatol* 1993; 28: 189–97.

In this randomized, double-blind study, patients with moderate-to-severe AD received recombinant human IFN- γ (rIFN- γ , 50 mcg/m²) or placebo by daily subcutaneous injection for 12 weeks. Significant reductions in erythema, pruritus, and excoriation occurred in rIFN- γ -treated patients. Edema, papulation, induration, scaling, dryness, and lichenification showed greater improvement in the rIFN- γ group, but differences were not statistically significant.

Do some patients with atopic dermatitis require long term oral steroid therapy? Sonenthal KR, Grammer LC, Patterson R. J Allergy Clin Immunol 1993; 91: 971–3.

Three patients with recalcitrant AD were successfully managed on oral corticosteroids.

Emerging therapies for atopic dermatitis: JAK inhibitors. Cotter DG, Schairer D, Eichenfield L. J Am Acad Dermatol 2018; 78(3 Suppl 1): S53–62.

The Janus kinase inhibitor class may be an effective alternative to conventional AD therapies; however, large safety and efficacy trials are needed.

Emerging treatment options in atopic dermatitis: topical therapies. Nygaard U, Deleuran M, Vestergaard C. Dermatology 2017; 233: 333–43.

Emerging treatment options in atopic dermatitis: systemic therapies. Nygaard U, Vestergaard C, Deleuran M. Dermatology 2017; 233: 344–57.

These review articles describe systemic and topical therapies in the pipeline that focus on targeting the skewed immune response in AD.

Atypical fibroxanthoma

Zoe Begun, Bilal Fawaz, Ashley Decker

Atypical fibroxanthoma (AFX) is an uncommon cutaneous neoplasm arising from mesenchymal or fibrohistiocytic cells. AFX is found predominantly in sun-damaged skin, especially of the head and neck of elderly males, and comprises approximately 0.2% of all skin tumors. Rare cases have also been reported in children with xeroderma pigmentosum. Risk factors include male sex, ultraviolet (UV) exposure, history of radiation therapy, immunosuppression, and trauma. Typically, these lesions appear as rapidly growing, ulcerated, exophytic, dome-shaped nodules, usually <2 cm in diameter. Despite its severe cytologic atypia, it tends to be less aggressive. Care should be taken to distinguish these tumors from pleomorphic dermal sarcoma (PDS) and undifferentiated pleomorphic sarcoma (UPS).

The classification of fibrohistiocytic tumors is ambiguous and controversial. This has been compounded by the evolving nomenclature as understanding of the genetic and molecular basis of these tumors improved. Previously, fibrohistiocytic tumors encompassed the superficial AFX and its deep dermal/subcutaneous version, the malignant fibrous histiocytoma (MFH). However, the term MFH is no longer favored due to the heterogeneity of these tumors, most of which are better aligned under other classifications. In the current nomenclature, AFX is primarily a dermally based tumor that remains a diagnosis of exclusion by use of immunohistochemical stains. If invasion into subcutaneous tissue is observed, it is superficial and focal. The presence of extensive or deep subcutaneous tissue invasion, perineural invasion, lymphovascular invasion, abundant atypical mitoses, or tumor necrosis in a tumor that otherwise resembles an AFX histologically is more appropriately classified as a PDS, which carries a worse prognosis. PDS is a term newly proposed in 2012 by Dr. C.D. Fletcher, and therefore its adoption in the literature is included only in newer publications.

Although AFX and PDS likely represent a disease spectrum, this has not been conclusively proven. PDS is clinically indistinguishable from AFX, although reports suggest these tumors are

typically larger on presentation (>2 cm). It similarly predominantly arises on sun-damaged skin of elderly men, especially on the scalp. Unlike AFX, PDS is associated with a recurrence rate of 29%, and estimates of metastasis are as high as 20%.

UPSs are a diagnosis of exclusion for sarcomas that do not fit into other categories, including AFX and PDS. Due to the controversial nomenclature of sarcomas, UPS is still used by some authors to describe what would now be considered PDS or AFX. Since the adoption of PDS in 2012, however, the World Health Organization recommends limiting the use of the term UPS to sarcomas arising from deeper tissues, often involving the extremities or retroperitoneum.

MANAGEMENT STRATEGY

Proper management relies on an adequate biopsy specimen that includes subcutaneous tissue to help distinguish between AFX and PDS. Because these are typically rapidly growing tumors, first-line management is aimed at complete eradication with surgery. Incomplete removal results in recurrences that usually manifest within a year postoperatively. In instances of incomplete removal of PDS, recurrence can present as satellite lesions that represent in-transit metastases.

Due to the rarity of these tumors, the lack of consensus for an excisional safety margin, and the overlap clinically with PDS, Mohs micrographic surgery (MMS) with complete margin evaluation is preferable over wide local excision (WLE) for primary tumors, especially for tumors with substantial subcutaneous invasion. Recurrent tumors should be treated with MMS.

Although radiation and chemotherapy are often used as adjunctive therapies, local tumor control remains the first-line therapy. Because AFX and PDS are induced by radiation exposure, the utility of radiation therapy is unclear. There is also literature suggesting that radiation-induced sarcomas are less responsive to radiation therapy. Additionally, early reports suggest immunotherapy may have the potential to revolutionize the treatment of recurrent or metastatic AFX/PDS.

Specific Investigation

- Biopsy with adequate subcutaneous tissue

Diagnosis requires an adequate biopsy specimen with appropriate immunohistochemical stains (high-molecular-weight cytokeratins, S100, SMA, MelanA/MART1, EMA, CD34, and CD31) to exclude other spindle cell tumors, particularly squamous cell carcinoma, melanoma, angiosarcoma, and leiomyosarcoma. Biopsy and excision specimens should also be evaluated for the extent of subcutaneous invasion, perineural invasion, lymphovascular invasion, atypical mitoses, and tumor necrosis to distinguish between AFX and PDS.

First-Line Therapy

- Mohs micrographic surgery

C

Atypical fibroxanthoma: systematic review and meta-analysis of treatment with Mohs micrographic surgery or excision. Tolkachjov SN, Kelley BE, Alahdab F, et al. *J Am Acad Dermatol* 2018; 79: 929–34.

This systematic review and meta-analysis included studies published from 1946 to 20 March 2017 with at least five patients treated surgically for AFX. Twenty-three studies were selected,

none of which were randomized controlled trials, two were comparative studies, and 21 were non-comparative studies. The review included 907 patients and 914 tumors with a mean patient age of 74.3 (range 25–99) years. Most tumors were located on the head and neck. The mean length of time to follow-up was 41.6 months.

Mohs micrographic surgery (MMS) was used to treat 175 cases and 732 were treated with WLE. In the MMS treatment group, there were five cases of local recurrence (2.0%, 95% confidence interval [CI] 0–4.1%) and five cases of metastasis (1.9%, 95% CI 0.1–3.8%). Of those treated with WLE, 68 had local recurrence (8.7%, 95% CI 5–12.3%) and 17 had metastases (1.0%, 95% CI 0.2–1.9%). The margins for WLE were inconsistently reported. Eleven patients in the MMS group were immunocompromised, and none of these patients experienced local recurrence or metastasis. Ten patients in the WLE group were immunocompromised; four of them (40%) had local recurrence and one (10%) experienced metastatic disease.

In patients with atypical fibroxanthomas, treatment with MMS is associated with a lower risk of local recurrence compared to those treated with WLE (2.0% vs. 8.7%). Of note, studies that used the terms MFH, UPS, or PDS were excluded from analysis.

Atypical fibroxanthoma: The Washington University Experience. Phelan PS, Rosman IS, Council ML. *Dermatol Surg* 2019; 45: 1450–8.

This is a retrospective cohort analysis of 75 cases of AFX tumors treated at Washington University Medical Center from January 2000 through July 2016. Treatment information was available for 63 of the cases. Median age at diagnosis was 73 years; 56 cases occurred in men, and 19 in women. All subjects with known race were white. Of those with known immune status, 11 (16.2%) were immunosuppressed (secondary to solid organ transplant, hematologic malignancy, or inflammatory bowel disease). Most cases (90.7%) occurred in the head and neck. Forty-two tumors were removed by MMS, 12 by local excision (LE), four by both MMS and LE, two by staged excision, one by multiple LE, one by LE with adjuvant radiation therapy, and one by shave biopsy.

Although preoperative size did not vary significantly between treatment groups, the size of tissue removed was much greater in LE (2.6 cm, 4.5 cm²) compared with MMS (0.6 cm, 1.2 cm²; $p=.002$ [linear], $p=.093$ [area]). Follow-up information was available for 50 cases, including 29 treated by MMS (median follow-up 26 months) and 12 treated by LE (median follow-up 50 months). Of these 50 cases, six experienced recurrence. The observed intention to treat recurrence rates were 3.4% for MMS and 25% for LE (RR 0.14 [95% CI 0.02, 1.2], $p=.068$). After exclusion of the three cases for which the final diagnosis was not AFX, the recurrence rate for true AFX was 8.5%. Recurrence rate did not vary significantly based on immune status.

Although median follow-up time for LE was double that for MMS, bias is unlikely given both groups' median follow-up was over 2 years, which is what previous studies have shown to be the time during which most recurrent cases of AFX will present. Despite a small sample size of recurrent cases, this retrospective cohort analysis suggests improved outcomes with MMS with the benefit of significantly less tissue removal.

More than 2 decades of treating atypical fibroxanthoma at Mayo Clinic: what have we learned from 91 patients? Ang GC, Roenigk RK, Otley CC, et al. *Dermatol Surg* 2009; 35: 765–72.

This is an updated retrospective chart review of 93 AFX tumors treated at the Mayo Clinic from 1980 to 2004. The average age at time of diagnosis was 71.7 years old. The majority of tumors (83.9%) were located on the face and scalp. The average clinical

size was 1.5 cm, with immunosuppressed patients having slightly larger tumors (1.6 vs. 1.3 cm, $p = 0.10$). Treatment information was available for 88 cases. Sixty-six of 88 tumors (67%) were treated with MMS, 23 (26.1%) with WLE, five cases with electrodesiccation and curettage (ED&C), and one with shave excision. The authors report that based on their MMS experience, a 2-cm margin would be needed to clear 96.6% of AFX tumors. Tumors treated with MMS were larger than those treated with WLE (1.5 vs. 1.0 cm, $p = 0.02$). Of the 86 tumors with follow-up data, two recurred and both had been treated with WLE.

The median follow-up time for patients treated with MMS was shorter than those treated with WLE (4.5 years vs. 8.7 years); however, because recurrences typically occur within the first 2 years postoperatively, this retrospective chart review suggests improved outcomes with MMS despite larger preoperative tumor size.

Second-Line Therapies

• Wide local excision	C
• Chemotherapy	B
• Immunotherapy	C
• Radiation therapy	D

Pleomorphic dermal sarcoma: adverse histologic features predict aggressive behavior and allow distinction from atypical fibroxanthoma. Miller K, Goodlad JR, Brenn T. *Am J Surg Pathol* 2012; 36: 1317–26.

This is an excellent retrospective chart review of histologically confirmed PDS cases treated with WLE. Tumors were large, with a median diameter of 2.5 cm and thickness of 1.15 cm. Local recurrence occurred in 28% of patients (three treated with ED&C and three with WLE) and metastasis in 10% of patients. The median time to recurrence was 10 months.

Pembrolizumab in advanced soft-tissue sarcoma and bone sarcoma (SARC028): a multicenter, two-cohort, single-arm, open-label, phase 2 trial. Hussein AT, Burgess M, Bolejack V, et al. *Lancet Oncol* 2017; 18: 1493–501.

This prospective cohort study investigated the response of patients with soft-tissue and bone sarcomas to pembrolizumab (anti-PD-1) immunotherapy. Eligible patients had evidence of metastatic or surgically unresectable, locally advanced disease. Eighty-six patients were enrolled from 12 academic centers between 13 March 2015 and 18 February 2016; 84 received 200 mg of pembrolizumab via 30 min intravenous infusion every 3 weeks until disease progression or unacceptable toxicity.

The primary end point was investigator-assessed objective response. In the cohort of 40 patients with soft tissue sarcoma, 10 cases of undifferentiated pleomorphic sarcomas were included. Four patients (40%) with UPS achieved an objective response, including one patient with UPS achieving a complete response. Median progression-free survival was 30 weeks (95% CI 8–68) for the patients with UPS. Median 12-week progression-free survival for patients with UPS specifically was even higher than the rest of the cohort at 70% (42–98%). Seventy biopsies were analyzed pretreatment for PD-L1 expression, and it was found that PD-L1 was positive in only three (4%) samples, all of which were from patients with UPS. Two out of three of these patients were evaluated for response, one of which achieved complete response and the other a partial response. The most common adverse events in the soft-tissue sarcoma cohort were anemia, lymphopenia, and prolonged activated partial thromboplastin time. There were no fatal treatment-related adverse events.

Although the authors did not detail their definition of UPS, pembrolizumab therapy showed promising results in patients with metastatic or surgically unresectable UPS, with four out of 10 patients achieving an objective response to the therapy.

First report on two cases of pleomorphic dermal sarcoma successfully treated with immune checkpoint inhibitors. Klein S, Persa O, Mauch C, et al. *Oncoimmunology* 2019; 8: 12.

The authors present two patients with locally recurring PDS who were treated with the anti-PD-1 agent pembrolizumab. Patient A is a 77-year-old male who experienced local relapse and cutaneous metastasis of PDS 6 months after his initial excision with 1-cm margins. Both lesions were surgically excised and treated with radiotherapy. Five months later, the patient once again developed relapse of PDS at the initial site as well as multiple cutaneous metastases. The patient started pembrolizumab therapy (2 mg/kg every 3 weeks) and reached complete remission of the disease after eight cycles. Patient B is an 88-year-old male who, 2 years after surgical excision of PDS with 1-cm margins, developed an inoperable local relapse. He reached complete remission of disease 4 months after starting treatment with 200 mg of IV pembrolizumab every 3 weeks, along with adjuvant radiotherapy (2 Gy fractions and a total dose of 70 Gy).

Using next-generation gene sequencing and gene expression analysis, the authors were able to show that both PDS tumors demonstrated a proinflammatory microenvironment, with higher than normal levels of multiple checkpoint molecules, such as CD40LG, CTLA-4, HAVCR2/TIM-3, LAG-3, PDCD1, and TIGIT. The results were comparable to a previously published cohort, suggesting that immunotherapy is a promising therapeutic modality for recurrent or metastatic PDS.

Radiation-associated undifferentiated pleomorphic sarcoma is associated with worse clinical outcomes than sporadic lesions. Dineen SP, Roland CL, Feig R, et al. *Ann Surg Oncol* 2015; 22: 3913–20.

This is a retrospective chart review of 1068 patients with the diagnosis of UPS/MFH treated at a single institution from 1990 to 2012. Patients with sarcomas arising from bone were excluded. Of these cases, 55 (5.1%) were radiation-induced and the rest were sporadic. The median latency period between radiation and the development of radiation-associated sarcoma (RAS) was 9.33 years (range 1–40 years). The median dose of radiation these patients received was 50 ± 5.2 Gy. Twenty-four percent of patients with RAS underwent repeat radiation therapy without reduction in the rate of local recurrence.

Although radiation is often used as an adjunctive therapy to local control, this study suggests that radiation-induced sarcomas are not responsive to this treatment modality.

Randomized phase II study of gemcitabine and docetaxel compared with gemcitabine alone in patients with metastatic soft tissue sarcomas: results of sarcoma alliance for research through collaboration study 002. Maki RG, Wathen K, Patel SR, et al. *J Clin Oncol* 2007; 25: 2755–63.

In this multicenter, open-label, phase II clinical trial of 122 patients with recurrent or progressive soft-tissue sarcoma, patients were randomized to receive either gemcitabine alone or gemcitabine–docetaxel combination therapy. The combination therapy group achieved improved RECIST (Response Evaluation Criteria in Solid Tumors) partial response rate (16% vs. 8%). Within the subgroup of patients with MFH/UPS, four of 11 patients (31.6%) achieved partial response in the gemcitabine–docetaxel treatment arm compared with two of eight (25%) in the gemcitabine-only arm. The median overall survival was also improved in the combination therapy arm (17.9 months vs. 11.5 months).

The standard of care for the majority of soft-tissue sarcomas, including AFX and PDS, is local tumor control with surgery. Therefore, there is no literature for systemic chemotherapy treatment of localized tumors limited to the skin. However, metastatic soft-tissue sarcoma typically has a poor prognosis. In this phase II clinical trial, which included multiple types of metastatic soft-tissue sarcoma, the combination of gemcitabine with docetaxel showed improved outcomes in tumor size and overall survival.

Third-Line Therapies

• Electrochemotherapy	D
• Electrodesiccation and curettage	D

Electrochemotherapy as promising treatment option in rare recurrent cutaneous neoplasm of the scalp: case report of an elderly patient. Crimini E, Roberto M, Effetti VD, et al. *Case Reports in Oncological Medicine* 2019; Article ID 2507642. <https://doi.org/10.1155/2019/2507642>.

The authors report a case of a 78-year-old white male who presented with an AFX on the scalp. After failing WLE with unknown margins, electrochemotherapy utilizing bleomycin with 1-cm margins led to clinical remission. The authors report no disease relapse after 2 years.

Electrochemotherapy (ECT) is a treatment method in which electrical pulses are applied locally to a lesion to increase cell membrane permeability, thus augmenting intracellular chemotherapy levels in the skin and subcutaneous tissue. It has previously been indicated in the treatment melanoma, Kaposi sarcoma, and cutaneous metastases. This case report suggests ECT may be an effective treatment option for recurrent AFX, although larger studies are warranted to confirm its efficacy and safety.

Atypical fibroxanthoma: a case series and review of literature. Mahalingam S, Shah A, Stewart A. *Auris Nasus Larynx* 2015; 42: 469–71.

A case series of seven patients with AFX treated with ED&C (5) and LE (2). At 2 years' follow-up, two of the five patients (40%) treated with ED&C had developed local recurrence. These patients subsequently underwent complete excision without further recurrences.

This case series, along with multiple other case series previously discussed, have all demonstrated a high recurrence rate when the primary tumor is inadequately removed.

Atypical nevi

Ashfaq A. Marghoob, Emmanouil Chousakos

The dysplastic nevus, first described in 1978, continues to fuel much clinical, histopathologic, and molecular research. Despite four decades of study, clinicians and pathologists still debate the validity for the existence of this entity. While today the terms 'atypical nevus' and 'dysplastic nevus' are used interchangeably, dysplastic nevus continues to be the most favored term. Much of the controversy regarding dysplastic nevi (DN) stems from both diagnostic and biologic uncertainty.

DN are benign, acquired, melanocytic neoplasms. Once they are in a state of clinical senescence, they tend to be larger than 5 mm in greatest diameter and some may also display variable degrees of asymmetry, border irregularity, and color variegation. Some DN may be palpable but in all such lesions a macular component remains evident at their periphery. Before the advent of dermoscopy, clinicians often found it difficult to differentiate DN from melanoma and as such it was not uncommon to excise these nevi for fear of missing a melanoma. Fortunately, dermoscopy has greatly improved our ability to recognize DN and differentiate them from melanoma. This has contributed greatly to reducing the number of unnecessary biopsies being performed, noticeably reflected in improvements in clinicians' benign to malignant biopsy ratios.

Although agreement is lacking on what exactly defines an individual nevus as a DN or whether this entity even exists, there is good agreement that persons harboring many nevi including acquired nevi with diameter greater than 5 mm are at heightened risk for developing melanoma. Individuals manifesting this phenotype, known as atypical mole syndrome (AMS), will often display nevi of varying sizes, shapes, and colors, with varying hues of brown.

DN usually become clinically manifest during puberty or early adulthood. While some DN can evolve over time, most remain relatively unchanged. Individuals with AMS can continue to develop new nevi throughout life. It has been observed that the development of acquired nevi on the dorsum of feet, on the non-sun-exposed skin of the buttocks and suprapubic region, and

on the scalp of children is predictive for developing the AMS phenotype.

The risk of melanoma developing in association with DN remains an area of study. Publications to date show that, while melanoma may arise in association with DN, the vast majority of DN never progresses to melanoma. However, many studies have also shown that DN and AMS patients are at higher risk for developing melanoma. This apparent paradox is easily explained by the fact that DN, independent of the total nevus count, are stronger risk markers for developing melanoma than they are precursors to melanoma. In these patients, approximately 70% of melanomas arise *de novo* and only 30% arise in association with a nevus. It is important to underscore that the nevi found in association with melanoma are just as likely to be DN as they are to be non-DN. The annual risk of a single nevus transforming into melanoma has been calculated to be between 0.0005% (1 in 200,000) to 0.003% (1 in 33,000) in individuals <40 or >60, respectively, and the lifetime risk for a nevus to develop an associated melanoma was calculated to be between 0.03% (1 in 3164) to 0.009% (1 in 10,800). The clinical significance of DN and AMS primarily lies in their correlation with melanoma susceptibility. The presence of even one DN increases the risk for melanoma development 10-fold, and the higher the DN count, independent of total nevus count, the higher the risk for developing melanoma. It has been shown that individuals with sporadic AMS have a 10-year cumulative risk of developing melanoma of 10.7% compared with 0.62% risk for individuals without AMS. However, in patients with familial atypical multiple mole-melanoma, the lifetime risk approaches 100%.

MANAGEMENT STRATEGY

Differentiating DN from melanoma is the cornerstone of patient management and requires integrating information from multiple sources. The overarching goal in managing patients with DN and AMS is to find early melanoma while minimizing the unnecessary removal of nevi. The level of evidence-strength of recommendation of the various management options of DN is difficult to ascertain due to a paucity of prospective randomized studies.

Achieving the first objective of finding early melanoma requires patients' and physicians' vigilance for the presence of any new or changing lesions. Patients should be encouraged to perform *self-examination* on a periodic basis and if they notice any new, changing, or symptomatic lesions, to bring it to the attention of their physician. In addition, patients should visit their physician on a regular basis, at least annually.

Patient's profile is vitally important as patients with many nevi including multiple DN or personal or familial history of melanoma are at significantly higher risk for developing melanoma. Personal history of melanoma increases the risk for a subsequent melanoma by 100-fold; history of at least two family members with melanoma increases the risk 200-fold; and, for both personal and family history, the risk increases by 1200-fold.

The skin cancer surveillance examination should involve *examining the entire skin surface with dermoscopic evaluation of nevi and baseline photography*. Individuals with many nevi can get their entire skin surface imaged. These *total body photographs* serve as a baseline to which subsequent examinations of the patient are compared to detect new or changed lesions.

Once a lesion of interest has been identified, it can be examined further with dermoscopy to determine if a biopsy is warranted. Clinically distinguishing DN from melanoma using the clinical ABCD rule (Asymmetry, Border irregularity, Color variegation, Diameter >6mm) is of little use since DN and melanoma share

the same criteria. Dermoscopy of these lesions can help in distinguishing many DN from melanoma. In addition, the comparative approach, which relies on identifying the dermoscopic signature nevus pattern/s in a given individual and then isolating those lesions that deviate from the signature pattern/s (i.e., outlier lesion or ugly duckling lesion), is another means for finding lesions with a higher pre-test probability for being malignant. Baseline dermoscopy images of individual nevi can also be obtained for future comparison (digital dermoscopic monitoring). Over time these nevi can be examined and compared to their baseline dermoscopic images, with the aim of finding subtle changes that may herald the earliest signs of melanoma. Numerous studies have shown that total body photography and digital dermoscopy contribute to improvements in the clinician's diagnostic accuracy, both during in-person clinic visits and during teledermatology consultations.

Besides dermoscopy, other *in vivo* technologies such as *reflectance confocal microscopy* (RCM), optical coherence tomography, and electrical impedance spectroscopy may also help in differentiating nevi from melanoma. The most studied of these is RCM, which provides horizontal section images of the skin at cellular resolution. These quasi-histology RCM images can further enhance the clinician's diagnostic accuracy beyond that achieved with dermoscopy alone.

Specific Investigations

- Detailed history including personal and family history of melanoma and DN/AMS **B**
- History of any new, changing, symptomatic, or concerning lesions **B**
- Complete skin cancer surveillance examination using naked eye and dermoscopy **A**
- Juxtaposition and comparison of lesions to baseline images with total body photography **C**
- Juxtaposition and comparison of lesions to baseline images with digital dermoscopy **B**
- Suspicious lesions can be evaluated further via RCM or subjected to excisional biopsy **C**
- Genetic testing **C**

During the initial patient encounter, the dermatologist will need to evaluate all lesions and decide whether any are suspicious for skin cancer, based on patient history or findings noted on clinical-dermoscopic examination. Outlier lesions, lesions deviating from the normal dermoscopic nevus patterns, and lesions manifesting melanoma specific structures on dermoscopy require particularly close attention. Depending on the degree of concern, lesions can be subjected to further investigations with tools such as RCM or imaged for baseline for the purpose of close monitoring or subjected to excisional biopsy if concern for melanoma remains. For patients with AMS, total body photographs and digital dermoscopy imaging should be obtained and used for comparison during subsequent encounters. *Longitudinal monitoring* of lesions helps identify new and changing lesions with a higher pre-test probability for being melanoma. The monitoring intervals for individual lesions is separated into short-term (3–6-month interval) and long-term (>6-month interval) depending on the degree of concern. For lesions, where the index of suspicion for melanoma is high, a monitoring interval of between 3–6 months is recommended. Any dermoscopic changes noted comparing the baseline dermoscopy image and the follow-up dermoscopy image warrants strong consideration for biopsy. For lesions manifesting a benign clinical and dermoscopy morphology, follow-up

intervals of 6–12 months are recommended. Unlike short-term monitoring where the subtlest of changes warrants a biopsy, during long-term monitoring the changes that prompt a biopsy need to be more substantial.

The current recommendation by experts is that individuals at risk for developing melanoma should be screened at least annually. However, depending on the complexity of the examination, the number of nevi, the number of DN, and the history of melanoma, the examination frequency can be as short as 3 months.

First-Line Therapies

- Short-term (3–6 months) monitoring for single, non-palpable, somewhat concerning lesion/s **C**
- Long-term (>6 months) monitoring for patients with high-risk nevus phenotype with total body photography and digital dermoscopy **C**
- Excision of suspect lesions **C**
- Reexcision of equivocal, severe DN with positive margins **C**
- Patient education, self-examination **C**

Genetic testing should be considered after appropriate genetic counseling of AMS patients who have a strong family history of melanoma. Of all melanoma cases, 5–10% will be found to have one of the known germline mutations associated with familial AMS and melanoma. The most common of these mutations is in *CDKN2A*, with a frequency of 20–40% among those individuals. However, *CDKN2A* mutation carriers are not necessarily associated with an AMS phenotype. Individuals with germline *CDKN2A* mutations are at increased risk for developing mainly melanoma and pancreatic cancer. While there is strong evidence that skin cancer surveillance in these individuals leads to detection of thinner melanomas with improved survival, this cannot yet be said for pancreatic cancer surveillance. Other germline alterations that may be found in a subgroup of AMS patients are the BAP-1 mutations. These individuals are at increased risk for cutaneous melanoma, ocular melanoma, renal cell cancer, and mesothelioma, among other cancers.

The prophylactic excision of DN should be abandoned in favor of targeted excision of only those lesions that cannot be differentiated from melanoma. In such cases it will be necessary to perform a biopsy and the recommended technique, if feasible, is an *excisional biopsy* or deep shave/saucerization removal of the entire lesion with narrow margins. Incisional (partial) biopsy and shallow shave biopsies are discouraged and should only be considered in lesions located in certain anatomic sites such as the nose and eyelids, or in excessively large lesions. If the DN is completely excised with clear margins, no further action is required. However, if the margins of excision are positive, then the question of *re-excision* of DN to ensure clear margins needs to be addressed, and clinical–dermoscopic–pathologic correlation can prove helpful in shaping clinical management decisions. Clearly, the degree of cytologic atypia influences the management decisions, with DN manifesting severe atypia being reexcised much more commonly than DN manifesting lesser degree of atypia. In general, DN that clinically and dermoscopically display features consistent with melanoma or have severe atypia on histopathology should be re-excised. DN that manifest mild-to-moderate atypia can generally be followed up without the need to reexcise all such lesions.

Clinically recognized dysplastic nevi. A central risk factor for cutaneous melanoma. Tucker MA, Halpern A, Holly EA, et al. JAMA 1997; 277(18): 1439–44.

This case-control study of 716 newly diagnosed melanoma patients and 1014 controls found a twofold increased risk for melanoma associated with increased numbers of small nevi, a fourfold elevated risk associated with increased numbers of both small and large non-dysplastic nevi, a twofold increased risk associated with the presence of one clinically DN, and a 12-fold increased risk associated with 10 or more DN.

The genetic evolution of melanoma from precursor lesions. Shain AH, Yeh I, Kovalyshyn I, et al. *N Engl J Med* 2015; 373(20): 1926–36.

This study analyzed 293 cancer-related genes in 37 nevus-associated melanomas and compared the findings found in the melanoma with those found in its associated nevus. They found an accumulation of genetic alterations from banal nevi to an intermediate category of nevi (which presumably includes DN) to melanoma.

Their findings suggest that in nevus-associated melanomas there are successive genetic alterations that occur during melanoma progression from nevus to invasive melanoma.

Pathologists' diagnosis of invasive melanoma and melanocytic proliferations: observer accuracy and reproducibility study. Elmore JG, Barnhill RL, Elder DE, et al. *BMJ* 2017; 357: j2813.

In this study, 187 pathologists were asked to evaluate the same set of 36 or 48 histopathology slides of melanocytic neoplasms on two separate occasions at least 8 months apart. While the interobserver agreement for nevi with no to mild atypia and advanced invasive melanoma was good, the agreement for nevi with moderate-to-severe atypia, melanoma in situ, and early invasive melanoma was poor. The conclusion was that the diagnosis of moderate DN to early melanoma was neither reproducible nor accurate, highlighting the uncertainty present in pathologists' reports.

Total body skin examination for skin cancer screening in patients with focused symptoms. Argenziano G, Zalaudek I, Hofmann-Wellenhof R, et al. *J Am Acad Dermatol* 2012; 66(2): 212–9.

This prospective, cross-sectional, multicenter study included 14,381 patients presenting with a focused dermatology problem. The researchers found that for every 47 patients examined, one skin cancer was found, and for every 400 patients examined, one unsuspected melanoma was found at a location other than where their presenting focused problem was located. Furthermore, by not performing a total body skin examination in patients presenting with a focused dermatology problem, there is a 2.17% risk of missing a malignancy.

This study highlights the value of performing a skin cancer surveillance examination in patients presenting to the dermatology clinic.

Efficacy of skin self-examination for the early detection of melanoma. Hamidi R, Peng D, Cockburn M. *Int J Dermatol* 2010; 49(2): 126–34.

The results of this study were based on interviews conducted with melanoma patients. The study found that self-examination of at least some part of their skin was associated with finding thinner melanomas. The thoroughness of the self-skin examination was the best predictor of melanoma thickness (adjusted ratio, 0.58; 95% CI, 0.36–0.75) and highlights the importance of this practice in patients with DN/AMS.

Dermoscopy compared with naked eye examination for the diagnosis of primary melanoma: a meta-analysis of studies

performed in a clinical setting. Vestergaard ME, Macaskill P, Holt PE, et al. *Br J Dermatol* 2008; 159(3): 669–76.

This meta-analysis of nine eligible studies comparing the diagnostic accuracy of dermoscopic versus naked eye examination for melanoma detection found that dermoscopy had a superior sensitivity and specificity. Exclusion of two outlier studies resulted in sensitivity estimation of 0.69 and 0.87 for naked eye examination and dermoscopy, respectively, and specificity of 0.88 and 0.91, respectively.

Melanoma thickness: the role of patients' characteristics, risk indicators and patterns of diagnosis. Haenssle HA, Hoffmann S, Holzkamp R, et al. *J Eur Acad Dermatol Venereol* 2015; 29(1): 102–108.

The objective of this study was to identify factors that impacted thickness of melanomas in 347 melanoma patients. The screening of patients in specialized surveillance clinics resulted in thinner melanomas. On multivariate analysis the use of dermoscopy was independently associated with significantly thinner melanomas.

Benefits of total body photography and digital dermatoscopy ('two-step method of digital follow-up') in the early diagnosis of melanoma in patients at high risk for melanoma. Salerni G, Carrera C, Lovatto L, et al. *J Am Acad Dermatol* 2012; 67(1): e17–27.

This study investigated the impact of total body photography and digital dermoscopy in the monitoring of 618 high risk patients with a total of 11,396 lesions. During a median of 96 months of follow-up, only 1.86 lesions were excised per patient due to the development of concerning changes. Of the excised lesions, 8.5% proved to be melanoma. Approximately 53% of the melanomas were in situ and the remainder were invasive with a median thickness of 0.5 mm.

Both short-term and long-term dermoscopy monitoring is useful in detecting melanoma in patients with multiple atypical nevi. Moscarella E, Tion I, Zalaudek I, et al. *J Eur Acad Dermatol Venereol* 2017; 31(2): 247–51.

This study investigates the impact of short-term follow-up (evaluation of a single atypical lesion over a period of between 3 and 6 months in order to identify subtle morphological changes) versus long-term follow-up in patients with AMS. A total of 3823 lesions from 541 patients were monitored and 197 lesions were excised during follow-up with 60 of these lesions proving to be melanoma. It was determined that both short-term and long-term monitoring helped in melanoma detection, with 23 melanomas found on short-term monitoring and 37 found on long-term monitoring. There was no difference in the thickness of melanomas found via short- (mean thickness 0.42 mm) versus long-term (mean thickness 0.47 mm) monitoring. The number needed to excise during short-term monitoring was calculated to be 1.96, and for long-term monitoring it was determined to be 3.4.

This study highlights the synergy between short- and long-term monitoring.

Meta-analysis of digital dermoscopy follow-up of melanocytic skin lesions: a study on behalf of the International Dermoscopy Society. Salerni G, Terán T, Puig S, et al. *J Eur Acad Dermatol Venereol* 2013; 27(7): 805–14.

This meta-analysis evaluated 14 eligible studies with a total of 5787 patients with 52,739 lesions followed for a mean of 30 months. During follow-up, 4388 lesions were excised (<1 lesion per patient). The number needed to monitor to find a melanoma ranged from 31 to 1008 and, with every additional month

of monitoring, one additional melanoma was detected. The use of digital dermoscopy follow-up increased the proportion of in situ melanomas and thin melanomas found compared to the expected number in the general population. The authors also show that the chances to detect a melanoma during monitoring increased as the length of follow-up increased.

Systematic review of diagnostic accuracy of reflectance confocal microscopy for melanoma diagnosis in patients with clinically equivocal skin lesions. Stevenson AD, Mickan S, Mallett S, Ayya M. *Dermatol Pract Concept* 2013; 3(4): 19–27.

Based on five eligible studies with a total of 909 equivocal lesions, this study calculated the sensitivity and specificity for melanoma detection via RCM to be 93% and 76%, respectively.

The impact of partial biopsy on histopathologic diagnosis of cutaneous melanoma: experience of an Australian tertiary referral service. Ng JC, Swain S, Dowling JP, et al. *Arch Dermatol* 2010; 146(3): 234–9.

This study investigated the correlation between biopsy type and histopathologic misdiagnosis of melanoma. The authors found that misdiagnosis was least common when the lesion was completely excised (excisional biopsy). Misdiagnosis was more common in lesions sampled via punch biopsy (OR, 16.6 compared with excision) than sampled via shave biopsy (OR, 2.6 compared with excision).

A broad and deep shave biopsy likely provides the pathologist with more tissue, which is essential in rendering an accurate diagnosis, in

comparison to the amount of tissue obtained from a small punch biopsy. While an excisional biopsy remains the preferred means to sample a suspect melanocytic neoplasm, a broad shave biopsy remains an acceptable alternative if an excisional biopsy is not feasible.

Surgical re-excision vs. observation for histologically dysplastic naevi: a systematic review of associated clinical outcomes. Vuong KT, Walker J, Powell HB, et al. *Br J Dermatol* 2018; 179(3): 590–8.

A systematic review, including 12 eligible studies, investigating the outcomes of monitoring versus reexcision of biopsy-proven DN. The rates of biopsy-site primary melanoma were low for both the reexcision group (0.44%) and for the observation group (0.39%) among 2673 biopsied DN.

Addressing the knowledge gap in clinical recommendations for management and complete excision of clinically atypical nevi/dysplastic nevi: Pigmented Lesion Subcommittee consensus statement. Kim CC, Swetter SM, Curiel-Lewandrowski C, et al. *JAMA Dermatol* 2015; 151(2): 212–8.

Management consensus recommendations of the Melanoma Prevention Working Group concerning, among other issues, incompletely excised DN (DN with positive margins). The consensus opinion was that excised DN (no evidence of clinical residual pigment) revealing mild-to-moderate atypia with histopathologic positive margins can be safely observed rather than reexcised.

Autoimmune progesterone dermatitis

Adam R.A. Daunton, Ian H. Coulson

Autoimmune progesterone dermatitis (APD) is an uncommon, cyclical, pruritic dermatosis affecting women of childbearing age. The diagnosis is suggested by premenstrual flares and improvement during pregnancy. It can present in a variety of morphologies, including eczematous, vesicular, and papulovesicular, with urticarial and erythema multiforme-like lesions the commonest. Angioedema or anaphylaxis may accompany the skin eruptions. Hypersensitivity after exposure to exogenous progesterone, usually in the form of an oral contraceptive pill, has been implicated in some cases of APD. Endogenous progesterone may also serve as a trigger for APD in cases arising during menarche or pregnancy. The diagnosis is one of exclusion and is based upon the occurrence of cyclical premenstrual flares, the response to inhibition of ovulation, and the results of intradermal testing and hormone challenge.

MANAGEMENT STRATEGY

The mainstay of treatment is to *inhibit endogenous progesterone secretion* by suppressing ovulation. Classically, *conjugated estrogens* 0.625–1.25 mg daily in a 21-day cycle was a mainstay of therapy, but recently this treatment has been supplanted by gonadotropin-releasing hormone (GnRH) agonists. A transient worsening of the skin eruption is expected after initial treatment with GnRH agonists, with improvement thereafter. A major side effect of GnRH agonists is loss of bone density, which generally limits their use to 6 months of therapy. However, concomitant administration of osteoprotective agents may partly mitigate this risk and may allow longer treatment in carefully selected cases. Patients frequently require estrogen replacement while on GnRH agonist therapy.

The *antiestrogen tamoxifen*, 20 mg daily or 10 mg twice a day, exerts its effect by interfering with clinical estrogen sensitivity, possibly by competitive binding of the estrogen receptors.

Oral contraceptive pills have been implicated in triggering some cases of APD. However, in patients naive to exogenous

progesterone, inducing anovulation with oral contraceptive pills may be successful.

Mild cases of APD may be controlled with *short courses of systemic corticosteroids* before the luteal phase of the menstrual cycle. Very limited disease may respond to potent *topical corticosteroids* and *oral antihistamines*.

Danazol 200 mg twice daily for 1–2 days before menses and continued for 3 days thereafter may prevent the skin eruptions by inhibiting pituitary gonadotropins.

For severe, intractable cases, bilateral oophorectomy is curative.

Autoimmune estrogen dermatitis is a separate entity that can be difficult to distinguish clinically from APD. Intradermal testing that is positive to estrone and negative to progesterone clarifies the diagnosis. Autoimmune estrogen dermatitis responds to tamoxifen, progesterone, and oophorectomy.

The only alternative approach to the inhibition of endogenous progesterone production by suppressing ovulation is progesterone desensitization. This represents the only treatment option that preserves a patient's fertility, and it may be especially useful for patients undergoing in vitro fertilization (IVF) treatment, who are required to take high doses of exogenous progesterone.

There is wide variation between desensitization protocols. There is also a theoretical concern that desensitization treatment could aggravate latent autoimmunity in genetically predisposed women.

Specific Investigations

- Intradermal testing with progesterone
- Progesterone challenge (oral or intravaginal)
- Enzyme-linked immunosorbent assay (ELISA) and ELISpot testing

Different authors have advocated intradermal testing with progesterone in varying amounts and dilutions. One common method of intradermal testing is with 0.1 mL of aqueous progesterone suspension at 100 mg/mL diluted with normal saline to 0.1 mg/mL, 0.01 mg/mL, and 0.001 mg/mL, with normal saline serving as the control. There may be an immediate urticarial reaction within 30 minutes, or a delayed-type hypersensitivity reaction at 24–48 hours.

Progesterone challenge may also be attempted intramuscularly (medroxyprogesterone 10–20 mg) or orally (10 mg) in the first half of the menstrual cycle. Intramuscular skin testing with the depot form of medroxyprogesterone acetate is not advised because of the risk of severe systemic reactions.

ELISA and ELISpot testing can detect elevated levels of IFN- γ -producing peripheral blood mononuclear cells in response to progesterone.

If progesterone testing is negative, consider estrogen sensitivity. Intradermal testing with either estrone (0.1 mL at 1 mg/mL) or conjugated estrogen (0.1 mL of 1, 10, and 100 mcg/mL) can be attempted. A positive reaction may be immediate or delayed for several hours and should persist for more than 24 hours.

The use of a progesterone pessary has recently been proposed as an effective tool in the diagnosis of APD.

Autoimmune progesterone dermatitis: update and insights.

Nguyen T, Ahmed R. Autoimmun Rev 2016; 15: 191–7.

A systematic review of the 89 cases published in English, examining diagnostic tests and treatment methods.

Sixty four of 67 patients who underwent an intradermal progesterone challenge experienced a positive response within 24 hours. All six patients who underwent an intramuscular challenge

experienced a positive response. One patient was diagnosed after an intravaginal challenge. The remaining patients did not undergo a progesterone challenge.

Complete remission was attained in 4/86 (5%) patients without any intervention. Of the 86 patients, 14 (16%) eventually underwent bilateral oophorectomy after failure of other treatment modalities, and all subsequently attained complete remission. Of seven patients who underwent desensitization therapy, 4/7 (57%) attained complete remission, and 1/47 (14%) attained partial control; 4/12 (33%) attained complete remission on GnRH analogs, whereas 3/12 attained partial remission. All five of the patients treated with tamoxifen attained a partial remission. One of 19 patients treated with conjugated estrogen/ethinyl estradiol attained complete remission, and 8/19 attained partial remission. Seven of nine patients treated with the combined oral contraceptive pill attained partial remission.

The role of intradermal skin testing and patch testing in the diagnosis of autoimmune progesterone dermatitis. Stranahan D, Rausch D, Deng A, et al. *Dermatitis* 2006; 17: 39–42.

A case report and a detailed review of the various methods of performing intradermal progesterone testing, highlighting the need for standardization.

Progesterone sensitive interferon- γ -producing cells detected by ELISpot assay in autoimmune progesterone dermatitis. Cristaudo A, Bordignon V, Palamara F, et al. *Clin Exp Dermatol* 2007; 32: 439–41.

Describes the ELISpot technique of diagnosing APD.

Estrogen dermatitis. Kumar A, Georgouras KE. *Australas J Dermatol* 1999; 40: 96–8.

A case report comparing progesterone dermatitis and estrogen dermatitis, as well as useful information on the technique and interpretation of intradermal testing for both disorders.

Iatrogenic autoimmune progesterone dermatitis caused by 17 α -hydroxyprogesterone caproate for preterm labor prevention. Bandino JP, Thoppil J, Kennedy JS, et al. *Cutis* 2011; 88: 241–3.

A 30-year-old woman, gravida 2, para 1, developed APD 4 days after her third injection of 17- α -hydroxyprogesterone caproate (17P), presenting as an urticarial exanthema. Direct immunofluorescence was negative. The injections were discontinued and lesions resolved within 7 days.

The use of progestational agents, most recently 17P, to reduce preterm labor for patients at risk may result in more cases of APD being recognized.

First-Line Therapies

• Gonadotropin-releasing hormone agonists	A
• Tamoxifen	D
• Oral contraceptive pill	E
• Oral corticosteroids	E
• Potent topical corticosteroids	E
• Antihistamines	E

Recurrent anaphylaxis in menstruating women. Treatment with a luteinizing hormone-releasing hormone agonist – a preliminary report. Slater JE, Raphael G, Cutler GB, et al. *Obstet Gynecol* 1987; 70: 542–6.

A double-blind, placebo-controlled crossover study of four women with cyclic anaphylaxis associated with progesterone secretion. Two of the subjects experienced dramatic reduction in the severity and number of attacks while receiving an investigational luteinizing hormone-releasing agonist imbzl-D-his⁶-pro⁹-NEt-LHRH, 4 mcg/kg/day for 4 months. Liaison with a gynecologic endocrinologist may help in the selection of an appropriate GnRH agonist and estrogen combination of therapies.

Autoimmune progesterone dermatitis: a diagnosis easily missed. Toms-Whittle L, John L, Griffiths D, et al. *Clin Exp Dermatol* 2010; 36: 378–80.

Successful treatment with intranasal buserelin 150 mcg thrice daily. Symptoms recurred after cessation of buserelin after the maximum licensed period of 6 months, and consideration is being given to continuing it off-license with osteoprophylaxis.

Autoimmune progesterone dermatitis. Cocuroccia B, Gisondi P, Gubinelli E, et al. *Gynecol Endocrinol* 2006; 22: 54–6.

Treatment with tamoxifen 20 mg daily produced complete and durable clearing of the eruption after 3 months.

A case of autoimmune progesterone dermatitis in an adolescent female. Kakarla N, Zurawin RK. *J Pediatr Adolesc Gynecol* 2006; 19: 125–9.

A case report describing a patient with no prior exogenous hormone exposure who cleared on oral contraceptive therapy. For patients naive to exogenous progesterone, an oral contraceptive pill, is considered to be first-line therapy (the preparation used contained 30 mcg of ethinyl estradiol and 0.15 mg of levonorgestrel).

Autoimmune progesterone dermatitis. Anderson RH. *Cutis* 1984; 33: 490–1.

A case successfully treated with prednisolone 20 mg/day for 10 days during menstruation. The dosage of prednisolone was reduced slowly over several cycles, and the patient was eventually managed on topical corticosteroids only.

Autoimmune progesterone dermatitis associated with infertility treatment. Jenkins J, Geng A, Robinson-Bostom L. *J Am Acad Dermatol* 2008; 58: 353–5.

Oral contraceptives and GnRH agonists were contraindicated in this patient undergoing treatment for infertility. The limited disease was well controlled with halobetasol propionate 0.05% cream.

Autoimmune progesterone dermatitis. Case report with histologic overlap of erythema multiforme and urticaria. Walling HW, Scupham RK. *Int Soc Dermatol* 2008; 47: 380–2.

Durable improvement on cetirizine 10 mg every morning and hydroxyzine 10 mg at bedtime taken on the days of the menstrual cycle previously associated with skin eruptions.

Second-Line Therapies

• Conjugated estrogens	E
• Danazol	E
• Azathioprine	E
• Progesterone desensitization	D
• Omalizumab	E

Autoimmune progesterone anaphylaxis. Bermanian MH, Gharagozlu M, Farashahi MH, et al. *Iran J Allergy Asthma Immunol* 2007; 6: 97–9.

A case report of a patient with perimenstrual urticaria associated with angioedema and respiratory symptoms, all of which improved on conjugated estrogen 0.625 mg once daily.

Autoimmune progesterone dermatitis: effective prophylactic treatment with danazol. Shahar E, Bergman R, Pollack S. *Int J Dermatol* 1997; 36: 708–11.

Successful prophylactic treatment with danazol in two patients at a dose of 200 mg twice daily, starting 1–2 days before menstruation and continuing for 3 days thereafter.

Case 2. Diagnosis: erythema multiforme as a presentation of autoimmune progesterone dermatitis. Warin AP. *Clin Exp Dermatol* 2001; 26: 107–8.

Successful treatment with azathioprine 100 mg daily.

Autoimmune progesterone dermatitis: clinical presentation and management with progesterone desensitization for successful in vitro fertilization. Prieto-Garcia A, Sloane DE, Gargiulo AR, et al. *Fertil Steril* 2011; 95: 1121. e9–13.

Six patients with documented APD were desensitized by a rapid 8- or 10-step protocol, receiving escalating intravaginal progesterone suppositories. The initial dose of intravaginal progesterone was either 0.05 mg or 0.1 mg. The same dose was repeated for a total of 2–3 doses, before being increased by a factor of 10. This pattern was completed for a total of 8–10 doses. Intravaginal suppositories were administered every 20 minutes. One of the patients received an oral protocol. Four patients achieved desensitization. Three patients received successful IVF subsequently.

Iatrogenic autoimmune progesterone dermatitis treated with a novel intramuscular progesterone desensitization protocol. Hill JL, Carr TE. *J Allergy Clin Immunol Pract* 2013; 1: 537–8.

A single case of a patient desensitized with an intramuscular progesterone protocol.

Autoimmune progesterone dermatitis. Soloman M, Itsekson A, Lev-Sagie A. *Curr Derm Rep* 2013; 2: 258–63.

Authors' description of their own protocol for both diagnosis and desensitization. For desensitization, they suggest monthly intradermal progesterone injections, commencing with 0.04 mL of 50 mg/mL progesterone, doubled each month for a total of 3 months.

Progesterone hypersensitivity in 24 cases: diagnosis, management, and proposed renaming and classification. Foer D, Buchheit K, Gargiulo A, et al. *J Allergy Clin Immunol Pract* 2016; 4: 723–9.

Nine patients with symptomatic APD underwent oral desensitization therapy aimed at symptom control, while three underwent rapid intramuscular (IM) desensitization aimed at permitting IVF therapy. Of those who underwent oral desensitization, 8/9 attained symptomatic improvement, while 3/3 who underwent IM desensitization tolerated IVF, and 2/3 attained pregnancy.

Anaphylaxis due to progesterone hypersensitivity successfully treated with omalizumab. Heffler E, Fichera S, Nicolosi G, et al. *J Allergy Clin Immunol Pract* 2017; 5: 852–4.

An adolescent female treated with omalizumab 300 mg s/c monthly experienced complete resolution of her symptoms. Omalizumab was stopped after 6 months, and no recurrence of symptoms at time of last follow-up 5 months after last injection. Progesterone prick and intracutaneous tests were negative immediately following her final injection (positive pretreatment).

Third-Line Therapy

- Bilateral oophorectomy

E

Autoimmune progesterone dermatitis: treatment with oophorectomy. Medeiros S, Rodrigues-Alves R, Costa M, et al. *Clin Exp Dermatol* 2010; 35: e12–3.

Bilateral oophorectomy was curative in this case of APD that was unresponsive to oral corticosteroids and GnRH agonist.

21

Bacillary angiomatosis

Floriane Kouby, Olivier Chosidow

First described in 1983, bacillary angiomatosis (BA) is a vasculoproliferative disorder caused by the *intraerythrocytic* bacteria *Bartonella henselae* and *Bartonella quintana* (previously *Rochalimaea* spp.). It typically presents in profoundly immunocompromised patients (e.g., advanced HIV infection, posttransplant, or during cytotoxic chemotherapy), although the incidence in patients receiving newer biologic therapies is unknown. Cutaneous lesions can be superficial, cherry-red, round papules with an eroded surface, similar to pyogenic granulomas; violaceous, lichenoid plaques; or deep subcutaneous nodules. Single lesions have been reported in immunocompetent patients at inoculation sites, whereas in the immunocompromised the entire body surface may be affected. Lesions can be mistaken for Kaposi sarcoma or in-transit metastatic amelanotic melanoma because of the highly vascular and erosive nature of the lesions. In advanced HIV, deep fungal infection (e.g., cryptococcosis and histoplasmosis) should also be considered. Patients with extracutaneous disease may or may not have skin signs and can present with vomiting, abdominal pain, and deranged liver function (peliosis hepatis) or pancytopenia and splenomegaly (peliosis splenis). Fever, lymphadenopathy, night sweats, endocarditis, blindness, and anemia can also be present.

B. henselae is transmitted through a cat scratch or bite and can also result in a localized skin papule and regional lymphadenitis known as *cat scratch disease*. *B. quintana* is transmitted by the human body louse and also causes trench fever (fever, headache, dizziness, and shin pain). (*B. quintana* has also been found on head lice in poor-resource children.) A few cases of BA were described in immunocompetent individuals. More frequently, localized cutaneous lesions virtually identical to BA and typically in immunocompetent individuals are seen in *verruca peruana*, which occurs in Peru, Ecuador, and Colombia due to *B. bacilliformis*, which is transmitted by sandflies. Preceding acute infection known as *Oroya fever/Carrion disease* results in massive hemolytic anemia with >85% mortality if untreated.

MANAGEMENT STRATEGY

Prompt diagnosis is essential to prevent dissemination, which can be fatal. Clinical suspicion should be aroused in the context of a low CD4 lymphocyte count (<100) or other immunosuppression, especially with a history of exposure to cats (>35% harbor *B. henselae*) or body lice (*B. quintana*). Treatment is determined by species, clinical course, and immunologic status.

The response of BA to antibiotic treatment is usually dramatic, in contrast to cat scratch disease. Due to antiinflammatory and antiangiogenic effects, *erythromycin* is the first-line therapy at a dose of 500 mg four times daily, but *doxycycline* 100 mg twice daily is also consistently successful. In patients who are not able to tolerate erythromycin or doxycycline, *azithromycin* or *clarithromycin* may be used. In severe or complicated disease either of these drugs combined with rifampicin 300 mg twice daily has been advocated and intravenous treatment may be required. Treatment should be continued for 3 months where there is only skin disease and 4 months where there is bone/visceral involvement. Should relapse occur on these regimens, long-term prophylaxis with erythromycin or doxycycline may be indicated. However, in practice highly active antiretroviral therapy should reverse the immunocompromised state, making long-term antibiotic therapy less necessary. The patient should be evaluated for parenchymal and osseous disease before treatment and warned that a Jarisch–Herxheimer reaction may occur after the first few doses of antibiotic.

In the case of *verruca peruana* oral rifampicin at a dose of 10 mg/kg/day for 2–3 weeks achieved a cure in over 93% of patients. *Streptomycin* (15–20 mg/kg/day for 2–3 weeks) has a reported cure rate of 56% and is therefore considered second line.

In the absence of randomized clinical trials, treatment is guided by anecdotal experience, retrospective cohort studies/case series, and microbiologic susceptibility data. A wide variety of therapeutic agents are mentioned in the literature, but there is a lack of correlation between the *in vitro* and *in vivo* drug susceptibility of *Bartonella* spp., which reduces the usefulness of laboratory data. The picture is clouded further by the different response of *Bartonella* spp. to drugs in each of the diseases it causes.

Specific Investigations

- Full blood count, liver function tests, HIV serology, and CD4 lymphocyte count
- Biopsy, hematoxylin and eosin stain, and Warthin–Starry stains/electron microscopy
- Prolonged culture of blood and biopsy tissue
- Polymerase chain reaction (PCR) of biopsy material
- Serology – indirect fluorescence assay

Multiple investigations are frequently required to confirm infection. Culture of the fastidious Gram-negative rods of *Bartonella* spp. is extremely difficult, requiring special media and prolonged incubation of up to 45 days; it is invariably negative if antibiotics have been given. Skin biopsy is the essential diagnostic tool and shows a characteristic lobular proliferation of capillaries and venules with swollen endothelial cells containing clumps of bacteria. Hematoxylin and eosin stain demonstrate endothelial-lined peliosis spaces. *Bartonella* spp. can also be visualized using the Warthin–Starry silver stains or electron microscopy and PCR can confirm the species. Reliance on serology in the immunosuppressed is hazardous, but the Centers for Disease Control (CDC) definition of a positive test is an indirect fluorescence assay titer >1:64.

Exams to exclude peliosis of the liver and spleen should be conducted: liver enzyme assay, complete blood count, eventually radiologic evaluation, and liver biopsy. Further evaluation can be done based on the associated symptoms and physical exam (e.g., bone radiography, echocardiography, lumbar puncture).

Bacillary angiomatosis and bacillary peliosis in patients infected with human immunodeficiency virus: clinical characteristics in a case-control study. Mohle-Boetani JC, Koehler JE, Berger TG, et al. Clin Infect Dis 1996; 22: 794–800.

Forty-two cases were compared with 84 matched controls and the distinguishing clinical characteristics were evaluated. Significant differences included the presence of anemia (hematocrit <0.36), raised alkaline phosphatase and aspartate aminotransferase levels, and a low CD4 lymphocyte count (median being 21/mm³ compared with 186/mm³ in controls). Clinical signs included fever, abdominal pain, and lymphadenopathy.

Cutaneous manifestations of bartonellosis. Lins KA, Drummond MR, Velho PENE. An Bras Dermatol 2019; 94(5): 594–602.

There are three main histological features: (1) angioproliferation in lobules, with vessels formed by prominent endothelial cells, with atypia and mitoses being seen in areas with dense cellularity; (2) predominance of neutrophils in the inflammatory infiltrate and occasional leukocytoclasia; and (3) presence of interstitial or intracellular bacterial clumps found with Warthin–Starry staining, immunohistochemistry, transmission electron microscopy, or confocal microscopy.

Laboratory diagnosis of Bartonella infections. Agan BK, Dolan MJ. Clin Lab Med 2002; 22: 937–62.

Culture methods have improved but are still prolonged. Serologic testing for *B. henselae* has become the cornerstone for diagnosis in the immunocompetent patient. Ideal antigens for enzyme immunoassays have yet to be clearly identified. PCR currently offers the ability to establish the diagnosis when other tests fail.

Development of a specific and sensitive enzyme-linked immunosorbent assay as an in vitro diagnostic tool for detection of Bartonella henselae antibodies in human serum. Jost M, Latz A, Ballhorn W, et al. J Clin Microbiol 2018; 56(12): e01329–18.

The authors report the development of an enzyme-linked immunosorbent assay (ELISA) that can detect human anti-*B. henselae* antibodies from serum samples. By use of well-characterized human sera from the strictly quality-controlled serum library of the German National Consiliary Laboratory for *Bartonella* infections, the sensitivity of this ELISA was 100% for PCR-proven infections and 76% for clinically suspected infections at a specificity of 93%.

Development of a real-time PCR for Bartonella spp. detection, a current emerging microorganism. Parra E, Segura E, Tijero J, et al. Mol Cell Probes 2017; 32: 55–9.

The single-step assay described provided a simple and rapid means of identifying *Bartonella* spp.

Utility of molecular identification and quantitation of Bartonella species with species-specific real-time PCR for monitoring treatment response: a case series. Mazzitelli M, Lamberti AG, Quirino A, et al. Open Microbiol J 2018; 12: 148–53.

This case series indicated the utility of molecular identification and quantification of *Bartonellae* spp. infections with species-specific RT PCR both for **diagnosis and monitoring** of treatment response. Indeed, RT PCR was consistent with the clinical course of patients, permitting to stop therapy after *Bartonella* DNA was found to be persistently negative.

First-Line Therapies

• Erythromycin	C
• Doxycycline	C
• Rifampicin	D

Bacillary angiomatosis. Akram SM, Rawla P. StatPearls. Treasure Island (FL): StatPearls; 2020.

The drug of choice in this article is erythromycin or doxycycline. Mild cutaneous BA can be treated for 12 weeks. The response is seen by 3–4 weeks. If the response is not satisfactory, the duration of therapy can be extended. In patients who are immunosuppressed or in HIV patients, therapy should be continued until the CD4 T-helper cell count normalizes.

Cryotherapy, electrodesiccation with curettage, and surgical excision of solitary cutaneous lesions can be useful as adjunctive therapy after treatment with antibiotics to prevent occult bacteremia during the procedure.

Pathogenicity and treatment of Bartonella infections. Angelakis E, Raoult D. Int J Antimicrob Agents 2014; 44: 16–25.

An excellent review of existing data and treatment recommendations for all *Bartonella* infections based on pathogenicity. A table clearly summarizes the various organisms, disease manifestations, and current treatment regimens (including doses and durations).

Treatment outcomes of human bartonellosis: a systematic review and meta-analysis. Prutsky G, Domecq JP, Mori L, et al. Int J Infect Dis 2013; 17: e811–9.

This systematic review of treatment regimens for *B. henselae*, *B. quintana*, and *B. bacilliformis* identified only two randomized controlled trials analyzing the treatment of cat scratch disease and chronic bacteremia along with seven observational studies. With respect to BA they concluded that erythromycin might be better than other antibiotics, but there was no statistically significant difference compared with doxycycline.

Guidelines for prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. Kaplan JE, Benson C, Holmes KK, et al. Centers for Disease Control and Prevention (CDC); National Institutes of Health; HIV Medicine Association of the Infectious Diseases Society of America. MMWR Recomm Rep 2009; 58(RR-4): 1–207.

These guidelines recommend a combination therapy with the addition of rifampin to either erythromycin or doxycycline for immunocompromised patients with acute, life-threatening *Bartonella* infections.

AIDS commentary: bacillary angiomatosis and bacillary peliosis in patients infected with human immunodeficiency virus. Koehler JE, Tappero JW. Clin Infect Dis 1993; 17: 612–4.

This review article refers to 50 patients whose lesions and symptoms responded to erythromycin, 500 mg four times daily, or doxycycline, 100 mg twice daily.

Molecular epidemiology of *Bartonella* infections in patients with bacillary angiomatosis-peliosis. Koehler JE, Sanchez MA, Garrido CS, et al. *N Engl J Med* 1997; 337: 1876–83.

A case-control study of 49 patients (92% HIV positive) in whom macrolides, doxycycline, tetracycline, and rifampin were found to be effective. This was in contrast to patients treated with trimethoprim-sulfamethoxazole, ciprofloxacin, penicillins, and cephalosporins in whom *Bartonella* spp. could be isolated on PCR or culture.

Bacillary angiomatosis: presentation of six patients, some with unusual features. Schwartz RA, Nychay SG, Janniger CK, et al. *Br J Dermatol* 1997; 136: 60–5.

This article describes a variety of successful treatment regimens, including tetracycline 2 g daily and ciprofloxacin 750 mg twice daily.

Second-Line Therapies	
• Azithromycin	C
• Clarithromycin	C
• Streptomycin	D

MICs of 28 antibiotic compounds for 14 *Bartonella* (formerly *Rochalimaea*) isolates. Maurin M, Gasquet S, Ducco C, et al. *Antimicrob Agents Chemother* 1995; 39: 2387–91.

The newer macrolides were highly effective in preventing bacterial growth with minimal inhibitory concentration (MIC) 90s, defined as the minimum concentration at which 90% of the isolates are inhibited, of 0.03 mcg/mL for azithromycin and

clarithromycin. Erythromycin, doxycycline, and rifampin all had MIC 90s of 0.25 mcg/mL.

Recommendations for the treatment of human infections caused by *Bartonella* species. Rolain JM, Brouqui P, Koehler JE, et al. *Antimicrob Agents Chemother* 2004; 48: 1921–33.

A good review article. Although erythromycin and clarithromycin are the authors' first-line treatments for BA, their use has been based on case series and case reports rather than on controlled clinical trials.

Third-Line Therapies	
• Gentamicin	E
• Third- and fourth-generation cephalosporins	E

Identification of FDA-approved drugs with activity against stationary phase *Bartonella henselae*. Li T, Feng J, Xiao S, et al. *Antibiotics (Basel)* 2019; 8(2): E50.

In this study, authors performed a high-throughput screen of an FDA-approved drug library against stationary phase *B. henselae*. While the currently used drugs for treating bartonellosis, including rifampin, erythromycin, azithromycin, and doxycycline had very low MIC against growing *B. henselae*, they had relatively poor activity against stationary phase *B. henselae*, except aminoglycosides, which had the capacity to completely eradicate stationary phase *B. henselae* after 3-day drug exposure in subculture.

Bacillary angiomatosis in a pregnant patient with acquired immunodeficiency syndrome. Riley LE, Tuomala RE. *Obstet Gynecol* 1992; 79: 818–9.

A pregnant patient was treated with a third-generation cephalosporin, ceftizoxime. However, there are inadequate data to recommend use at present.

Balanitis

R. Matthew McLarney, Warren R. Heymann

Balanitis is a general term for inflammation of the glans penis, which may also extend to the foreskin (prepuce), in which case it is called balanoposthitis. It may be seen in all age groups and occurs more frequently in the uncircumcised. Etiologies include inflammatory, infectious, and neoplastic disorders. All types of balanitis may be aggravated by poor hygiene, warmth, and friction. This chapter will focus on Zoon balanitis and balanitis xerotica obliterans (BXO, lichen sclerosus).

Balanitis plasmacellularis (Zoon balanitis) represents a non-venereal, non-specific, chronic inflammation of the glans penis occasionally extending to the foreskin. It normally occurs in uncircumcised men past the second decade of life, but has been reported in children. The shiny, red, sharply demarcated patch is often asymptomatic, though symptoms of pruritus, dysuria, and pain may be reported. The evaluation for Zoon balanitis should include a thorough history and clinical workup to exclude genital herpes, secondary syphilis, and other etiologies of penile lesions. Zoon balanitis can also be associated with dermatoses of the genital area such as erosive lichen planus, lichen sclerosus, and penile psoriasis as a type of reaction pattern.

Other differential diagnoses (allergic contact dermatitis, erythroplasia of Queyrat or Bowen disease of the glans penis, and pemphigus vulgaris) should be ruled out. Biopsy demonstrates an atrophic epidermis with diamond-shaped keratinocytes overlying a predominately plasma cell-rich, bandlike infiltrate in the papillary dermis. Complications may include fissuring and pain, phimosis (inability to retract the foreskin due to agglutination/scarring), and stenosis of the urethral meatus; surgical correction of sequelae may be necessary.

Lichen sclerosus (BXO) is treated similarly to Zoon (plasma cell) balanitis. Lichen sclerosus is also of unclear etiology, although an autoimmune pathogenesis associated with other autoimmune conditions may be involved. This condition may be underrecognized in boys. It is important to identify the disorder and have continued follow-up because of the approximately 5% lifetime risk of developing a squamous cell carcinoma.

MANAGEMENT STRATEGY

Evaluation of a patient with balanitis should include a chief complaint, history of present illness, past medical and surgical history, medications, allergies, and review of systems. Specific information should be sought regarding sexual habits and alleviating or exacerbating factors. To identify potential allergens and/or irritants, the patient's genital hygiene practices and the use of oral and topical agents (condoms, spermicides, sexual-enhancing products, lubricants, etc.) should be sought. A complete mucocutaneous examination, including extragenital sites, should be performed. The genital examination includes skin and soft tissue structures extending from the lower abdomen to the perianal skin/gluteal cleft. Examination findings should direct the acquisition of microbiologic studies (KOH preparation; bacterial, fungal, and viral cultures), biopsy (hematoxylin and eosin, direct immunofluorescence), and serologic studies. All males with balanoposthitis should be screened for diabetes.

Patients with balanitis should be instructed about appropriate local hygiene, including retraction of the foreskin before cleansing. The glans and shaft should be cleaned with plain water or normal saline twice daily and after sexual activity. Soap and topical products may be irritants or allergens and should be avoided. A bland emollient applied twice daily will minimize friction and improve barrier function.

Medical therapy for balanitis is directed by etiology. Circumcision is indicated in refractory cases. Surgical procedures may be required for patients with significant anatomic distortion or compromised urinary function. Collaboration with urologic specialists is essential.

Specific Investigations

- KOH microscopy for fungi
- Tzanck smear or direct fluorescent antigen testing for herpes viruses
- Swab culture for bacteria, viruses, and fungi
- Biopsy for routine histopathology and direct immunofluorescence, if indicated
- Hemoglobin A1c
- Urinalysis and urine glucose
- Serologic tests for syphilis, herpes virus, and human immunodeficiency virus
- Serologic tests for vesiculobullous diseases (systemic lupus erythematosus, pemphigus vulgaris, bullous pemphigoid, etc.)
- Patch testing

2013 European guideline for the management of balanoposthitis. Edwards S, Bunker C, Ziller F, et al. *Int J STD AIDS* 2014; 25: 615–26.

Comprehensive review of the many causes of balanitis with specific recommendations for evaluation and management.

Zoon balanitis: a comprehensive review. Dayal S, Sahu P. Indian J Sex Transm Dis 2016; 37: 129–38.

A complete review of Zoon balanitis with history, differential diagnosis, and treatment.

Balanitis xerotica obliterans: an update for clinicians. Nguyen ATM, Holland AJA. Eur J Pediatr 2020; 179(1): 9–16

A summary of studies on topical and intralesional corticosteroids, topical immunomodulators, ozonated olive oil with vitamin E acetate, preputioplasty, and circumcision.

Diagnostic criteria, severity classification and guidelines of lichen sclerosus et atrophicus. Hasegawa M, Ishikawa O, Asano Y, et al. Journal of Dermatology 2018; 45: 891–7.

Comprehensive reference for diagnosis and guidelines for management of lichen sclerosus.

Zoon's plasma cell balanitis: clinical and dermoscopic features in pediatric patients. Chessa MA, Sechi A, Baraldi C, et al. Int J Dermatol 2018; 57: 142–4.

A case series of three pediatric patients aged 7, 8, and 13 months with Zoon balanitis demonstrated serpentine, linear-irregular, and spermatozoa-like vessels; orange-brown structureless areas; and dotted vessels on dermoscopy. The patients were treated with 4 weeks of fusidic acid cream and betamethasone twice daily. Two patients experienced resolution, while one required a shift to 1% pimecrolimus cream twice daily, which led to resolution.

First-Line Therapies

• Hygiene	B
• Emollients	B

Clinical features and management of recurrent balanitis: association with atopy and genital washing. Birley HD, Walker MM, Luzzi GA, et al. Genitourin Med 1993; 69: 400–3.

Forty-three patients with recurrent balanitis were evaluated. Thirty-one patients diagnosed with irritant contact dermatitis had a greater lifetime incidence of atopy and more frequent genital hygiene habit; 90% responded to conservative treatment, use of emollient creams, and restriction of soap use.

Second-Line Therapies

• Topical corticosteroids	A
• Circumcision	B
• Mupirocin	E

Systematic review and meta-analysis of randomized controlled trials on topical interventions for genital lichen sclerosus. Chi C, Kirtschig G, Baldo M, et al. J Am Acad Dermatol 2012; 67: 305–12.

Topical clobetasol propionate 0.05% applied for 3 months and mometasone furoate 0.05% applied for 5 weeks were both superior to placebo. Pimecrolimus 1% cream and clobetasol propionate 0.05% cream after 12 weeks of application were both effective at relieving pruritus and burning; there were no significant differences between clobetasol propionate and pimecrolimus. No evidence was found supporting the topical use of androgens and progesterone.

Randomized open-label trial comparing topical prescription triamcinolone to over-the-counter hydrocortisone for the treatment of phimosis. Chamberlin JD, Dorgalli C, Abdelhalim A, et al. J Pediatr Urol 2019; 15 (4): 388.e1–5.

Fifty-two boys with grades 4–5 phimosis (phimosis grade scale 0–5) were randomized to over-the-counter hydrocortisone or triamcinolone 0.1% cream with manual retraction of the foreskin twice daily for 12 weeks. Hydrocortisone and triamcinolone yielded 61.5% and 68.4% success rates at 12 weeks, which were not statistically different.

Plasma cell balanitis of Zoon: response to Trimovate cream. Tang A, David N, Horton LW. Int J STD AIDS 2001; 12: 75–8.

Ten patients with plasma cell balanitis treated with a topical mixture of oxytetracycline 3%, nystatin 100,000 U/g, and clobetasone butyrate 0.05% (Trimovate) for 3–12 weeks had complete resolution. Four required retreatment(s).

Does application of topical steroids for lichen sclerosus (balanitis xerotica obliterans) affect the rate of circumcision? A systematic review. Folaranmi SE, Corbett HJ, Losty PD. J Pediatr Surg 2018; 53: 2225–7.

This is a systematic review comprising 89 boys with lichen sclerosus, who were treated with topical corticosteroids. Circumcision was avoided in 31/89 (35%) with median follow-up of 4 months.

The diagnosis and management of male genital lichen sclerosus: a retrospective review of 301 patients. Kravvas G, Shim TN, Dorion PR, et al. J Eur Acad Dermatol Venereol 2018; 32: 91–5.

A retrospective review of 301 males with lichen sclerosus (41 with concomitant penile intraepithelial neoplasia) who were treated with circumcision or ultrapotent topical steroids. Over 90% of patients were cured. None progressed to squamous cell carcinoma.

Surgical management of genitourinary lichen sclerosus et atrophicus in boys in England: a 10-year review of practices and outcomes. Green PA, Bethell GS, Wilkinson DJ, et al. J Pediatr Urol 2019; 15(1): 45.

In total, 7893 boys had circumcision, primary preputioplasty, or preputioplasty plus concomitant steroid injection for lichen sclerosus; 22% of boys receiving primary preputioplasty required subsequent circumcision – this risk was reduced if concomitant steroid injection was given.

Plasma cell balanitis: clinical and histopathological features – response to circumcision. Kumar B, Sharma R, Rajagopalan M, et al. Genitourin Med 1995; 71: 32–4.

Twenty-seven patients with plasma cell balanitis were cured with circumcision. There were no recurrences at 3-year follow-up.

Plasma cell balanitis: clinicopathologic study of 112 cases and treatment modalities. Kumar B, Narang T, Dass Radotra B, et al. J Cutan Med Surg 2006; 10: 11–5.

A study of 112 males with plasma cell balanitis demonstrated complete resolution and no recurrence in the 85 who underwent circumcision. Twenty-two of 27 showed healing at 2–3 months with topical therapy (corticosteroids, corticosteroids–antifungal, or tacrolimus).

Successful management of Zoon's balanitis with topical mupirocin ointment: a case report and literature review of

mupirocin-responsive balanitis circumscripta plasmacellularis. Bari O, Cohen PR. *Dermatology and Therapy* 2017; 7: 203–10.

Two patients with Zoon balanitis that had failed to improve with topical clotrimazole experienced complete resolution within 90 days using mupirocin 2% ointment applied three times a day. The authors propose that mupirocin 2% ointment may be used as a diagnostic and monotherapeutic agent as similar-appearing dermatoses lack response to this agent.

Third-Line Therapies

• Topical tacrolimus	B, C (for Zoon's)
• Topical pimecrolimus	A/D (for Zoon's)
• Imiquimod	E
• CO ₂ laser	C
• Erbium:YAG laser	B
• Photodynamic therapy	E
• Acitretin	A
• Thalidomide	E
• Water of the three sulfates	A
• Intraurethral steroids	C

Treatment of male genital lichen sclerosis with clobetasol propionate and maintenance with either methylprednisolone aceponate or tacrolimus: a retrospective study. Kyriakou A, Patsialas C, Parsatsi A, et al. *J Dermatolog Treat* 2013; 24: 431–4.

Forty-one males with genital lichen sclerosis were treated with clobetasol propionate cream 0.05% twice a day for 8 weeks; 37 patients were responsive to treatment. These patients were further treated with either methylprednisolone aceponate 0.1% cream twice weekly or tacrolimus 0.1% ointment once daily as maintenance. At week 20, there were no significant differences noted in global assessment, pruritus, or quality of life scores between the patients treated with methylprednisolone aceponate and tacrolimus.

Multicentre, phase II trial on the safety and efficacy of topical tacrolimus ointment for the treatment of lichen sclerosis. Hengge UR, Krause W, Hofmann H, et al. *Br J Dermatol* 2006; 155: 1021–8.

Prospective, multicenter phase II study of tacrolimus 0.1% ointment in 84 patients (49 women, 32 men, 3 girls) with lichen sclerosis twice daily for 16 weeks demonstrated clearance of clinical disease in 43% and partial resolution in 34% at 24 weeks. Maximal response occurred at 10–24 weeks. No gender difference in response to therapy was noted.

Safety and tolerability of adjuvant topical tacrolimus treatment in boys with lichen sclerosis: a prospective phase 2 study. Ebert AK, Rosch WH, Vogt T. *Eur Urol* 2008; 54: 932–7.

Twenty boys with biopsy-confirmed lichen sclerosis underwent circumcision followed by topical tacrolimus 0.1% ointment twice daily for 3 weeks. All completed treatment without adverse side effects and no evidence of clinical disease at follow-up.

Therapeutic efficacy of topical calcineurin inhibitors in plasma cell balanitis: case series and review of the literature. Kyriakou A, Patsatsi A, Patsialas C, et al. *Dermatology* 2014; 228: 18–23.

Nine cases of Zoon balanitis, seven of which were previously treated with topical steroids or antifungals, were treated with tacrolimus 0.1% ointment twice daily for 4 weeks. Eight out of

nine cases had a complete response. One patient remained refractory and underwent circumcision. Two patients experienced a burning sensation with application that resolved within 2–3 days.

Although the use of calcineurin inhibitors appears to be effective for both BXO and Zoon balanitis, with continued use, surveillance for the development of squamous cell carcinoma (notably in BXO) is essential because of the theoretical possibility that these agents increase the risk of malignancy.

Zoon's balanitis treated with imiquimod 5% cream. Marconi B, Campanati A, Simonetti O, et al. *Eur J Dermatol* 2010; 20: 134–5.

A case series of Zoon balanitis successfully treated with imiquimod 5% cream three times weekly for 12 weeks.

Ablative erbium:YAG laser treatment of idiopathic chronic inflammatory non-cicatricial balanoposthitis (Zoon's disease). A series of 20 patients with long-term outcome. Wollina U. *J Cosmet Laser Ther* 2010; 12: 120–3.

Ablative erbium:YAG laser treatment was used in 20 patients with Zoon balanitis with complete reepithelialization within 2–3 weeks in all patients.

Genital lichen sclerosis treated by carbon dioxide laser. Aynaud O, Plantier F. *Eur J Dermatol* 2010; 20: 387–8.

A report of four cases of penile lichen sclerosis successfully treated with CO₂ laser and a review of the literature on CO₂ laser treatment for genital lichen sclerosis.

Zoon's balanitis: presentation of 15 patients, five treated with a carbon dioxide laser. Retamar RA, Kien MC, Chouela EN. *Int J Dermatol* 2003; 42: 305–7.

Discussion of CO₂ laser treatment in five patients with Zoon balanitis with variable efficacy.

Zoon's balanitis successfully treated with photodynamic therapy: case report and literature review. Borgia F, Vaccaro M, Foti A, et al. *Photodiagnosis Photodyn Ther* 2016; 13: 347–9.

A patient with recalcitrant Zoon balanitis who refused circumcision was treated with 10% aminolevulinic acid in polyethylene glycol ointment under occlusion for 3 hours followed by diode red light at 630 nm at a distance of 50 mm from the skin surface for a total time of 8 minutes with a resulting light dose of 75 J/cm². Almost complete clearance was seen at 3 months' follow-up after a total of three treatments at 2-week intervals.

Feasibility of 5-aminolevulinic acid mediated photodynamic therapy for male genital lichen sclerosis. Hao J, Liu J. *Photodiagnosis Photodyn Ther* 2020; 29: 101666.

Three male patients with genital lichen sclerosis and a history of circumcision were treated with ALA-PDT (patient 1: 12 treatments at 4-week intervals; patients 2 and 3: four treatments at 2-week intervals), and demonstrated a 30–70% reduction of lesion size after treatments. Adverse effects included pain and swelling, which disappeared soon after irradiation and without medication.

Acitretin for severe lichen sclerosis of male genitalia: a randomized, placebo-controlled study. Ioannides D, Lazaridou E, Apalla Z, et al. *J Urol* 2010; 183: 1395–9.

A randomized, double-blind, placebo-controlled study to evaluate the efficacy of a 35-mg daily dose of acitretin for 20 weeks compared with placebo in men with severe, recalcitrant lichen sclerosis. Of 49 patients completing the study, 24 of the 33 in the

acitretin group had complete or partial resolution, whereas only 3 out of 16 in the control group responded. This study found acitretin to be safe and effective.

Thalidomide in plasma cell balanitis refractory to conventional topical treatment. Serrao LM, Sarmenghi KDA, Pinto BCBP, et al. *An Bras Dermatol* 2018; 93: 881–3.

A 32-year-old male with HIV and Zoon balanitis was refractory to topical tacrolimus and systemic antibiotics. He refused circumcision. Thalidomide 100 mg/day for 6 weeks resulted in remission of disease and no relapse through 8 months of follow-up.

Clinical study of the effectiveness of the ‘water of 3 sulfates’ on balanitis and balanoposthitis. Gonzalvo V, Polo A, Serralach F, et al. *Actas Urol Esp* 2015; 39: 118–21.

Fifty patients with acute balanitis or balanoposthitis were randomized to ‘water of the three sulfates’ (copper sulfate, zinc

sulfate, and alum) or saline solution. Exudate, erythema, edema, burning, and itching were assessed. The outcomes obtained for water of the three sulfates for all clinical parameters were higher than control, although significant differences were only found for amount of exudate.

Intraurethral steroids are a safe and effective treatment for stricture disease in patients with biopsy-proven lichen sclerosis. Potts BA, Belsante MJ, Peterson AC. *J Urol* 2016; 195: 1790–6.

A retrospective review of 28 males with lichen sclerosis complicated by urethral stricture, who underwent topical intraurethral steroid application. The protocol was clobetasol 0.05% cream used to lubricate a urinary catheter or meatal dilator, applied twice daily for 2–3 months, at which point the patient was able to titrate medication use as needed. The success rate was 89% and no patient went on to require urethroplasty.

Basal cell carcinoma

Kalee Shah, Maxim Polansky, Kishwer Nehal

Basal cell carcinoma (BCC) is a slow-growing, locally destructive keratinocyte carcinoma (KC) that rarely metastasizes. It is the most common type of skin cancer, with nearly 4.3 million new cases diagnosed annually in the United States alone. BCCs most commonly arise in areas that are chronically exposed to ultraviolet light, especially the head and neck. Although the risk of metastasis is low, BCCs can be challenging to treat given their frequent location in functionally and cosmetically sensitive areas on the face.

MANAGEMENT STRATEGY

Therapeutic intervention for BCC is geared toward complete tumor eradication with maximal preservation of function and the optimal cosmetic result. Based on the best available evidence and consensus from leading experts, the National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology (NCCN) divide BCC into low- and high-risk based on the likelihood of local recurrence.

BCC is considered low-risk if it is less than 1 cm in diameter and located on the cheeks, forehead, scalp, neck, and pretibial lower extremities (area M) or if it is less than 2 cm and located on the trunk or extremities (excluding the hands, nail units, pretibial skin, ankles, and feet) (area L). Other tumor-related factors that are considered low-risk are primary nature, well-circumscribed clinical borders, non-aggressive growth pattern (nodular, superficial, keratotic, infundibulocystic, and fibroepithelioma of Pinkus), and absence of perineural involvement. Patient-related factors that are considered low-risk by the NCCN include immunocompetent patients and those without a prior history of radiotherapy (RT) at the site of the primary BCC.

BCCs that are high-risk for local recurrence include any tumor that occurs in the 'mask' areas of the face including the central face, eyelids, eyebrows, periorbital nose, lips, chin, mandible, preauricular skin, postauricular skin, temple, and ear, as well as the genitalia, hands, and feet (area H). Tumors that are greater than 1 cm in area M or 2 cm in area L are also considered high-risk. The presence of an aggressive growth pattern (infiltrative, micronodular, morphea, basosquamous, or sclerosing), perineural invasion, ill-defined clinical borders, and recurrent nature is considered a high-risk feature. BCCs occurring in patients that are immunosuppressed or with a history of RT at the tumor site are also high-risk.

Individual patient characteristics, such as medical comorbidities/life expectancy, functional status, and patient preference, may also inform shared decision-making. It is important to note that in the very elderly population, age alone is inadequate for making treatment decisions.

Comorbidity scores associated with limited life expectancy in the very elderly with nonmelanoma skin cancer. Rogers EM, Connolly KL, Nehal KS, et al. *J Am Acad Dermatol* 2018; 78: 1119–24.

In a single-center, retrospective study of 488 patients, age 85 or older, who presented to dermatologic surgeons for management of non-melanoma skin cancer, the Adult Comorbidity Evaluation-27 (ACE-27) and Age-Adjusted Charlson Comorbidity Index (ACCI) predicted limited life expectancy at scores of 3 and 7 or more, respectively. Use of validated comorbidity indices such as the ACE-27 or ACCI may help inform the shared decision-making approach in the treatment of BCC in the very elderly.

Mohs micrographic surgery (MMS) is considered the gold standard for treatment of high-risk BCCs, providing the highest cure rate. Given its unique ability to have precise margin control and tissue sparing qualities, it is the favored approach for tumors in the high-risk H zone. Recurrence rates from a well-designed, prospective study over a 10-year follow-up period are 4.4%, compared with 12.2% for surgical excision. In 2012, the American Academy of Dermatology (AAD), American College of Mohs Surgery, American Society for Dermatologic Surgery Association, and the American Society for Mohs Surgery created appropriate use criteria (AUC) for MMS. A Mohs surgery AUC mobile application is available to assist practitioners and can be downloaded from the AAD website.

Surgical excision can be considered for both low- and high-risk tumors. Long-term (greater than 5 years) recurrence rates are higher with surgical excision compared with MMS for high-risk facial BCCs. The NCCN guidelines recommend at least a 4-mm margin for BCCs with low-risk features that are less than 2 cm in diameter. Tumors with larger size, aggressive growth pattern, and history of recurrence require larger margins, staged excision with delayed repair, or intraoperative histologic control, such as with MMS.

Curettage and electrodesiccation (C&E) is a simple, rapid, and inexpensive method to treat low-risk BCC. Prospective studies directly comparing C&E with other therapeutic modalities are lacking, and retrospective studies not controlled for size, histology, location, and history makes comparisons with other treatment modalities impossible. The NCCN guidelines acknowledge the utility of C&E for properly selected, low-risk BCC but highlight that C&E should not be used in areas of terminal hair growth due to risk of follicular extension. Furthermore, if the subcutaneous layer is reached during C&E, surgical excision should be performed instead.

RT can be considered as a first-line therapy for tumors that are unresectable either due to location, size, patient comorbidities, or patient preference. Contraindications to RT include genetic syndromes that predispose to skin cancer such as xeroderma pigmentosum and nevoid BCC syndrome, and connective tissue diseases. The NCCN guidelines suggest avoiding RT in patients less than 60 years old due to long-term toxicity and risk of secondary malignancy. Postradiation adverse events include skin toxicity, increased risk of subsequent skin cancers, and increased difficulty in management of tumor recurrences within the radiation field. Adjuvant RT should be considered for deeply invasive BCCs with positive margins following resection or those with clinically significant perineural invasion.

Imiquimod is a toll-like receptor 7 agonist that exerts an anti-tumor effect by modulating the immune system and stimulating apoptosis of BCC tumor cells. It is FDA-approved for non-surgical management of superficial BCC; tumor-free survival is 80% at 5 years.

Topical 5-fluorouracil (5-FU) is a chemotherapy agent that, when applied topically, induces cancer cell death in the top layers of the skin. It is FDA-approved for the treatment of small superficial BCCs. In a recent randomized, controlled trial (RCT), tumor-free survival at 5 years was 70%.

Photodynamic therapy (PDT) performed with photosensitizers, methyl-aminolevulinate (MAL), or aminolevulinic acid (ALA) yields a lower cure rate but may offer a better cosmetic outcome than surgical excision. PDT is approved for the treatment of BCCs in Europe, but remains off-label in the United States. It should only be used to treat small, superficial BCCs in patients that decline surgical treatment or when surgery is impractical.

Cryosurgery is a simple and cost-effective modality for treating low-risk superficial BCCs, but recurrence rates are high. Studies have found a large variability in recurrence rates of BCCs treated with cryosurgery, likely due to differences in interoperator techniques. This treatment modality should be considered in very specific cases only when other treatment options are impractical or prohibitive. Recommended regimens include two freeze-thaw cycles and the use of a cryoprobe to assess tissue temperature achieved: -50°C is generally regarded as sufficiently cytotoxic.

Systemic therapies are reserved for metastatic tumors or for tumors not amenable to surgery. Mutations in the sonic hedgehog pathway occur in up to 90% of BCCs. Essential to this pathway is the protein smoothened, and two inhibitors of this protein are now FDA-approved for treatment of advanced BCC, *vismodegib* and *sonidegib*. Trials have shown an objective response rate (ORR) between 30% and 60% and a complete response rate (CR) between 4% and 5%. Given the low rates of CR, hedgehog pathway inhibitors are often

seen as a neoadjuvant therapy to bridge to definitive treatment with surgery or radiation. Long-term tolerability is low; side effects include muscle spasms, weight loss, abnormal taste, and alopecia. Alternative dosing regimens have been proposed to reduce the side effect profile. Other systemic therapies used for advanced BCC include immunotherapy and cytotoxic chemotherapy.

Secondary prevention should focus on sun protection and regular skin cancer screening. The risk of developing a subsequent KC after first lifetime KC is 40.7% at 5 years and 59.6% at 10 years. There is limited evidence to support chemoprevention for BCC in high-risk, non-transplant patients; however, early data are promising for oral nicotinamide supplementation. Oral retinoids and topical 5-FU do not alter the incidence of subsequent BCC in those with a history of KC.

National Comprehensive Cancer Network. Basal Cell Skin Cancer (Version 1.2021). The NCCN guidelines are created based on the best available evidence as well as expert opinion from a multidisciplinary group of specialists including dermatologists, surgical oncologists, medical oncologists, radiation oncologists, and dermatopathologists. They are available for free on the NCCN website. For low-risk BCC, the NCCN recommends C&E, standard excision with 4 mm margins and postoperative margin assessment, or RT for non-surgical candidates. High-risk BCC should be treated with MMS, resection with complete circumferential peripheral and deep margin assessment, or standard excision with wider margins and delayed repair. RT and systemic therapy should be employed for non-operable, high-risk BCC.

Specific Investigation

- Dermoscopy to improve diagnostic accuracy prior to tissue analysis
- Biopsy with adequate dermal component
- Radiologic examination (CT, MRI) if high-risk tumor

An adequate biopsy is critical in assessing BCC histologic subtype. Deep shave, punch, incisional, or excisional biopsy can all give sufficient dermis for such an evaluation. Curettage biopsy is often insufficient to establish the diagnosis and the tumor subtype. Use of dermoscopy may improve diagnostic accuracy (sensitivity 91.2%, specificity 95%).

A number of non-invasive imaging technologies are being investigated to improve diagnostic accuracy including reflectance confocal microscopy (RCM), optical coherence tomography, infrared spectroscopy, and ultrasound. RCM demonstrates 91.7% sensitivity and 91.3% specificity for diagnosis of BCCs.

Rarely, a BCC may reach a size such that direct bony invasion or large nerve involvement has occurred. If this is strongly suspected, a preoperative computed tomography (CT) scan with contrast to assess for bony invasion or magnetic resonance imaging (MRI) to assess for perineural spread can be considered. When faced with a locally advanced or metastatic BCC, a multidisciplinary care team of dermatologists, medical oncologists, surgical oncologists, radiation oncologists, and palliative care physicians should be convened.

First-Line Therapies

• Mohs micrographic surgery	B
• Excisional surgery	B
• Radiation therapy	B
• Curettage and electrodesiccation	B

Surgical excision versus Mohs micrographic surgery for basal cell carcinoma of the face: a randomized clinical trial with 10 year follow up. van Loo E, Mosterd K, Krekels GA, et al. *Eur J Cancer* 2014; 50: 3011–20.

In a randomized, prospective study, 408 high-risk facial BCCs and 204 recurrent facial BCCs were randomized to conventional surgery or MMS. There was no significant difference between recurrence rate of primary BCC between MMS and conventional surgery at 5-year follow-up. At the 10-year follow-up, the recurrence rate for primary BCC treated with MMS was 4.4%, whereas for conventional surgery it was 12.2%. For recurrent facial BCC, MMS had a 3.9% recurrence rate versus 13.55% for conventional surgery at 10-year follow-up. A substantial number of recurrences occurred more than 5 years following treatment: 56% for primary BCC and 14% for recurrent BCC.

Adverse events associated with Mohs micrographic surgery: multicenter prospective cohort study of 20,821 cases at 23 centers. Alam M, Ibrahim O, Nodzenski M, et al. *JAMA Dermatol* 2013; 149: 1378–85.

A multicenter prospective cohort study of 20,821 MMS procedures recorded 149 adverse events (0.72%) including four serious events (0.02%). There were no deaths reported. The most common adverse events were infections (61.1%), dehiscence and partial or full necrosis (20.1%), and bleeding (15.4%). Most bleeding and wound healing complications occurred in patients on anticoagulation.

FACE-Q Skin Cancer Module for measuring patient-reported outcomes following facial skin cancer surgery. Lee EH, Klasen AF, Cano SJ, et al. *Br J Dermatol* 2018; 179: 88–94.

The FACE-Q Skin Cancer Module is a new, validated, patient-reported outcomes measurement for patients undergoing surgery for facial skin cancers. Dermatologic and reconstructive surgeons may use this tool to evaluate patient satisfaction with regard to facial/scar appearance, psychosocial stress, cancer worry, and patient experience.

Suggested excisional margins for cutaneous malignant lesions based on Mohs micrographic surgery. Schell AE, Russell MA, Park SS. *JAMA Facial Plast Surg* 2013; 15: 337–43.

A retrospective review of 495 lesions treated with MMS recorded margins necessary for clearance of both low- and high-risk BCC. The margin required to completely excise 95% of low-risk BCCs was 4.75 mm and high-risk BCCs was 8 mm. Established high-risk zones, such as the H zone, were not associated with larger margins in this study.

Surgical margins for basal cell carcinoma. Wolf DJ, Zitelli JA. *Arch Dermatol* 1987; 123: 340–4.

One hundred seventeen low-risk BCCs were prospectively studied to determine the extent of subclinical tumor invasion. Normal skin surrounding the tumor was marked in 2 mm intervals and the tumor was subsequently excised using the MMS method. A surgical margin of 4 mm histologically cleared 98% of the tumors less than 2 cm.

Basal cell carcinoma of the face: surgery or radiotherapy? Results of a randomized study. Avril MF, Auperin A, Margulis A, et al. *Br J Cancer* 1997; 76: 100–6.

A randomized trial in which 347 primary BCCs less than 4 cm in size were assigned to surgical excision or RT. The 4-year recurrence rate was 0.7% for surgical excision and 7.5% for RT. Cosmesis, as judged by the patient and blinded judges, was significantly better in the surgery group than in the RT group.

Therapeutic ionizing radiation and the incidence of basal cell carcinoma and squamous cell carcinoma. The New Hampshire Skin Cancer Study Group. Lichter MD, Karagas MR, Mott LA, et al. *Arch Dermatol* 2000; 136: 1007–11.

This study demonstrated a statistically significant increased risk (relative risk 3.30) of the development of BCC in the exposure window after therapeutic RT. The development of subsequent tumors is a significant possible side effect of radiation therapy.

Recurrence rates of treated basal cell carcinomas. Part 2: curettage–electrodesiccation. Silverman MK, Kopf AW, Grin CM, et al. *J Dermatol Surg Oncol* 1991; 17: 720–76.

This retrospective study of 2314 primary BCCs treated by C&D at a university dermatology clinic reported a 13.2% 5-year recurrence rate after C&D. Further analysis showed that size and location were important variables, with 5-year recurrence rates varying from 9.5% in low-risk locations to over 16.3% in high-risk sites. Similarly, 5-year recurrence rates ranged from 8.5% for tumors less than 5 mm to 19.8% for tumors 20 mm or more.

Recurrence rates of aggressive histologic types of basal cell carcinoma after treatment with electrodesiccation and curettage alone. Blixt E, Nelsen D, Stratman E. *Dermatol Surg* 2013; 39: 719–25.

Of 37 primary, aggressive BCCs (infiltrative, desmoplastic, morpheaform, or micronodular subtype), 10 recurred within 3.3 years (27%). The median follow-up was 6.5 years.

Second-Line Therapy

• Topical imiquimod	A
• Topical 5-fluorouracil	A
• Photodynamic therapy	A
• Cryosurgery	B
• Topical ingenol mebutate	B

Comparing treatments for basal cell carcinoma in terms of long-term treatment-failure: a network meta-analysis. Fukumoto T, Fukumoto R, Oka M, et al. *J Eur Acad Dermatol Venereol* 2019; 33: 2050–7.

In patient-level meta-analysis of 1738 tumors, surgery had the lowest odds of treatment failure, followed by radiotherapy [odds ratio (OR) 3.38], imiquimod (OR 12.29), cryotherapy (OR 19.91), 5-FU (OR 22.37), and PDT (OR 30.49). In tumor-level meta-analysis, MMS had the lowest odds of treatment failure (OR 0.50), followed by surgery (OR 1.00), cryotherapy (OR 4.06), and PDT (10.30). This rank order was maintained with subgroup analysis based on histologic subtype.

Surgery versus 5% imiquimod for nodular and superficial basal cell carcinoma: 5-year results of the SINS randomized controlled trial. Williams HC, Bath-Hextall F, Ozolins M, et al.; Surgery Versus Imiquimod for Nodular and Superficial Basal Cell Carcinoma (SINS) Study Group. *J Invest Dermatol* 2017; 137: 614–9.

Participants of this controlled trial were randomized to imiquimod 5% cream once daily (total course 6 weeks for superficial BCC and 12 weeks for nodular BCC) or excisional surgery with 4-mm margins. Five-year success rates for imiquimod were 83.8% for superficial BCC and 81.1% for nodular BCC. The 5-year success rates for surgery were 96.8% for superficial BCC and 98.8% for nodular BCC. Most imiquimod failures occurred in the first year after treatment.

Five-year results of a randomized controlled trial comparing effectiveness of photodynamic therapy, topical imiquimod, and topical 5-fluorouracil in patients with superficial basal cell carcinoma. Jansen MHE, Mosterd K, Arits AHMM, et al. *J Invest Dermatol* 2018; 138: 527–33.

A prospective, non-inferiority, randomized, controlled, multicenter trial with 601 patients showed that 5% imiquimod cream was superior to 5-FU and MAL-PDT at 1 and 3 years after treatment of superficial BCC. Five years after treatment, the probability of tumor-free survival was 80.5% for imiquimod compared with 70.0% for 5-FU and 62.7% for MAL-PDT.

Comparison of long-term cosmetic outcomes for different treatments of superficial basal cell carcinoma. Jansen MHE, Koekelkoren FHJ, Nelemans P, et al. *J Am Acad Dermatol* 2018; 79: 961–4.

MAL-PDT had a statistically significant better cosmetic outcome than imiquimod or 5-FU therapy for the treatment of superficial BCC at 5 years' posttreatment in recurrence-free patients. However, treatment failure occurred more frequently after treatment with MAL-PDT necessitating retreatment with surgery, which was associated with a lower chance of favorable cosmetic outcome.

Photodynamic therapy of basal cell carcinoma: clinical and pathological determinants of response. Fantini F, Greco A, Del Giovane C, et al. *J Eur Acad Dermatol Venereol* 2011; 25: 896–901.

Clinical and pathological characteristics of 194 BCCs that were treated with MAL-PDT were analyzed. Complete response was 82% for superficial BCC and 33% for nodular BCC. Factors associated with complete response were superficial histotype, location on the trunk, absence of ulceration, and thickness less than 5 mm. Patient age, gender, and tumor size were not significant predictors of treatment response.

Five year follow-up of a randomized prospective trial of topical methyl aminolevulinate photodynamic therapy vs. surgery for nodular basal cell carcinoma. Rhodes LE, de Rie MA, Leifsdottir R, et al. *Arch Dermatol* 2007; 143: 1131–6.

Fifty-three nodular BCCs were treated with 2–4 sessions of MAL-PDT and 52 nodular BCCs were treated by surgical excision. At 5-year follow-up there was a 14% recurrence rate in the PDT group versus 4% in the surgical excision group. The cosmetic outcome was rated to be better in the PDT group than in the excision group.

Photodynamic therapy in the treatment of basal cell carcinoma: a systematic review and meta-analysis. Wang H, Xu Y, Shi J, et al. *Photodermatol Photoimmunol Photomed* 2015; 31: 44–53.

A systematic review and meta-analysis of eight RCTs (1583 patients) comparing PDT versus non-PDT treatments for BCC found that PDT was associated with a lower complete clearance rate and higher 1-year and 5-year recurrence rates when compared with surgical excision. There was no statistically significant difference between PDT and cryotherapy or topical therapy (imiquimod and 5-FU). PDT had a significantly better cosmetic outcome than all other modalities.

A systematic review on the use of cryotherapy versus other treatments for basal cell carcinoma. Tchanque-Fossuo CN, Eisen DB. *Dermatol Online J* 2018; 24.

A systematic review of six RCTs demonstrated similar efficacy between PDT and cryosurgery for the treatment of primary superficial and nodular BCC. Recurrence rates for cryotherapy range

from 6.3% to 39% at 2 years' follow-up. One study with 5-year follow-up data reported a recurrence rate of 20%.

Locally Advanced and Metastatic BCC

• Adjuvant radiation therapy	D
• Hedgehog pathway inhibitors	A
• Immunotherapy	C
• Cytotoxic chemotherapy	D

Outcomes of radiation therapy for advanced T3/T4 non-melanoma cutaneous squamous cell and basal cell carcinoma. Kim SK, Barker CA. *Br J Dermatol* 2018; 178: e30–2.

Outcomes of curative-intent RT and adjuvant RT for 25 T3/T4 BCCs were reviewed in a retrospective study from a single institution. Three-year disease specific survival was 87.8% for patients treated with curative-intent RT and 85.7% for adjuvant RT. Survival was not associated with tumor stage or treatment intent.

Hedgehog pathway inhibitor therapy for locally advanced and metastatic basal cell carcinoma: a systematic review and pooled analysis of interventional studies. Jacobsen AA, Aldahan AS, Hughes OB, et al. *JAMA Dermatol* 2016; 152: 816–24.

A review of eight pooled articles included 744 total patients with 704 patients clinically evaluable. Sonidegib did not yield enough publications for a formal analysis. ORR to vismodegib for locally advanced BCC had a weighted average of 64.7%; CR averaged 31.1%. ORR for metastatic BCC was 33.6%; CR averaged 3.9%. Median duration of therapy was 35.8 weeks.

Long-term efficacy and safety of sonidegib in patients with advanced basal cell carcinoma: 42-month analysis of the phase II randomized, double-blind BOLT study. Dummer R, Guminski A, Gutzmer R, et al. *Br J Dermatol* 2020; 182(6): 1369–78.

At 42 months, the ORR for locally advanced BCC treated with sonidegib 200 mg daily was 56% compared to 46.1% in the 800 mg daily group. CR for locally advanced BCC were 5% and 1.6% in the 200 mg daily and 800 mg daily groups, respectively. ORR for metastatic BCC was 8% in the 200 mg daily group versus 17% in the 800 mg daily group. No patients with metastatic BCC demonstrated complete response regardless of dose.

Pembrolizumab for advanced basal cell carcinoma: an investigator-initiated, proof-of-concept study. Chang ALS, Tran DC, Cannon JGD, et al. *J Am Acad Dermatol* 2019; 80: 564–6.

Nine patients received pembrolizumab monotherapy at a dose of 200 mg intravenously every 3 weeks and seven patients received pembrolizumab with vismodegib in this open-label, non-randomized study. The ORR for pembrolizumab monotherapy group was 44% and for dual therapy was 29%. The median time to response for all responders was 10.4 weeks and the median duration of response was 67.3 weeks.

Chemoprevention

• Oral nicotinamide	A
• Oral retinoids	A
• Topical 5-fluorouracil	A
• (not effective)	

A phase 3 randomized trial of nicotinamide for skin-cancer chemoprevention. Chen AC, Martin AJ, Choy B, et al. *N Engl J Med* 2015; 373: 1618–26.

In this randomized, double-blind, placebo-controlled trial of oral nicotinamide 500 mg twice daily for the prevention of actinic keratosis and KCs, 386 patients with a history of KC were randomized to nicotinamide or placebo arm for 12 months. The mean number of BCCs per person through the 12-month intervention period was reduced by 20%; however, the difference was not statistically significant.

Randomized controlled trial of acitretin versus placebo in patients at high-risk for basal cell or squamous cell carcinoma of the skin. Kadakia KC, Barton DL, Loprinzi CL, et al. *Cancer* 2012; 118: 2128–37.

Prospective, randomized, double-blind, placebo-controlled trial of oral acitretin in 70 non-transplant patients with a history of KC. After 2 years of treatment, the patients treated with acitretin 25 mg five times weekly did not have a statistically significant reduction in BCC.

Chemoprevention of basal and squamous cell carcinoma with a single course of fluorouracil, 5%, cream: a randomized clinical trial. Weinstock MA, Thwin SS, Siegel JA, et al. *JAMA Dermatol* 2018; 154: 167–74.

A randomized, double-blind, placebo-controlled trial in which 932 participants were assigned to placebo or topical 5% FU application to the face and ears twice daily for 2–4 weeks. There was no statistically significant reduction in subsequent BCCs between the treatment and placebo groups at 12 months.

Becker nevus

Aiteh S. Jibbe, Bahar F. Firoz, Leonard H. Goldberg

Becker nevus, also called pigmentary hairy epidermal nevus, is a cutaneous hamartoma that may have increased epidermal pigmentation (melanocyte), appendageal (hair follicle), and dermal (smooth muscle) components. Becker nevus is first noticed around puberty on the shoulders and chest but may also be congenital and involve any area of the body with a sixfold greater prevalence in men. This direct relationship to puberty is thought to be due to the increased density of androgen receptors within the Becker nevus.

MANAGEMENT STRATEGY

Becker nevus is asymptomatic and may come to the attention of a physician for cosmetic or diagnostic purposes. Management of asymptomatic benign lesion should comprise confirmation of diagnosis and an evaluation for any associated pathology such as developmental abnormalities that can accompany Becker nevus or within the spectrum of Becker nevus syndrome. Reported cutaneous associations include an acneiform eruption, eczematous dermatitis, hypohidrosis, lichen planus, localized lipoatrophy, localized scleroderma, polythelia, psoriasisiform dermatitis, unilateral breast hypoplasia, osteoma cutis, capillary malformations, dermal melanocytosis, and neurofibromatosis type-1. Musculoskeletal associations include limb asymmetry, pectus excavatum/carinatum, scoliosis, and other vertebral defects.

Association of Becker nevus with cutaneous malignancies, including basal and squamous cell carcinoma, was described separately in three young individuals without significant risk factors. Although melanoma has been described in patients with Becker nevus, the risk of malignant transformation of the nevus itself is very low, thus enhanced screening is unnecessary.

The treatment of a Becker nevus depends on multiple factors including skin type, desired treatment end point, pigmentary involvement, hypertrichosis, and extent of musculoskeletal

involvement. Becker nevus is primarily treated for pigment or hair removal with lasers. *Surgical excision, oral and topical antian-drogens, topical depigmenting agents, and topical glycolic acid* and a variety of *light and laser sources* have also been used to treat both the pigmentary and musculoskeletal manifestations of Becker nevus.

Postzygotic mutations in beta-actin are associated with Becker's nevus and Becker's nevus syndrome. Cai ED, Sun BK, Chiang A, et al. *J Invest Dermatol* 2017; 137: 1795–8.

A postzygotic lethal mutation in ACTB, a gene encoding beta-actin, underlies the development of Becker nevi in both isolated Becker nevi and Becker nevus syndrome. These mutations potentiate the Hedgehog signaling pathway, thereby disrupting hair follicle and pilar muscle development causing this clinical phenotype.

Specific Investigations

- Skin biopsy – although skin biopsy is diagnostic, it is often unnecessary
- Inquire about family history and evaluate for associated pathology
- Dermoscopy – reticulated pigment network, focal hypopigmentation, furrow hypopigmentation, hair follicles, perifollicular hypopigmentation, and vessels are the main dermoscopic features

First-Line Therapies

Treatment can be divided into two components:

- Reduction of hyperpigmentation
- Removal of hair

Reduction of Hyperpigmentation

• Intense pulsed light	B
• Erbium:YAG laser	C
• Long-pulsed alexandrite laser	D
• Long-pulsed Nd:YAG	D
• Erbium-doped fiber laser (Fraxel)	D

Intense pulsed light for treatment of Becker's nevus. Wu PR, Lan-Ju L, Zhang Y-X, et al. *J Dermatolog Treat* 2019; 2: 1–6.

A prospective study of 24 patients with Becker nevus treated with intense pulsed light at a filter of 590nm. Treatments were repeated a mean of five times with 3-month duration between treatments. The majority of patients experienced at least 50% improvement in their lesion in both hyperpigmentation and hypertrichosis without signs of repigmentation at 6-month follow-up.

Efficacy and safety of short-pulse erbium:yttrium aluminum garnet laser treatment of Becker's nevus in Saudi patients: a pilot study. Al-Saif F, Al-Mekhadab E, Al-Saif H. *Int J Health Sci (Qassim)* 2017; 11: 14–7.

This study evaluated the use of 2940nm Er:YAG to treat pigmentation of Becker nevus in a series of seven patients. The study showed improvement in pigmentation in all seven patients with no infections, hypertrophic, or keloids posttreatment and no recurrence at 1 year.

Lasers for Becker's nevus. Zhong Y, Yang B, Huang L, et al. *Lasers Med Sci* 2019; 34: 1071–79.

This paper reviewed the efficacy of lasers from the range of 504–10,600 nm to treat Becker nevi. If a single laser is desired to treat both the pigmentary changes and hypertrichosis changes seen in Becker's nevus, a diode laser (808/810 nm) may be optimal over Nd:YAG laser (1064 nm) in order to minimize damage to uninvolved tissue. The greatest clinical efficacy for pigmentary changes was seen with Er:YAG 2940 nm laser after only one treatment with 1–5 passes.

Becker's naevus: a comparative study between Erbium:YAG and Q-switched Neodymium:YAG; clinical and histopathological findings. Trelles MA, Allones I, Moreno-Arias GA, et al. *Br J Dermatol* 2005; 152: 308–13.

Twenty-two patients with Becker nevi were studied, 11 with each laser. Both Erbium:YAG and Nd:YAG safely treated the lesions. For pigment removal, one pass with Erbium:YAG was superior to three treatment sessions with Nd:YAG.

Treatment of Becker's nevi with a long-pulse alexandrite laser. Choi JE, Kim JW, Seo SH, et al. *Dermatol Surg* 2009; 35: 1105–8.

Eleven Korean patients with Becker nevi were treated with a 755-nm long-pulse alexandrite laser (20–25 J/cm² fluence, 3 ms pulse duration, 15–18 mm spot size). Two patients had an excellent response, five good, and four a fair response. There was one case of partial hypertrophic scarring, and some patients had mild hypopigmentation; all outcomes were noted to be cosmetically acceptable.

Successful treatment of Becker's nevus with long-pulsed 1064-nm Nd:YAG and 755-nm alexandrite laser and review of the literature. Wulkan AJ, McGraw T, Taylor M. *J Cosmet Laser Ther* 2018; 20: 211–4.

Significant reduction in both pigment and hair seen in a Becker nevus on a 20-year-old male with Fitzpatrick skin type IV treated with a combination of six sessions of long-pulsed 1064-nm Nd:YAG (26–27 J/cm² fluence, 10-ms pulse duration, 15-mm spot size) 6 weeks apart followed by five sessions of long-pulsed 75-nm alexandrite laser (60–70 J/cm², 1.5 ms, 6 mm) at 3-month interval.

Hypertrichotic Becker's nevi treated with combination 1,550nm non-ablative fractional photothermolysis and laser hair removal. Balaraman B, Friedman PM. *Lasers Surg Med* 2016; 48: 350–3.

Retrospective analysis of three patients with Becker nevi treated with long-pulsed 1064 nm Nd:YAG in combination with non-ablative fractional erbium-doped (1550 nm). This combination resulted in greater than 75% clinical improvement in pigmentation and hypertrichosis.

Reduction of Hypertrichosis

- Diode laser **C**
- Normal mode ruby laser **D**
- Long-pulsed Nd:YAG **D**

Treatment of a Becker's nevus using a 694-nm long-pulsed ruby laser. Nanni CA, Alster TS. *Dermatol Surg* 1998; 24: 1032–4.

Single case report that showed reduction in pigmentation and a 90% reduction in hair growth after three treatments with the long-pulsed ruby laser with improvement for 10 months.

Hypertrichosis in Becker's nevus: effective low-fluence hair removal. Lapidoth M, Adatto M, Cohen S, et al. *Lasers Med Sci* 2014; 29: 191–3.

Fifteen patients treated with low-fluence, 808–810-nm diode laser had decreased hair growth at 6 and 12 months, without adverse effects.

800 nm diode laser does not display long-term benefit for hair removal in Becker's nevus: a retrospective analysis of 24 cases. Zhong Y, Huang L, Chen Y, et al. *Photodermatol Photoimmunol Photomed*. 2020; 36: 387–9.

Retrospective study of 24 patients with Becker nevi and Fitzpatrick type III skin treated with 800-nm diode laser. The study noted all patients showed at least a 25% reduction in hair within the nevus and 50% showed greater than 75% reduction in hair. However, hair regrowth of unknown extent was noted in all patients within 6-months of follow-up.

Second-Line Therapy

Reduction of hyperpigmentation

- Frequency-doubled Q-switched (QS) Nd:YAG **D**
- QS ruby laser **D**
- Picosecond alexandrite laser **E**

Laser treatment of epidermal nevi: a multicenter retrospective study with long-term follow-up. Alkhalifah A, Fransen F, Le Duff F, et al. *JAAD* 2019 Jun 13 [Epub ahead of print].

A study of 26 patients with Becker nevi treated with Q-switched laser ranging from 1064 nm, 755 nm, 694 nm, to 532 nm. Only three patients experienced any degree of improvement with only one patient maintaining the results after four sessions of Q-switched laser at 755 nm after a 12-month follow-up. Thus, this study concludes that Q-switched lasers are not an optimal treatment for Becker nevus regardless of their wavelengths.

Treatment of flat and elevated pigmented disorders with a 755-nm alexandrite picosecond laser: clinical and histological evaluation. Alegre-Sanchez A, Jiménez-Gómez N, Moreno-Arrones ÓM, et al. *Lasers Med Sci* 2018; 33: 1827–31.

Significant improvement in a Becker nevus of a 22-year-old female with type II Fitzpatrick skin treated with a 755-nm picosecond alexandrite laser after two sessions of 3.5 mm–2.08 J/cm².

Reduction of Excess Hair

- Electrolysis **E**

Electrolysis is a well-established method of epilation, but its use in removing hair from Becker nevus has not been published.

Third-Line Therapies	
• Spironolactone	E
• Topical flutamide	E
• Topical glycolic acid	E
• Topical azelaic acid	E
• Corrective camouflage	E

Becker’s nevus with ipsilateral breast hypoplasia: improvement with spironolactone. Jung JH, Kim YC, Park HJ, et al. *Journal of Dermatology* 2003; 30: 154–6.

A 17-year-old female with improvement of ipsilateral breast hypoplasia associated with Becker nevus on spironolactone on 50 mg a day.

Two similar cases have been reported in the literature at the same dose with similar outcomes.

Treatment of Becker nevus with topical flutamide. Taheri A, Mansoori P, Sandoval F, et al. *JAAD* 2013; 6: e147–8.

A 22-year-old Caucasian woman with a 10-year history of Becker’s nevus treated with topical 4% solution of flutamide applied twice daily. After 8 weeks of therapy there was significant improvement; no follow-up.

Lightening Becker nevus with topical glycolic acid. Zhong Y, Chen Y, Huang L, et al. *JAAD* 2019; 80: e3.

Application of topical 70% glycolic acid solution immediately followed by 10% sodium bicarbonate showed marked improvement in the pigmentation of a Becker nevus after five treatments with each treatment, with no recurrence at 3-month follow-up.

A case of Becker’s nevus with pityriasis versicolor. Sharma M, Kansal NK, Gautam RK. *J Eur Acad Dermatol Venereol* 2014; 28: 1827–8.

A 22-year-old male patient with Becker nevus developed pityriasis versicolor within the lesion. Hypopigmentation of pityriasis versicolor is hypothesized to be due to competitive inhibition of the enzyme tyrosinase by certain dicarboxylic acids (like azelaic acid) produced by the fungus, so the authors suggest topical azelaic acid as an option for treatment.

Corrective camouflage in pediatric dermatology. Tedeschi A, Dall’Oglio F, Micali G, et al. *Cutis* 2007; 79: 110–2.

Corrective camouflage using a variety of water-resistant and light to very opaque products was used in two patients with Becker nevi with great cosmetic results.

Bed bugs

Whitney A. High, Glen R. Needham

Human bed bugs (*Cimex lectularius*) are insects that require a blood meal to complete their life cycle, and this meal is typically acquired by biting sleeping humans. The bite can elicit an allergic reaction, creating pruritic, erythematous papules that are often excoriated and may become secondarily infected.

MANAGEMENT STRATEGY

Bed bug infestations are more common due to resistance and/or subsequent banning of the pesticide, dichlorodiphenyltrichloroethane (DDT).

Bed bugs usually bite just before dawn and lie in close proximity to humans' sleeping quarters. Although the bite of a bed bug is painless, an allergic reaction may ensue in some individuals, resulting in a skin lesion. Bed bugs typically bite exposed surfaces, such as the extremities or head/neck. The insect will not usually venture beneath bedding or bed clothes. A linear arrangement to bites is common.

The insect does not reside or lay eggs upon humans. Treatment focuses upon *detection and eradication of the household infestation*. *Insecticides, growth-regulating agents, and destructive modalities* may be employed to kill adults, progeny, and eggs. Many authorities believe that safe and successful eradication requires professional assistance.

Use of insecticides in the United States is regulated by the Environmental Protection Agency. The extended residual effect of DDT resulted in environmental damage; its use was banned. Resistance, first to DDT and later to malathion, may be an issue with its reemergence of bed bugs. More recently, pyrethroids (e.g., deltamethrin) have been utilized in controlling bed bug infestations, but, again, resistance has emerged.

There is interest in use of temperature extremes to eradicate infestations. *Steam* may be utilized to sterilize a mattress or similar materials for which insecticides are inappropriate, but a target temperature of 160–180°F must be reached over the entirety of the surface.

Commercial *whole room/whole home heating*, using propane heaters and fans, is available. Most of these systems achieve

a target temperature of around 113°F, held for 15–60 min. Although this temperature is less than the thermal death point of bed bugs (118°F), such treatments are often successful, presumably due to powerful convection currents that desiccate the insects. Other comparatively simplistic measures, such as impermeable mattress covers, are also widely employed.

The manipulation of insect pheromones is gaining interest, as bed bugs use pheromones to aggregate for mating and to increase local humidity and avoid desiccation. Ergo, blocking of this pheromone signaling may have disastrous effects upon a bed bug colony.

Treatment of bed bug bites among humans is directed at symptoms. Skin lesions are due to an allergic reaction to the saliva leaked during feeding. Sensitization is not universal, and some individuals will not react to bites.

Symptomatic bed bug bites produce an erythematous wheal, followed by a firm, reddish papule, sometimes with a central hemorrhagic punctum. Papulonecrotic and bullous forms have been described. Bites are often pruritic and are usually present on surfaces that are exposed during sleep, such as the head, neck, and extremities. Bite symptoms are treated with *potent topical steroids and antihistamines*.

The position of the US Centers for Disease Control and Prevention (CDC), and the bulk opinion of other experts, is that, as of yet, there is no clear evidence of successful transmission of a bloodborne pathogen via bed bug bites. Additional laboratory testing beyond bacterial culture of superinfected bites is not recommended.

Travel is a widely recognized contributing factor to the 'epidemic' of bed bug infestations. Hotels and other lodging facilities, regardless of cleanliness or cost, may be infested, and it is possible to bring an infestation home after a stay in infested lodgings.

It is important to inspect lodging facilities upon check-in. Luggage should be kept closed, or even sealed in plastic bags, to be left at the destination upon departing. Use of dressers and bureaus in a hotel room is discouraged. Metal luggage stands are preferable to wooden stands.

The re-emergence of the bed bug as a nuisance pest: implications of resistance to the pyrethroid insecticides. Davies TG, Field LM, Williamson MS. *Med Vet Entomol* 2012; 26: 241–54.

Resistance of bed bugs to insecticides is contributing to its resurgence as a pest. Reports of increasing resistance to pyrethroids exist throughout the world. The authors of this review report deltamethrin resistance in colonies obtained from more than 20 cities in the United States.

Insecticide resistance among bed bugs may be mediated by genetic mutations on target proteins, by overexpression of detoxifying enzymes, or by thickening of the insect cuticle with reduced insecticide penetration. The existence of multiple pathways of resistance bodes ominously for ever-increasing problems with eradication of infestations.

Acute illnesses associated with insecticides used to control bed bugs – seven states, 2003–2010. Centers for Disease Control and Prevention (CDC). *MMWR* 2011; 60: 1269–74.

Although subject to concerns of over/underreporting, the CDC recently detailed 111 illnesses spanning 2003–2010, including one fatality, attributed to excessive and/or inappropriate use of insecticides for bed bugs. The authors encourage persons with bed bug infestations to seek the services of a certified exterminator; strict adherence is necessary with regard to product instructions and warnings.

Use of consumer-grade indoor 'foggers' or 'bombs' for bed bugs is discouraged by experts because such products typically only scatter bed bugs over a larger area. Silica gel or diatomaceous earth may be used as a less toxic (but also less effective) alternative that kills via dehydration. There is no effective 'repellent' for bed bugs.

Bed bug aggregation pheromone finally identified. Gries R, Britton R, Holmes M, et al. *Angew Chem Int Ed Engl* 2015; 54: 1135–8.

Adult males, virgin adult females, and juvenile bed bugs respond to an airborne aggregation pheromone. In this article, the authors identified five volatile components (dimethyl disulfide, dimethyl trisulfide, (*E*)-2-hexenal, (*E*)-2-octenal, 2-hexanone) that attract bed bugs to safe shelters, and one less-volatile component (histamine), which causes arrestment upon contact.

Bed bugs reproduce via traumatic insemination, and females have structural adaptations to deal with this insult, whereas males have no such adaptations. Young males secrete pheromones to discourage other adult males from destructive same-sex copulation, and this represents another avenue of potential susceptibility.

Bedbugs as vectors for drug-resistant bacteria. Lowe CF, Romney MG. *Emerg Infect Dis* 2011; 17: 1132–4.

A report from Canada demonstrated that bed bugs may be capable of transmitting methicillin-resistant *Staphylococcus aureus* within an impoverished community.

Bedbugs. Kolb A, Needham GR, Neyman KM, et al. *Dermatol Ther* 2009; 22: 347–52.

In this review article the authors instruct that, upon returning home, immediate inspection of luggage and other belongings aids in the discovery of bed bugs or eggs in the midst of transport. Unpacking in the garage and/or vacuuming the exterior and interior of bags, with immediate disposal of the vacuum bag in a sealed plastic bag, may be of benefit in preventing undesired translocation.

Specific Investigations

- Visualization of the bed bugs by inspection, traps, or trained dogs
- Skin biopsy

The eggs, adults, and nymphal stages of the organism may be seen with the human eye. Therefore, when bed bug bites are suspected clinically, an appropriate starting point in investigation is careful inspection of sleeping quarters. Other techniques to detect infestation include simple taping of bed legs with sticky tape, placing bed posts in isolating devices or traps (homemade or purchased), or using trained dogs to localize areas of infestation.

Visual Inspection

Visual inspections should begin around the bed area. Adult bed bugs are 5–7 mm in length and vary in color from light brown to dark brown or even violaceous if they recently have fed. Nymphs are smaller and are often clearer in appearance, again unless having fed. Eggs are about 1 mm long, are ovoid with an operculum, and are sticky, adhering to surfaces in small aggregates.

In addition to detecting the organism, there should be a search for fecal smears or flecks of blood upon the bed linens and upon the edges of the mattress and box springs. Bed bugs, even adults, may fit within extraordinarily narrow cracks and crevices in furniture and walls, behind peeling wallpaper, and even behind switch plates. If a credit card can be inserted into a crevice, then it may also host bed bugs!

Lastly, when populations of bed bugs are particularly dense, a pungent but sweet odor, likened to coriander or cut cilantro, may permeate an infested room or an entire house.

Canine Inspection

Dogs have been successfully trained to detect the odor of bed bugs. The training protocol of the commercial kennels is proprietary, and the exact odor the dogs are detecting is unknown.

Bed Bug Traps

Bed bugs are attracted to humans via a combination of heat, carbon dioxide exhalation, and perhaps other detectable scents, such as human body volatiles, such as aldehydes and sulcatone.

Using this information, two commercial bed bug trapping devices have been marketed, and plans to build a homemade trap (using a cat feeding bowl, dry ice, and a Thermos vessel) have been widely published.

The principle in all these devices is to attract bugs coupled with a 'pitfall area' into which the bed bugs fall and cannot escape, or where sticky material entraps the bugs.

Other Monitoring Devices

A marketed device (Climbup Interceptor) consists of two nested plastic bowls, one inside the other, into which the feet of the bed are placed. Bugs migrating into or away from the bed are entrapped between the bowls. Along these same lines, inverted duct tape may be placed, 'sticky-side out,' upon the legs of the bed to entrap bed bugs as they traverse.

Effectiveness of a sugar–yeast monitor and a chemical lure for detecting bed bugs. Singh N, Wang C, Cooper R. *J Econ Entomol* 2015; 108: 1298–1303.

Many active bed bug monitoring devices are expensive or ineffective. Homemade dry ice traps require significant preparation and inconvenience. The authors designed a simple and affordable active bed bug monitor that used a sugar–yeast fermentation reaction to generate CO₂, instead of dry ice or bottled gas, as well as an experimental chemical lure to detect bed bugs. The authors concluded the tool was useful for monitoring bed bug infestations.

Ability of bed bug-detecting canines to locate live bed bugs and viable bed bug eggs. Pfister M, Koehler PG, Pereira RM. *J Econ Entomol* 2008; 101: 1389–96.

The authors examined dogs trained to locate bed bugs by smell. Under test conditions they were able to discriminate bed bugs from other insects with a 97.5% positive indication rate (correct indication of bed bugs when present) and with zero false positives (incorrect indication of bed bugs when not present). They were able to discriminate live bed bugs and viable bed bug eggs from dead bed bugs, cast skins, and feces, with a 95% positive indication rate and a 3% false-positive rate on bed bug feces. In experimentally contrived 'hotel rooms', canines were 98% accurate in locating live bed bugs.

Dermoscopy

Dermoscopy is useful for bed bug (*Cimex lectularius*) bites. Shirato T, Iwata H, Yoshimoto N, et al. J European Acad Dermatol 2016; 30: 539–40.

In this article, the authors report hemorrhagic spots observed by dermoscopy at bite sites, confirmed by biopsy and histologic exam. While not reporting pathognomonic dermoscopic findings, the authors feel dermoscopy is a convenient tool to identify potential bites.

Skin Biopsy

The histology of bed bug bites is non-specific, and similar to other insect and arthropod assault reactions. It includes a perivascular infiltrate of lymphocytes, histiocytes, eosinophils, and mast cells in the upper dermis, perhaps with dermal edema and/or extravasated erythrocytes.

Bullous reactions to bedbug bites reflect cutaneous vasculitis. De Shazo RD, Feldlaufer ME, Mihm MC, et al. Am J Med 2012; 125: 688–94.

The authors examined 'severe' cutaneous reactions, termed *bullous* or *complex reactions*, to bed bug bites and concluded the phenomenon is not rare. Of 357 photographs of bed bug bites posted on the Internet, 6% were bullous. Histopathologic evaluation of

bullous reactions showed a polymorphous picture with histologic evidence of an urticarial-like reaction early on that rapidly developed into a hybrid leukocytoclastic vasculitis, similar to the dermal vasculitis in patients with Churg–Strauss disease.

First-Line Therapies

• Identify and eradicate the infestation	A
• Control symptoms associated with the bites using antihistamines, topical steroids, and, in rare cases, oral steroids	E

Toxicity and potential utility of ivermectin and moxidectin as xenointoxicants against the common bed bug, *Cimex lectularius*. Sheele JM, Ridge GE. Parasitol Res 2016; 115: 3071–81.

In a controlled laboratory experiment, laboratory-reared bed bugs were exposed to varying concentrations of ivermectin and moxidectin using a feeding apparatus. Exposure to ivermectin, more than moxidectin, resulted in long-term sequelae among the insects to include reduced fecundity, feeding difficulty, and incomplete molting, but this was not a clinical trial.

Although interest in a xenotoxicant approach persists, the authors speculated that if ivermectin were used in such a schema, it might require a daily dose of 0.2 mg/kg for a 20-day period, and the safety of such a regimen in humans is not yet well established.

Behçet disease

Erkan Alpsoy

Behçet disease (BD) is a chronic, relapsing, inflammatory, multi-system disease of unknown etiology characterized by oral ulcers (OU), genital ulcers (GU), cutaneous lesions (e.g., erythema nodosum [EN]-like lesions, papulopustular lesions [PPL], superficial thrombophlebitis, extragenital ulcers, pathergy test positivity), ocular, vascular, articular, gastrointestinal, urogenital, neurologic, and cardiac involvement. Diagnosis in most patients can be made clinically only based on mucocutaneous symptoms, which figure prominently in the presentation and diagnosis and are considered the hallmarks of the disease. Therefore, their recognition may permit earlier diagnosis and treatment with beneficial results for prognosis. Due to the lack of a universally recognized pathognomonic laboratory test, the diagnosis is based on clinical criteria. Worldwide, the International Study Group criteria are the most widely used and well-accepted criteria among the experts of this field, which depends on the presence of recurrent OU, relapsing at least three times in 12 months, plus any two of recurrent GU, typical eye lesions, typical cutaneous lesions, or a positive pathergy test.

MANAGEMENT STRATEGY

BD generally runs a chronic course with unpredictable exacerbations and remissions. Male sex and a younger age of onset are associated with more severe disease. Each or any combination of mucocutaneous, articular, and ocular symptoms of the disease may produce significant pain or loss in function, or both. Besides considerable morbidity, the disease confers increased mortality, mainly because of pulmonary as well as large vessel involvement, neurologic, gastrointestinal, and cardiac involvement. BD usually starts with relatively milder manifestations, and severe involvement, in general, appears later. The main aim of the treatment should be the suppression of new inflammatory attacks to prevent irreversible organ damage, especially during the early, active phase of the disease.

In the absence of severe organ involvement, BD treatment is primarily based on the severity and extent of the mucocutaneous symptoms. *Colchicine* 0.5 mg two to four times daily should be the first choice in the treatment of OU, GU, EN-like lesions, and PPL. In resistant patients, *benzathine penicillin* (1.2 MU per month) can be used in addition to colchicine. Short-term corticosteroids (prednisolone, initial dose 40–60 mg daily for 2–4 weeks, tapered over the ensuing 4–6 weeks) in combination with other drugs such as colchicine should be considered as an effective treatment for acute attacks of OU, GU, EN-like lesions, and superficial thrombophlebitis. *Dapsone* 100–150 mg daily can also be used in the treatment of mucocutaneous symptoms as an effective alternative to colchicine but requires more frequent laboratory follow-up. Apremilast (30 mg twice daily) can be evaluated as an important alternative in the first-line treatment in patients who do not respond to previous treatments.

In patients inadequately controlled with the treatments above, azathioprine (2–2.5 mg/kg daily), anti-TNF- α agents (etanercept 25 mg, twice weekly, and infliximab and adalimumab in their usual dosages in psoriasis) and IFN- α (3–12 MU, thrice weekly) can represent effective second-line treatments of mucocutaneous lesions in BD. Cyclosporin (5 mg/kg daily), thalidomide (100–300 mg daily), zinc sulfate (300 mg daily), rebamipide (300 mg daily), isotretinoin (20 mg daily) are other alternatives to control the disease.

Secukinumab (150–300 mg at weeks 0, 1, 2, 3, and 4 and monthly after that), ustekinumab (90 mg at inclusion, at week 4, and then once every 12 weeks), IL-1 receptor antagonist anakinra (100 mg daily) and the full human anti-IL-1 β antibody canakinumab (150 mg every 6–8 weeks), methotrexate (7.5–20 mg weekly), pentoxifylline (400 mg thrice daily) can be used as third-line therapies.

The topical therapeutic agents used in the treatment of BD in randomized, controlled studies are still limited. It is imperative to ensure for the clinician that topical treatment of the disease has an only local effect and should almost always be associated with systemic treatment. *Topical corticosteroids* alone (triamcinolone acetonide in oral paste or dexamethasone ointment, thrice daily) for OU and in conjunction with *antiseptics* (e.g., fusidic acid/beta-methasone) for GU are useful, especially when they are used in the early stage of these lesions. Although the efficacy of anecdotal use of *intralesional triamcinolone acetonide* 5–10 mg/mL has been noted, it should be reserved for large and deep OU or GU since it is a very painful intervention. Topical corticosteroid eye drops are also used in mild attacks of anterior and intermediate uveitis together with mydriatics or cycloplegic agents. *Sucralfate* (5 mL solution, four times daily) can also accelerate healing and diminish the pain in both OU and GU. *Pimecrolimus* cream, twice daily, seems to be safe and efficient in the treatment of GU. *Wet dressings such as aluminum acetate* 3–5% (Burow's solution) can be applied in the early stage of EN-like lesions and superficial thrombophlebitis. This treatment should be combined with rest in bed.

Most experience in the treatment of OU in patients with BD comes from the studies performed in patients with recurrent aphthous stomatitis (RAS). OU of BD are identical to RAS in appearance. Therefore, therapeutic remedies related to RAS, to some extent, can be applied to OU of BD. Topical antibiotics, such as *tetracyclines* (four times daily) and their derivatives (doxycycline once at the initial visit and minocycline four times daily) in gel or mouthwash, *antimicrobial agents* (Listerine mouth rinse and chlorhexidine gel, 2–4 times daily), *amlexanox* (5% in the oral paste, four times daily), and *triclosan mouthwash* twice daily are beneficial by accelerating healing and can be used as first-line treatments of OU of BD. *Hydroxypropyl cellulose*, *diclofenac*, *lidocaine*, *silver nitrate*, *CO₂ laser*, and *Nd:YAG laser* are useful in decreasing pain and can be used in the topical treatment of OU as second-line options (see Ch. 16).

In the presence of severe organ involvement such as ocular, neurologic, gastrointestinal, or large vessel involvement, working in collaboration with other specialties to improve patient outcomes is mandatory. Depending on the organ involved, the drugs listed below can be used alone or in combination: *prednisolone, azathioprine, ciclosporin-A, cyclophosphamide, anti-TNF- α agents, IFN- α , interleukin-1 receptor antagonists, alemtuzumab, tocilizumab, rituximab, and stem cell transplantation.*

Specific Investigations

- Skin pathergy test
- Culture/PCR from oral or GU to exclude herpes simplex virus (HSV) infection
- Serum iron, folate, zinc, and vitamin B₁₂
- Complete blood count
- Urinalysis
- Comprehensive blood biochemistry
- HLA-B51
- A thorough review of systems, and referral for ophthalmologic, rheumatologic, neurologic, gastroenterologic, etc. assessment as appropriate
- Advanced laboratory and/or imaging methods based on organ involvement
- Tissue biopsy, in selected cases (skin primarily, but also tissue from the involved organs such as intestines)

Behçet's disease: a comprehensive review with a focus on epidemiology, etiology and clinical features, and management of mucocutaneous lesions.

Alpsoy E. J Dermatol 2016; 43: 620–32. This review reflects a dermatologist's view of BD. Besides the current state of knowledge regarding the epidemiology, etiopathogenesis, clinical features, and diagnosis, therapeutic approaches, including local and systemic agents for the treatment of mucocutaneous BD, are reviewed.

2018 update of the EULAR recommendations for the management of Behçet's syndrome.

Hatemi G, Christensen R, Bang D, et al. Ann Rheum Dis 2018; 77: 808–18. In this updated systematic literature review, management of BD was analyzed for treating different aspects of the disease.

First-Line Therapies

• Colchicine	A
• Colchicine + benzathine penicillin	B
• Corticosteroids	A
• Dapsone	A
• Apremilast	A
• Topical corticosteroids	A
• Sucralfate	A
• Pimecrolimus	A
• Topical antibiotics (tetracycline, doxycycline, minocycline)	A
• Topical amlexanox	A
• Topical antimicrobials (chlorhexidine, Listerine)	A
• Triclosan	A

A double-blind trial of colchicine in Behçet's syndrome.

Yurdakul S, Mat C, Tuzun Y, et al. Arthritis Rheum 2001; 44: 2686–92. In a prospective, randomized and placebo-controlled study, colchicine 1–2 mg daily reduced the occurrence of GU, EN-like lesions, and arthritis among women, and the occurrence of arthritis among men.

Colchicine and benzathine penicillin in the treatment of Behçet disease: a case comparative study.

MM Al-Waiz, KE Sharquie, MH A-Qaissi, et al. Dermatol Online J 2005; 11: 3. This study found the combined use of colchicine (1 g daily) and benzathine penicillin (1.2 MU monthly) treatment more effective in decreasing clinical manifestation index, the numerical sum of the clinical features, than either drug alone.

A double-blind trial of depot corticosteroids in Behçet's syndrome.

Mat C, Yurdakul S, Uysal S, et al. Rheumatology (Oxford) 2006; 45: 348–52. Low-dose depot steroid (40 mg methylprednisolone acetate every 3 weeks) in 86 patients who had active mucocutaneous lesions without eye and major organ involvement was found to be helpful in controlling EN-like lesions, especially among females.

Several retrospective studies and case series reported the efficacy of corticosteroids in daily and/or higher doses, especially in mucocutaneous lesions, acute uveitis, and neurologic disease. Corticosteroids can be used as monotherapy or in combination with other drugs such as colchicine, interferon (IFN)- α , ciclosporin, or azathioprine.

Dapsone in Behçet's disease: a double-blind, placebo-controlled, cross-over study.

Sharquie KE, Najim RA, Abu-Raghib AR. J Dermatol 2002; 29: 267–79. Study of 20 patients treated with either dapsone 100 mg daily or placebo reported significant reductions in the number, duration, and frequency of OU and number of GU in dapsone-treated patients. Dapsone treatment also decreased the frequency of EN-like lesions and PPL, and suppressed arthritis and epididymitis.

Comparing the effect of phenytoin syrup and triamcinolone acetonide ointment on aphthous ulcers in patients with Behçet's syndrome.

Fani MM, H Ebrahimi, S Pourshahidi, et al. Iran Red Crescent Med J 2012; 14: 75–8. In this randomized, controlled study, 30 patients were treated with 0.1% triamcinolone acetonide ointment thrice daily and other 30 patients with phenytoin syrup thrice daily. The healing response to triamcinolone acetonide (86.7%) was more than phenytoin (53.3%) 1 week later.

The use of sucralfate suspension in the treatment of oral and genital ulceration of Behçet disease: a randomized, placebo-controlled, double-blind study.

Alpsoy E, Er H, Durusoy C, et al. Arch Dermatol 1999; 135: 529–32. Sucralfate (1 g/5 mL), four times daily, for 3 months' duration used as an oral rinse for 1–2 minutes after routine oral care and before bed, decreased significantly the frequency, healing time, and pain of OU and healing time and pain of GU compared with the pretreatment period.

Pimecrolimus versus placebo in genital aphthous ulcers of Behçet's disease: a randomized double-blind controlled trial. Chams-Davatchi C, Barikbin B, Shahram F, et al. *Int J Rheum Dis* 2010; 13: 253–8.

Pimecrolimus, a topical immunomodulator, twice a day seems to be safe and efficient in the treatment of GU, by accelerating healing.

Second-Line Therapies

• Azathioprine	A
• Anti-TNF- α agents	A/B
• IFN- α	A
• Ciclosporin-A	A
• Thalidomide	A
• Zinc sulfate	A
• Rebamipide	A
• Isotretinoin	A
• Diclofenac	A
• Lidocaine	A
• Hydroxypropyl cellulose	C
• Silver nitrate	A
• CO ₂ laser	A
• Nd:YAG laser	A
• Intralesional corticosteroids	E

A controlled trial of azathioprine in Behçet's syndrome. Yazici H, Pazarli H, Barnes CG, et al. *N Engl J Med* 1990; 322: 281–5.

In a randomized, double-blind, placebo-controlled study of 73 patients, azathioprine 2.5 mg/kg daily was sufficient in OU and GU besides ocular inflammation and arthritis. Azathioprine was significantly better than placebo in preventing the development of new eye disease.

Thalidomide in the treatment of the mucocutaneous lesions of Behçet syndrome: a randomized, double-blind, placebo-controlled trial. Hamuryudan V, Mat C, Saip S, et al. *Ann Intern Med* 1998; 128: 443–50.

A remission of OU, GU, and PPL treated with thalidomide 100 mg or 300 mg daily was detected in 22% of 63 patients over 8 weeks. During the 6-month treatment, 30% of the patients remained free of lesions. However, the efficacy was temporary, and discontinuation of the treatment resulted in recurrence of the OU and GU.

Thalidomide therapy was associated with exacerbation of nodular lesions.

Apremilast for Behçet's syndrome – a phase 2, placebo-controlled study. Hatemi G, Melikoglu M, Tunc R, et al. *N Engl J Med* 2015; 372: 1510–8.

One hundred eleven patients have received 30 mg apremilast twice daily or placebo for 12 weeks followed by a 12-week extension phase in which the placebo group was switched to apremilast with a 28-day posttreatment observation phase. Apremilast was useful, particularly in decreasing OU count and pain. It also decreased the number of GU significantly.

The Food and Drug Administration has approved apremilast for the treatment of mucocutaneous manifestations in BD.

Third-Line Therapies

• Secukinumab	D
• Ustekinumab	C
• Anti-interleukin-1	C
• Methotrexate	E
• Pentoxifylline	E
• Mycophenolate sodium	C
• Sulfasalazine	B
• Minocycline	C
• Indomethacin	B
• Cyclophosphamide	E
• Chlorambucil	D
• Tacrolimus	B
• Rituximab	B
• Alemtuzumab	C
• Allicin	B
• Azithromycin	D
• Irsogladine	D
• Tocilizumab	E
• Stem cell transplantation	E
• Intravenous immunoglobulin	E

Short-term trial of etanercept in Behçet's disease: a double blind, placebo controlled study. Melikoglu M, Fresko I, Mat C, et al. *J Rheumatol* 2005; 32: 98–105.

In a study of 40 male patients, etanercept (25 mg twice weekly for 4 weeks) was effective in suppressing most of the mucocutaneous lesions. The drug had an apparent effect on OU and nodular lesions, and the response was as early as the first week. There was a significant decrease in the mean numbers of OU and nodular lesions as well as PPL.

Efficacy of anti-TNF alpha in severe and/or refractory Behçet's disease: multicenter study of 124 patients. Vallet H, Riviere S, Sanna A, et al. *J Autoimmun* 2015; 62: 67–74.

Anti-TNF- α treatments (mainly infliximab [62%] and adalimumab [30%]) in 124 BD patients showed an overall clinical response rate of 90.4%. Clinical responses were found to be 96.3%, 88%, 70%, 77.8%, 92.3%, and 66.7% of patients with severe and/or refractory ocular, mucocutaneous, articular, gastrointestinal, neurologic, and cardiovascular manifestations, respectively.

Anti-TNF- α treatment seems to be efficient in all severe and refractory BD manifestations, and effectiveness is almost similar regardless of the anti-TNF agent used (infliximab or adalimumab).

Interferon alfa-2a in the treatment of Behçet disease: a randomized placebo-controlled and double-blind study. Alpsoy E, Durusoy C, Yilmaz E, et al. *Arch Dermatol* 2002; 138: 467–71.

Interferon (IFN)- α_{2a} treatment, 6 MU thrice weekly, was found to be an effective alternative, particularly for the management of mucocutaneous lesions, and its effect decreased gradually after the cessation of treatment. IFN- α_{2a} treatment decreased the duration and pain of OU and the frequency of GU and PPL significantly at the end of the 3-month treatment.

Many open studies evaluated IFN- α treatment in cases of sight-threatening refractory uveitis with promising results. IFN- α seems to be able to control and achieve remission of uveitis in most patients.

Double-masked trial of cyclosporine versus colchicine and long-term open study of cyclosporine in Behçet's disease. Masuda K, Nakajima A, Urayama A, et al. *Lancet* 1989; 1: 1093–6.

Ciclosporin-A is capable of markedly ameliorating uveitis as well as mucocutaneous lesions. In a controlled study of 96 patients with recurrent uveitis, ciclosporin-A (10 mg/kg) was superior to colchicine (1 mg/day) in reducing the number and frequency of OU and cutaneous lesions (EN-like lesions, thrombophlebitis, and PPL).

Lower doses were also found to be as effective as higher doses. For this reason, 5 mg/kg doses are preferred today.

Oral zinc sulfate in the treatment of Behçet's disease: a double blind cross-over study. Sharquie KE, Najim RA, Al-Dori WS, et al. *J Dermatol* 2006; 33: 541–6.

In a controlled study of 32 patients with mucocutaneous and/or joint disease treated with zinc sulfate 100 mg thrice daily, Sharquie et al. reported an improvement in the clinical manifestations index of mucocutaneous lesions without any side effect.

Efficacy of rebamipide as adjunctive therapy in the treatment of recurrent oral aphthous ulcers in patients with Behçet's disease. Matsuda T, Ohno S, Hirohata S, et al. *Drugs R&D* 2003; 4: 19–28.

In a randomized, double-blind, placebo-controlled study, 35 BD patients, having as the main symptom OU, were treated with rebamipide 300 mg daily plus usual therapy for 3–6 months. Moderate to marked improvement in OU count and pain was 36% in the placebo group and 65% in the drug group.

Rebamipide, an amino acid derivative of 2-quinolinone, is used for mucosal protection, healing of gastroduodenal ulcers, and treatment of gastritis that enhances mucosal defense, scavenging free radicals, and temporarily activating genes encoding cyclooxygenase.

Pulse cyclophosphamide (PCP) for ocular lesions of Behçet's disease: double blind crossover study. Davatchi F, Shahram F, Chams H et al. *Arthritis Rheum* 1999; 42: S320.

Combination of cyclophosphamide (1 g/m² monthly) and corticosteroid therapy was found superior to corticosteroid therapy alone in eye involvement.

Many open studies reported this compound as a beneficial treatment for systemic vasculitides, such as neurologic involvement and arterial aneurysms. However, due to the severe toxicity (e.g., myelosuppression, pulmonary fibrosis, renal toxicity, hemorrhagic cystitis, infertility, malignancy, alopecia),

cyclophosphamide should be selected in cases with the clinically significant disease who are refractory to other agents.

The therapeutic role of isotretinoin in the management of Behçet's disease: a single-blinded, controlled therapeutic study. Sharquie KE, Helmi RM, Noiami AA, et al. *J Drugs Dermatol* 2013; 12: e68–73.

Thirty patients received isotretinoin 20 mg daily. At week 12, isotretinoin was stopped, and patients were given placebo therapy for another 3 months. Authors reported significant reductions in OU parameters and other cutaneous manifestations with isotretinoin treatment.

Efficacy and safety profile of anti-interleukin-1 treatment in Behçet's disease: a multicenter retrospective study. Emmi G, Talarico R, Lopalco G, et al. *Clin Rheumatol* 2016; 35: 1281–6.

Thirty patients receiving anti-IL-1 agents (anakinra 100 mg daily and canakinumab 150 mg every 6–8 weeks) were evaluated. Anti-IL-1 β drugs are efficacious and safe with overall acceptable retention on treatment.

Efficacy of the anti-IL 17 secukinumab in refractory Behçet's syndrome: a preliminary study. Di Scala G, Bettiol A, Cojan RD, et al. *J Autoimmun* 2018; 97: 108–13.

Secukinumab, either 150 mg or 300 mg monthly, improved active mucocutaneous and articular manifestations refractory to colchicine, conventional disease-modifying anti-rheumatic drugs (DMARDs), and at least one anti-TNF- α agent in five patients.

Long term outcome of ustekinumab therapy for Behçet's disease. Mirouse A, Barete S, Desbois A, et al. *Arthritis Rheumatol* 2019; 71: 1727–32.

In a multicenter, prospective study with 30 patients with active oral ulcers resistant to colchicine, ustekinumab (90 mg at inclusion, at week 4, and then once every 12 weeks) decreased the median number of OU significantly at week 12 compared to baseline. Complete response was achieved in 60.0% and 88.9% of patients at weeks 12 and 24, respectively.

Mycophenolate sodium in the treatment of mucocutaneous Behçet's diseases. Köse O, Sizmek I, Pay S. *Int J Dermatol* 2011; 50: 895–6.

Eight of 10 patients with recalcitrant mucocutaneous BD experienced a remarkable improvement of the mucocutaneous lesions after 6 months of treatment with mycophenolate sodium 720 mg twice daily.

Bites and stings

Dirk M. Elston

MANAGEMENT STRATEGY

Bite Reactions

DEET is effective against a broad range of arthropods, but despite many years of use there are still concerns about systemic absorption and safety. Picaridin is effective against mosquitoes and many other arthropods. Permethrin can be used on fabric and has a persistent effect against ticks and chiggers. It paradoxically attracts Southwest Asian *Hyalomma* ticks that carry Congo-Crimean hemorrhagic fever and should be avoided where these ticks are endemic. If prevention fails, second-line treatments aim to improve pruritus. *Topical antipruritics*, such as 1/4% camphor and menthol, *topical anesthetics* such as pramoxine and lidocaine can be helpful. For persistent bite reactions, topical or intralesional corticosteroids may be helpful. Bites are an occasional cause of eosinophilic cellulitis. A veterinarian should be consulted about flea infestation in pets. Antivenin is available for many arachnid toxins, but most respond to rest, ice, and elevation.

Individuals who experience anaphylaxis in response to stings should be referred to an allergist for *desensitization*. Rush desensitization is possible for those with life-threatening allergy. Patients with a history of anaphylaxis should also carry an *epinephrine autoinjector* (EpiPen).

Proteins, formic acid, histamine, and kinins are involved in the pathogenesis of various bite and sting reactions. Both exaggerated local and systemic responses may be IgE-mediated. *Amblyomma testudinarium* tick bites are associated with increased galactose- α -1,3-galactose carbohydrate IgE levels and red meat allergy. Implicated ticks include *Amblyomma species* in the US, *Ixodes* in Australia and Europe, and *Haemaphysalis* in Japan. Basophils serve as antigen-presenting cells and allergic symptoms may be noted with beef, pork, and lamb.

Most arthropod reactions are self-limiting and treatment is largely symptomatic. Most tickborne illnesses other than babesiosis respond to tetracyclines and the prognosis relates to how quickly definitive antibiotic therapy is instituted.

Vectorborne Disease

Most tickborne illness responds to *doxycycline*. For early Lyme disease, evidence suggests that a 10-day course is as effective as longer courses of antibiotic. Babesiosis responds to *clindamycin* and *quinine*, but *azithromycin* and *atovaquone* may be as effective with a lower incidence of side effects. *Atovaquone-proguanil* has been effective in refractory cases in immunocompromised patients.

Specific Investigations

- CBC and fibrin split products after brown recluse spider bite
- Rickettsial immunofluorescence and immunoperoxidase
- Lyme serology
- Enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), and immunofluorescence for virus such as West Nile, dengue, and chikungunya

PCR assays can also be used to identify biting insects that are too small for conventional identification. IgE typing, skin testing, and basophil activation testing can be used to confirm the cause of anaphylaxis. Tryptase levels can be used to predict severe reactions and in forensic investigations to confirm death from anaphylaxis. Expression of Th1 and Th2 trafficking can be used to follow the course of immunotherapy.

Insect bites as a trigger factor of eosinophilic cellulitis. Kucharzyk M, Slowik-Rylska M, Krecisz B. Ann Agric Environ Med 2019; 17: 256–9.

Several biopsies may be required to establish diagnosis. Prior administration of corticosteroids may alter biopsy findings.

If clinical manifestations are suggestive, multiple biopsies may be required. Treated lesions may be misleading.

First-Line Therapies

Prevention

• DEET	A
• Permethrin and other pyrethroids	A
• Picaridin	B
• Combinations of DEET and permethrin	A

Flea treatments for pets

• Lufenuron	A
• Fipronil	A
• Imidacloprid	A

Anaphylaxis

• Epinephrine	A
• Immunotherapy	A

Spider bites

• Rest, ice, and elevation	B
• Tetracycline or triamcinolone for brown recluse bites	C
• Antivenin for brown recluse bites	C
• Antivenin for black widow and redback spider bites	A

Scorpion stings

• Antivenin for some toxic scorpions	B
• Prazosin for Indian red scorpion stings	A

First-Line Therapies—cont'd

Arthropod-borne infections

• Lyme borreliosis	A
• Tetracycline	A
• Amoxicillin in children	A
• Ceftriaxone	A
• Rocky Mountain spotted fever	
• Doxycycline	A
• Human monocytic ehrlichiosis	
• Doxycycline	A
• Human anaplasmosis	
• Doxycycline	A
• Babesiosis	
• Azithromycin and atovaquone	A
• Quinine and clindamycin	A

Insect repellents: an updated review for the clinician. Nguyen QD, Vu MN, Hebert AA. *J Am Acad Dermatol* 2018 Nov 2 [Epub ahead of print].

The use of insect repellents (IR) to prevent systemic infections constitutes a fundamental tenet of public health efforts to eradicate disease. DEET has an excellent safety profile and remarkable protection against mosquitoes and various other arthropods. Other EPA-registered ingredients include permethrin, picaridin, IR3535, oil of lemon eucalyptus, oil of citronella, catnip oil, and 2-undecanone.

Arthropod-borne disease remains a major cause of morbidity and mortality around the globe. Zika virus, malaria, West Nile virus, dengue fever, and Lyme disease are among the best-known of these diseases. This excellent review summarizes currently available EPA-registered repellents.

Effects of sublethal exposure to metofluthrin on the fitness of *Aedes aegypti* in a domestic setting in Cairns, Queensland. Buhagiar TS, Devine GJ, Ritchie SA. *Parasit Vectors* 2017; 10: 274.

Metofluthrin has been shown to be highly effective at reducing bites from *Aedes aegypti*. Its efficacy relates to rapid onset of confusion, knockdown, and subsequent kill of the mosquito. Sublethal exposure does not affect the ability of the mosquito to reproduce, creating opportunities for development of pyrethroid resistance.

Resistance to pyrethroids is common among headlice and is emerging as an issue with pyrethroids used to prevent insect bites.

Canadian recommendations on the prevention and treatment of Zika virus: update. Zika Working Group; Committee to Advise on Tropical Medicine; Travel (CATMAT). *Can Commun Dis Rep* 2016; 42: 101–11.

All travelers to endemic areas should use personal protective measures including IR and barriers against mosquito entry to living areas. Pregnant women should avoid travel to endemic areas. Sexual transmission from male partners has been documented and couples should practice abstinence or use condoms until viral shedding has likely ceased.

Zika virus is a cause of microcephaly and other congenital abnormalities as well as Guillain-Barré syndrome, and these guidelines serve as an important reference.

Reduced effectiveness of repellents in a pyrethroid-resistant strain of *Aedes aegypti* (Diptera: Culicidae) and its correlation with olfactory sensitivity. Yang L, Norris EJ, Jiang S, et al. *Pest Manag Sci* 2019 July 24 [Epub ahead of print].

Behavioral performance in 15-, 30-, and 60-min exposures was assessed for N,N-diethyl-3-methylbenzamide (DEET), ethyl 3-[acetyl(butyl)amino] propanoate (IR3535), and 2-undecanone, as well as pyrethrum extract, transfluthrin, and metofluthrin in susceptible and pyrethroid-resistant *Aedes aegypti*. Reduced sensitivity to these repellents correlated with the *kdr* mutation present in resistant mosquitoes.

Aedes aegypti (Diptera: Culicidae) is a vector of dengue fever, Zika, chikungunya, and yellow fever viruses, and in many areas possesses significant levels of resistance to pyrethroids. Pyrethroid resistance correlates with resistance to other repellents.

Environmentally responsive and anti-bugs textile finishes - Recent trends, challenges, and future perspectives. Saleem F, Iqbal HMN. *Sci Total Environ* 2019 Nov 10; 690: 667–82.

Repellent textile finishes have numerous applications such as in-home textiles, bed nets, and tenting, camping gear, as well as in military uniforms. A large number of insect repellent textile finishes (i.e., N-N-diethyl-m-toluamide, permethrin, cypermethrin, pyrethrum, picaridin, bioallethrin, Citriodiol, and essential oils), as well as commonly used antimicrobial agents (i.e., chitosan, zwitterionic compounds, silver and silver-based compounds, titanium dioxide nanoparticles, imidazolium salts, triclosan, and quaternary ammonium salts), have been evaluated.

Textile finishes have the potential to offer protection against bites and arthropod-borne disease with less impact on the environment.

Susceptibility of *Dermacentor reticulatus* tick to repellents containing different active ingredients. Gliniewicz A, Borecka A, Przygodzka M, et al. *Przegl Epidemiol* 2019; 73: 117–25.

The authors evaluated four different formulations containing DEET, icaridin, IR3535, and mixes of three compounds: DEET, IR3535, and geraniol, against *Dermacentor reticulatus* ticks.

At 90 minutes after application the repellent A (DEET 30%), repellent D (DEET 30%, IR3535 20%, geraniol 0.1%), and repellent G (IR3535 12%) exhibited a 100% effectiveness in protection against ticks, but icaridin 20% dropped to 95%.

DEET remains the 'gold' standard for IR. At 7 hours after application, DEET retained up to 90% efficacy while the other formulation containing DEET 30%, IR3535 20%, and geraniol 0.1% dropped to 60%. Icaridin 20% and IR3535 12% were only effective up to 4 hours after application (85% and 40%, respectively).

Is DEET a dangerous neurotoxicant? Swale DR, Bloomquist JR. *Pest Manag Sci* 2019; 75: 2068–70.

This study reviews data regarding DEET toxicity. There have been few lethal cases of DEET poisoning, usually due to deliberate overdoses. Deleterious effects typically involve skin reactions and encephalopathies, such as seizures; they often abate without sequelae. There is little direct effect on acetylcholinesterase, but G protein-coupled receptors deserve further investigation. Studies with pregnant women found no effect on the developing fetus from proper use and its continued deployment as a repellent is endorsed by both the Centers for Disease

Control and Prevention and the Environmental Protection Agency.

With the rise of Zika virus, there is renewed interest in the safety of DEET products during pregnancy. Overall, the results are reassuring, and the risk–benefit ratio favors use of repellents in areas with a high risk of disease transmission.

Bug off! Severe toxicity following inhalational exposure to N,N-diethyl-meta-toluamide (DEET). Tavares EM, Judge BS, Jones JS. *Am J Emerg Med* 2019; 37(7): e3–e1395. e4.

DEET has been used by millions of people since its introduction in 1956. Overall it has an excellent safety profile. Severe toxicity in this case following inhalational exposure to a ‘bug bomb’ containing 98% DEET.

Stimulation of eryptosis by broad-spectrum insect repellent N,N-Diethyl-3-methylbenzamide (DEET). Alfhili MA, Nkany MB, Weidner DA, et al. *Toxicol Appl Pharmacol* 2019; 370: 36–43.

DEET has been shown to possess cytotoxic and apoptotic properties in nucleated cells. Red blood cells lack intracellular organelles but can undergo programmed cell death, termed eryptosis.

Although generally safe, DEET should be used with caution in patients with severe anemia.

Insecticide resistance modifies mosquito response to DEET and natural repellents. Deletre E, Martin T, Duménil C, et al. *Parasit Vectors* 2019; 12: 89.

Pyrethroid and organophosphate resistance in the malaria vector *Anopheles gambiae* is a growing problem and resistance genes can modify the behavior of *An. gambiae*, increasing or decreasing the effectiveness of DEET and natural compounds.

There is a complex interaction between insecticide resistance genes and resistance to repellents.

Bioabsorption and effectiveness of long-lasting permethrin-treated uniforms over three months among North Carolina outdoor workers. Beard CB, White A, Balanay JA, et al. *Parasit Vectors* 2019; 12(1): 52.

State and county park employees from North Carolina wore treated uniforms for 3 months. The authors collected spot urine samples for biomonitoring of permethrin metabolites at 1 week, 1 month, and 3 months after first use of the uniform. Bioactive amounts of permethrin remained in all clothing swatches tested, although there was great variability. Tick mortality was high overall, with 78% of pant and 88% of sock swatches having mean knockdown percentages ≥85%. In contrast, mosquito mortality was low. The absorbed dosage of permethrin was low.

Pyrethroid resistance associated with a decreased DEET repellency in the common bed bug (Hemiptera: Cimicidae). Vassena CV, Cáceres M, Santo-Orihuela PL. *J Econ Entomol* 2019; 112(2): 997–1000.

This study examined the repellence of DEET against two bed bug colonies from Argentina (one colony susceptible and the other field-collected pyrethroid-resistant) under two starving periods. DEET had a lower effect on the permethrin-resistant colony.

The global resurgence of the bed bug (Cimex lectularius L.) and widespread resistance to pyrethroid insecticides have created the need to find alternatives to chemical control. Unfortunately, this study suggests that permethrin resistance also translates to DEET resistance.

Second-Line Therapies

Repellents

- Botanicals C
- Novel pyrethroids C

Relief of pruritus

- Camphor and menthol E
- Pramoxine E
- Lidocaine E
- Benzocaine E
- Lidocaine/prilocaine E

Treatment of bite and sting reactions

- Superpotent and potent topical corticosteroids E
- For young children: mild-to-moderate strength topical corticosteroids E
- Local ice
- Topical camphor and menthol C
- Topical anesthetics C
- New immunotherapy agents B
- Omalizumab for patients with adverse reactions to immunotherapy C

Indian red scorpion stings

- Captopril C
- Antivenin D

Arthropod-borne infections

- Babesiosis
- Atovaquone-proguanil in immunosuppressed patients C

Cooling the itch via TRPM8. Liu B, Jordt SE. *J Invest Dermatol* 2018; 138: 1254–6.

Menthol causes a cooling sensation and is commonly used in a eutectic mixture with camphor. TRPM8, a menthol- and cold-activated ion channel, is essential for cooling to relieve itch.

Camphor and menthol have long been used in combination for their antipruritic effects. This study suggests that pharmacologic TRPM8 activation holds promise for development of other agents that target itch.

Chemical composition and repellency of *Origanum vulgare* essential oil against *Cimex lectularius* under laboratory conditions. Sharififard M, Alizadeh I, Jahanifard E, et al. *J Arthropod Borne Dis* 2018; 25: 12: 387–97.

The authors examined the repellency effect of oregano essential oil prepared from dried leaves using a hydrodistillation method. The 40% oregano essential oil exhibited 100% repellency against bed bugs at 3, 5, 9, and 24 hours after application while the repellency index of DEET 33% was 100% at 3 and 5 hours, and it decreased to 80% and 27% at 9 and 24 hours.

The common bed bug (Cimex lectularius) has reemerged as a modern plague. In this study, 40% oregano oil exhibited greater repellency compared with commercial insect repellent sticks containing 33% DEET.

Eave ribbons treated with the spatial repellent, transfluthrin, can effectively protect against indoor-biting and outdoor-biting malaria mosquitoes. Mmbando AS, Ngowo H, Limwagu A, et al. *Malaria J* 2018; 17: 368.

The authors studied ribbons treated with 0.02%, 0.2%, 1.5%, or 5% transfluthrin emulsion spatial repellents and wrapped around eaves of houses to prevent outdoor-biting and indoor-biting mosquitoes. Indoor- and outdoor-biting decreased >99% in huts fitted with eave ribbons having $\geq 0.2\%$ transfluthrin.

This technique offers a simple, low-cost means of mosquito control.

Bicomponent fibres for controlled release of volatile mosquito repellents. Sibanda M, Focke W, Braack L, et al., Mater Sci Eng C Mater Biol Appl 2018; 91: 754–61.

Core-sheath, high-density polyethylene with a concentrate containing volatile N,N-diethyl-m-toluamide (DEET) in poly(ethylene-co-vinyl acetate) (EVA) as core showed high residual repellence activity even after 20 cold washes or after 8 months aging under laboratory conditions.

New technology offers an alternative to spray repellents to prevent outdoor mosquito bites.

Repellent and mosquitocidal effects of leaf extracts of *Clausena anisata* against the *Aedes aegypti* mosquito (Diptera: Culicidae). Mukandiwa L, Eloff JN, Naidoo V. Environ Sci Pollut Res Int 2016; 23: 11257–66.

Clausena anisata is used traditionally as an insect repellent by various communities in Africa and Asia. In this study, the repellency and insecticidal activities of leaf extracts and compounds isolated from this plant were evaluated against *Aedes aegypti*, the yellow fever vector. Acetone crude extract (15%) demonstrated 93% repellence and the hexane fraction (7.5%) 67% repellence after 3 hours. Mosquitoes are rapidly developing resistance to insecticides and repellents, suggesting the urgent need for new agents. *C. anisata* leaf extracts have potential to be included in personal protection products against mosquitoes.

Plants traditionally used as mosquito repellents and the implication for their use in vector control. Tisgratog R, Sanguanpong U, Grieco JP, et al. Acta Trop 2016; 157: 136–44.

The authors identified 37 plant species that showed mosquito-repellent properties, and five essential oils extracted from plants demonstrated promising insect repellent activity.

These active ingredients show promise as alternatives to DEET and permethrin.

Larvicidal compounds extracted from *Helicteres velutina* K Schum (Sterculiaceae) evaluated against *Aedes aegypti* L. Fernandes DA, Barros RPC, Teles YCF, et al. Molecules 2019; 22: 24.

Helicteres velutina K. Schum (Sterculiaceae) is a Brazilian plant used by indigenous tribes as an insect repellent. Five molecules were isolated with potential larvicidal activity and three showed an ability to bind with sterol carrier protein-2 (1PZ4), a protein found in the larval intestine.

Tiliroside and 7,4'-di-O-methyl-8-O-sulfate flavone derived from this Brazilian plant showed in vitro larvicidal activity, with LC50 values of 0.275 mg/mL after 72 h and 0.182 mg/mL after 24 h of exposure, respectively, supporting H. velutina as an alternative source of

insecticide for the control of A. aegypti, which is a vector for severe arboviruses, including yellow fever, dengue, and chikungunya.

Andean flora as a source of new repellents against insect pests: behavioral, morphological and electrophysiological studies on *Sitophilus zeamais* (Coleoptera: Curculionidae). Romani R, Bedini S, Salerno G, et al. Insects 2019; 14: 10.

Plant-derived essential oils from *Clinopodium tomentosum* and *C. nubigenum* are promising tools for pest control.

The repellency and toxicity effects of essential oils from the Libyan plants *Salvadora persica* and *Rosmarinus officinalis* against nymphs of *Ixodes ricinus*. Elmhalli F, Garbouei SS, Borg-Karlson AK, et al. Exp Appl Acarol 2019; 77: 585–99.

The results suggest that essential oils have potential as alternative repellents and insecticides for tick control.

Chemical composition and biting deterrent activity of essential oil of *Tagetes patula* (Marigold) against *Aedes aegypti*. Ali A, Tabanca N, Amin E, et al. Nat Prod Commun 2016; 11: 1535–38.

Essential oil distilled from marigolds exhibited good activity against *Aedes aegypti* L. Sesquiterpenes have potential as IR, but also significant potential as contact sensitizers.

Third-Line Therapies

Treatment of bites

- Intralesional corticosteroids **E**
- Enhanced penetration topical antihistamines **B**

Repellents

- Newer agents and botanicals **C**
- New vaccines in development for vectorborne illness **E**

Evaluation of commercial agrochemicals as new tools for malaria vector control. Hoppé M, Hueter OF, Bywater A, et al. Chimia (Aarau) 2016; 70: 721–9.

Four new insecticides and three fungicides with promising activity against adult malaria-carrying mosquitoes were identified, namely acetamiprid, thiamethoxam, thiocyclam, and metaflumizone and the fungicides diflufenetorim, picoxystrobin, and fluazinam.

Commercial agricultural chemicals show promise as potential insecticides for control of malaria.

A preventive immunization approach against insect bite hypersensitivity: intralymphatic injection with recombinant allergens in Alum or Alum and monophosphoryl lipid A. Jonsdottir S, Svansson V, Stefansson SB, et al. Vet Immunol Immunopathol 2016; 172: 14–20.

IgE-mediated insect bite hypersensitivity was examined in a horse model. Immunotherapy demonstrated that induced antibodies could block binding of allergen specific IgE.

This is an important proof of concept study for desensitization against insect bites.

Blastomycosis

Wanda Sonia Robles, Mahreen Ameen

Mason, A.R., Cortes, G.Y., Cook, J., Maize, J.C. and Thiers, B.H. (2008), Cutaneous blastomycosis: a diagnostic challenge. *International Journal of Dermatology*, 47: 824-830. <https://doi.org/10.1111/j.1365-4632.2008.03732.x>; with permission.

Blastomycosis is a systemic, suppurative granulomatous fungal infection caused by thermally dimorphic fungi belonging to the genus *Blastomyces*. These pathogens show great genetic and geographic diversity. The most common pathogen is *Blastomyces dermatitidis*. However, there are other less common species including *Blastomyces gilchristii*, *Blastomyces parvus*, and atypical forms of the condition caused by *Blastomyces helicus*. Their natural habitat is considered to be woods and soil close to rivers. The disease has a primary pulmonary stage as it is acquired by the inhalation of conidia. This is transformed into the yeast form once in the lungs followed by dissemination to other body sites. It is an endemic mycosis more prevalent in the North American continent mainly in areas of the United States and Canada surrounding the Ohio and Mississippi river valleys and the Great Lakes. However, more recently, different species have been described in South Africa as responsible for human blastomycosis. These include *Blastomyces percursoris* and *Blastomyces emzantsi*. Cases have also been reported in other parts of Africa, Latin America, the Middle East, India, and Poland.

Blastomycosis is associated with a spectrum of disease from asymptomatic subclinical infection to acute or chronic pneumonia. Most cases are restricted to the respiratory system, and many are asymptomatic. Clinically there are three different forms of the disease: primary cutaneous, pulmonary, and disseminated. Most cases are restricted to the respiratory system, many of which are asymptomatic. Some individuals may have flu-like symptoms and others may have severe pneumonia. Extrapulmonary infection occurs in 25%–40% of cases and most commonly affects the skin. Cutaneous manifestations of the disease range from papules, pustules, and subcutaneous nodules to ulcers and crusty sores. Over a period of months and years lesions grow larger and may become raised, wart-like scars or verrucous lesions, causing disfigurement. The bones, genitourinary system, and central nervous system (CNS) may be involved. Dissemination occurs more frequently in the immunocompromised and those with human immunodeficiency virus (HIV) infection. The immunocompromised are at higher risk of CNS involvement and fast, progressive, severe acute

respiratory distress syndrome (ARDS). Their prognosis is poor and therefore they require more aggressive management.

MANAGEMENT STRATEGY

In the immunocompetent individual with mild disease, the condition may be self-limiting, requiring no treatment with spontaneous clearance. However, all diagnosed cases are treated in order to prevent extrapulmonary dissemination. When infection spreads and skin involvement is evident, spontaneous resolution does not occur and treatment is necessary. *Itraconazole* is the drug of choice for mild-to-moderate infection that is not life-threatening including pulmonary infection, disseminated infection and infection in children. For moderately severe to severe disease the drug of choice is a lipid formulation of *amphotericin B (AmB)* or *AmB deoxycholate*, including pulmonary, disseminated, immunosuppressed patients and in children until improvement becomes evident (1–2 weeks), followed by oral *itraconazole* for a total of 6–12 months. In pregnant women the treatment of choice is lipid AmB. This is also the drug of choice for those who fail on treatment with azoles. Patients with osteoarticular blastomycosis should be treated for at least 12 months. Patients with CNS blastomycosis should be treated with *AmB* for 4–6 weeks followed by oral azole, either *fluconazole* or *itraconazole*, for at least 12 months and until resolution of cerebrospinal fluid (CSF) abnormalities. This step-down therapy to an azole is common practice. Immunosuppressed patients including those with acquired immune deficiency syndrome (AIDS) should be treated with lipid AmB or deoxycholate AmB for 1–2 weeks followed by step-down therapy with *itraconazole*. In this population *fluconazole* is not as effective as *itraconazole*. Serum levels of *itraconazole* should be monitored during the first 2–4 weeks of treatment and lifelong suppressive therapy is recommended. In pregnancy azoles should be avoided due to possible teratogenicity. In infection of the newborn the recommended drug of choice is *AmB deoxycholate*.

Specific Investigations

- Direct microscopy
- Culture. Specimens for diagnosis:
 - Pneumonia: sputum, bronchial washing, bronchial lavage
 - Cutaneous or subcutaneous: skin or deep tissue biopsy, scrapings, exudate
 - Osteoarticular: joint fluid, synovial tissue biopsy, bone biopsy
 - Genitourinary: prostate biopsy specimen, urine
 - Meningitis: CSF
 - Disseminated disease: bone marrow
- Histopathology:
 - Antibody tests
 - Antigen detection
- Chest X-ray
- Bone scanning (radionuclide bone scan/computed tomography [CTI]/magnetic resonance imaging [MRI])
- Serology for HIV infection (where relevant)

Direct examination should be performed in addition to culture. The presence of yeast cells allows a rapid diagnosis. Definitive diagnosis is based on the identification of characteristic thick-walled, broad-based budding yeasts by direct examination of tissue or the isolation of *Blastomyces* in culture. Specimens for direct microscopy in 10% potassium hydroxide (KOH) solution can be skin scrapings, pus from skin lesions, sputum, and biopsy tissue

from any lesion suspicious of infection. This can be used with or without the addition of calcofluor white. Culture is the most sensitive method of diagnosis. Successful culture in a variety of media from sputum, tissue biopsy specimens, CSF, or urine produces a white mold at 25°C on Sabouraud agar and a brown wrinkled colony at 37°C in blood agar. Histopathology of infected tissues shows a granulomatous response without caseation and pseudo-epitheliomatous hyperplasia and the finding of the classic yeast form in tissues. Classic antibody testing has poor sensitivity and specificity. A newer antibody enzyme immunoassay (EIA) that uses *Blastomyces dermatitidis* surface protein BAD-1 has better sensitivity and specificity. Analysis of fungal microbiome (mycobiome) of the lungs during fungal infection by sequencing has lately been used as an adjunct to traditional microbiology testing.

First-Line Therapies

- Itraconazole **B**
- Lipid and deoxycholate amphotericin B **C**

Itraconazole therapy for blastomycosis and histoplasmosis. NIAID Mycosis Study Group; Dismukes WE, Badcher RW, Cloud JC, et al. *Am J Med* 1992; 93: 489–97.

A prospective non-randomized, multicenter trial involving 48 patients with pulmonary or disseminated blastomycosis without CNS involvement. Patients were treated with itraconazole 200–400 mg/day for a median period of 6.2 months with a 90% cure rate (43/48). Treatment was very well tolerated and there was no therapeutic advantage for patients treated with the higher dose.

Blastomycosis. Castillo CG, Kauffman CA, Miceli MH. *Infect Dis Clin North Am* 2016; 30: 247–64.

This very good review advocates the use of itraconazole for either mild-to-moderate pulmonary or extrapulmonary infection and lipid formulation AmB for severe or life-threatening infection followed by step-down therapy with itraconazole.

Clinical manifestations and treatment of blastomycosis. McBride JA, Gauthier GM, Klein BS. *Clin Chest Med* 2017; 38(3): 435–49.

A very good review focusing on the often diagnostic and therapeutic challenge of the condition. It also stresses the need for awareness from clinicians that Blastomyces spp. can infect and disseminate on both the immunocompetent and the immunocompromised, as well as the common issues associated with the use of polyene and azole antifungal drugs to minimize risks associated with treatment.

Blastomycosis of the central nervous system: a multicentre review of diagnosis and treatment in the modern era. Bariola JR, Perry P, Pappas PG, et al. *Clin Infect Dis* 2010; 50: 797–804.

A retrospective study of 22 patients with CNS infection treated with either AmB deoxycholate or lipid formulation AmB followed by a prolonged course of oral azole therapy (voriconazole, fluconazole, or itraconazole).

The most favorable outcomes were achieved with initial treatment with a lipid formulation of AmB followed by a prolonged course of oral voriconazole.

Blastomycosis. Schwartz IS, Kauffman CA. *Semin Respir Crit Care Med* 2020; 41: 31–41.

The latest formal review, which highlights the clinical spectrum of the disease from asymptomatic to fatal disease. It also contains good scientific evidence on treatment of severe complications of blastomycosis.

These include the need for early and effective treatment of blastomycosis-associated ARDS if the patients are to survive as well as reports on the increasing number of institutions using extracorporeal membrane oxygenation for these patients with good outcomes.

Second-Line Therapies

- Fluconazole **B**
- Voriconazole **C**
- Posaconazole **D**

Treatment of blastomycosis with higher doses of fluconazole. The National Institute of Allergy and Infectious Disease Mycoses Study Group; Pappas PG, Bradsher RW, Kauffman CA, et al. *Clin Infect Dis* 1997; 25: 200–5.

This multicenter, randomized, open-label study investigated the efficacy of high-dose fluconazole (400–800 mg/day) for the treatment of non-life-threatening blastomycosis. There was an 87% cure rate (34/39) after a mean period of treatment of 8.9 months.

This study demonstrates a much higher efficacy for fluconazole at dose of 400–800 mg daily.

The role of voriconazole in the treatment of central nervous system blastomycosis. Ta M, Flowers SA, Rogers PD. *Ann Pharmacother* 2009; 43: 1696–1700.

Seven cases of CNS blastomycosis successfully treated sequentially with AmB followed by voriconazole are described.

Animal and human studies indicate that high concentrations of voriconazole can be achieved in the CSF and brain tissue. The authors suggest that voriconazole may be considered an azole option for either follow-up therapy after lipid AmB or as salvage therapy in patients intolerant to AmB or other azoles.

Posaconazole: use in the prophylaxis and treatment of fungal infections. Clark NM, Grim SA, Lynch JP. *Semin Respir Crit Care Med* 2015; 36(5): 767–85.

A good review of the use of approved indications for the use of posaconazole by the US Food and Drug Administration as well as the European Medicines Agency. In addition to approved indications, posaconazole as salvage therapy for invasive fungal infections and endemic mycosis including coccidioidomycosis, histoplasmosis, and blastomycosis. It can also be used as a combination agent for difficult-to-treat fungal infections.

GUIDELINES

Clinical practice guidelines for the management of blastomycosis: 2008 update by the Infectious Disease Society of America. Infectious Disease Society of America; Chapman SW, Dismukes WE, Proia LA, et al. *Clin Infect Dis* 2008; 46: 1801–12.

There has been no updated evidence-based guideline since 2008 and this replaced the previous guidelines from 2000. The clinical manifestations of the disease vary from asymptomatic or subclinical infection to acute or chronic pneumonia or disseminated disease, any of which may become fatal. Those infected may have only pulmonary disease, but 25%–40% may develop infection that may be cutaneous, osteoarticular, genitourinary, or CNS disease. Blastomycosis may also affect special populations including immunocompromised hosts (HIV/AIDS, organ transplant recipients, or patients on biologic interventions), pregnant women, and children or the newborn.

Itraconazole is the drug of choice for the treatment of mild-to-moderate pulmonary or disseminated infection. The

recommendation is an initial loading dose of 200 mg three times daily for 3 days, followed by 200 mg once or twice daily for 6–12 months. Serum levels should be measured after 2 weeks to ensure adequate drug exposure.

AmB is the treatment of choice for those with moderately severe to severe pulmonary infection including children and in the immunocompromised. Either the lipid formulation (3–5 mg/kg/day) or AmB deoxycholate (0.7–1 mg/kg/day) is given for 1–2 weeks or until improvement is noted. Itraconazole is then recommended as step-down therapy (loading dose and then 200 mg twice daily for 6–12 months, except in the immunocompromised, who require at least 12 months of treatment or until immunosuppression has been reversed).

For CNS disease, lipid AmB at the dose of 5 mg/kg/day for 4–6 weeks is the recommended treatment, followed by an oral azole (fluconazole 800 mg daily, itraconazole 200 mg two to three times daily, or voriconazole 200–400 mg twice daily), which should be given for at least 1 year and until there is resolution of CSF abnormalities. Despite this recommendation by the Infectious Disease

Society of America Guidelines of either fluconazole or itraconazole for step-down therapy, voriconazole has become the preferred drug for CNS blastomycosis, mainly because voriconazole has better activity against *B. dermatitidis* than fluconazole and it has better CNS penetration than itraconazole.

Immunosuppressed patients are more likely to develop disseminated disease and may have more severe pulmonary symptoms like ARDS. It is therefore recommended that they are treated initially with lipid AmB until clinical response is evident. Then transition to oral itraconazole is appropriate.

AmB is the only drug approved for treatment of blastomycosis in pregnant women. The lipid formulation is the preferred one.

Children with mild-to-moderate blastomycosis should be treated with itraconazole 10 mg/kg/day for 6–12 months. Daily dose should not exceed 400 mg. Moderately severe to severe disease in children should be treated with AmB deoxycholate or lipid AmB.

AmB is the drug of choice for patients who have failed to respond to azole treatment.

Blistering distal dactylitis

Irshad Zaki

Courtesy of Joseph Bikowski, MD

Blistering distal dactylitis (BDD) is a superficial, tender, blistering infection seen in childhood and the early teens. It is usually caused by group A β -hemolytic streptococci, although group B organisms, staphylococci, and, more recently, methicillin-resistant *Staphylococcus aureus* (MRSA) have also been implicated. The distal volar fat pads of the fingers are the most common site of infection, but more extensive involvement of the nailfolds and toes can occasionally occur.

MANAGEMENT STRATEGY

BDD can cause considerable alarm to parents, as large, tense blisters rapidly develop. Despite the absence of constitutional symptoms, patients usually seek help soon after the onset of the infection. The condition does not resolve spontaneously, but prompt treatment results in rapid improvement. *Blisters should be incised to release fluid*, which can vary from clear and watery to frank pus. Subsequent application of topical antibiotics can be helpful, but systemic treatment is usually also required. *Penicillin V* is the treatment of choice for streptococcal infection, but *erythromycin* is an effective alternative for patients allergic to penicillin. It is important to exclude MRSA or immunosuppression for resistant cases.

The differential diagnosis of the condition includes traumatic blisters, herpetic whitlow, staphylococcal bullous impetigo, and the Weber–Cockayne variant of epidermolysis bullosa.

Specific Investigations

- Gram stain of blister fluid
- Culture of blister fluid
- Swab of nasopharynx for bacteriology

A clinically recognizable streptococcal infection. Hays GC, Mullard JE. *Paediatrics* 1975; 56: 129–31.

First large series report describing 13 patients with BDD. Streptococci were found on culture of blister fluid in all cases, and Gram-positive cocci were usually found on Gram staining. This report suggests a link with infection of the nasopharynx, but this has not been confirmed in other case reports.

Blistering distal dactylitis in an adult. Kollipara R, Downing C, Lee M, et al. *J Cutan Med Surg* 2015; 19: 397–9.

Although the majority of cases are in children over the age of 2, this has also been described in adults, particularly if immunosuppressed. Bacteriology should be considered for an isolated distal phalanx blister at any age.

Blistering distal dactylitis. Kowtoniuk R, Bednarek R, Maroon M. *JAMA Dermatol* 2018; 154(12): 1480.

Although this disorder affects the distal digit in most patients, this report demonstrates that it can be more extensive.

First-Line Therapies

• Incision and drainage of blister	C
• Topical antibiotics	C
• Systemic penicillin	C

Is blistering distal dactylitis a variant of bullous impetigo? Scheinfeld NS. *Clin Exp Dermatol* 2007; 32: 314–6.

Good review of literature and treatment. Confirms the importance of incision and drainage, adequate dressings, and the need to consider *S. aureus* as a cause if penicillin is ineffective.

Second-Line Therapies

• Systemic erythromycin	D
• Intravenous vancomycin	D

Blistering distal dactylitis: a manifestation of group A beta-haemolytic streptococcal infection. Schneider JA, Parlette HL. *Arch Dermatol* 1982; 118: 879–80.

Short report of the authors' personal experience, suggesting that this is a relatively common problem. Systemic penicillin and erythromycin were both found to be effective. It is likely that many cases of BDD are wrongly diagnosed as bullous impetigo by clinicians not familiar with this disorder.

MRSA blistering distal dactylitis and review of reported cases. Fretzayas A, Moustaki M, Tsagris V, et al. *Pediatr Dermatol* 2011; 28: 433–5.

First report of BDD due to MRSA infection. This case highlights the importance of culture of blister fluid, as infection with this organism may increase in the future.

Third-Line Therapies

• Amoxicillin/clavulanic acid	D
• Conservative measures for herpetic whitlow	D

A review and report of blistering distal dactylitis due to *Staphylococcus aureus* in two HIV-positive men. Scheinfeld N. *Dermatol Online J* 2007; 13: 8.

S. aureus was found to be the etiologic agent in two HIV-positive patients. The condition improved after treatment with a proprietary mixture of amoxicillin trihydrate and clavulanate potassium. The report highlights that blisters may not always be present and that BDD may present with erosions.

Coexistent infections on a child's distal phalanx: blistering dactylitis and herpetic whitlow. Ney AC, English JC 3rd, Greer KE. *Cutis* 2002; 69: 46–8.

Consider comorbidity if BDD does not respond to antibiotics.

Body dysmorphic disorder (dermatologic non-disease)

Synonyms: Dermatologic non-disease, Body dysmorphic disease, Dysmorphophobia

Richard Fried, Danielle Weitzer

Body dysmorphic disorder (BDD) is an alteration in perception of body image that causes preoccupation with minimal or imagined defect in appearance. The preoccupation can be markedly excessive, causing clinically significant emotional distress and impairment in social, occupational, or other important areas of functioning. Preoccupations commonly involve the face and head, with skin and hair being the most frequent areas of concern. However, any area of the body may be involved. Dermatologic preoccupations are distressing, time consuming, and difficult or impossible for patients to resist. Insight is typically poor and alterations in perception are often to delusional proportion. Most patients have ideas of reference, thinking that others take special notice or mock them for their perceived defect. Repetitive behaviors are present in almost all patients, such as excessive checking or grooming, innumerable consultations with dermatologists and plastic surgeons, constant need for reference and reassurance, and skin manipulations. Risk of suicidal ideation and attempts is high, affecting approximately one-quarter of BDD patients. BDD was reclassified in the DSM-5 under obsessive-compulsive and related disorders.

MANAGEMENT STRATEGY

BDD is common in dermatologic settings with prevalence estimated at 11.9%, 3–53% in cosmetic surgery settings, and 8–37% in those with obsessive-compulsive disorder. Recognition of these patients is extremely important because they typically have psychiatric comorbidities, diminished quality of life, and impairments in psychosocial and vocational function. They are usually poor candidates for cosmetic procedures. Dissatisfaction, anger, and even aggression directed toward the treating clinician have been reported. Patients with BDD often have associated psychiatric disorders including major depression, substance abuse and dependence, social phobia, and obsessive-compulsive disorder. Recent studies with MR imaging have suggested abnormal brain network organization, which may provide some biological basis for the characteristic distortions in self-perception. The majority of these patients also have a personality disorder. Appropriate psychiatric treatment can result in a generally favorable outcome.

Typical body areas of preoccupation include:

- **Face.** Preoccupation with facial itching and burning or obsessive preoccupation with imagined acne, scars, wrinkles, pigmentation, oiliness, redness, paleness, facial vessels, and facial hair are common. Preoccupation with the nose, ears, and pore size is reported. Despite the fact that others do not usually see these minimal or non-existent flaws, patients can spend hours in front of mirrors, preventing them from working or socializing.
- **Scalp.** Dysesthesias (burning or itch) and obsession with imagined hair loss are common.
- **Genital.** Genital size, scrotal, perineal, and perianal burning, as well as vulvar redness and burning are common symptoms. Preoccupation with sexually transmitted disease or neoplastic process is common. Symptoms can be incapacitating.

Hallmarks and Flags for Diagnosis of Body Dysmorphic Disorder

Patients presenting with extreme concern that appears out of proportion to their chief complaint accompanied by a paucity of objective physical findings should raise suspicion that BDD may be present. Obsession, rumination, and extreme psychological distress are striking features. These patients usually report dissatisfaction with previous physicians and describe poor outcomes from past medical and surgical interventions. Skin picking and related behaviors such as excessive tanning, excessive grooming, and relentless need for reassurance are characteristic. Attempts to correct their perceptions are inevitably futile since their perceptual distortions and associated cognitions are deeply entrenched. It can be argued that the distorted perceptions are delusional, which by definition suggests that they are unresponsive to objective logic and persuasion. Patients often wear heavy makeup, hats, sunglasses, scarves, and other clothing to hide their imperfections and perceived ugliness (Table 30.1).

Patients with BDD often make unusual and excessive requests for cosmetic procedures with the belief that the procedure will transform or fix their lives. Poor psychosocial functioning with difficulties in relationships, school, and work is almost always seen. Depression is frequently evident and previous suicide attempts are not infrequent. Bear in mind that there have been instances of violent behavior toward treatment providers.

Clinical interactions and consultations with these patients are typically long, difficult, and emotionally draining. Regardless of the actual length of time spent with them, BDD patients often feel that they were not given adequate time and attention. As already

Table 30.1 Screening questions

1. How much do you currently think about your skin?
2. On an average day, how many hours do you spend thinking about your skin? Please add up all the time that your feature is on your mind and make your best estimate.
3. Do you feel your skin is ugly or very unattractive?
4. How noticeable do you think your skin is?
5. Does your skin currently cause you a lot of distress?
6. How many times a day do you usually check your skin either in a mirror or by feeling it with your fingers?
7. How often do you feel anxious about your skin in social situations? Does it lead to you avoiding social situations?
8. Has your skin affected dating or an existing relationship?
9. Has your skin interfered with your ability to work or study, or your role as a homemaker?

(Adapted from Veale D, Ellison N, Werner TG, et al. Development of a cosmetic procedure screening questionnaire (COPSS) for body dysmorphic disorder. *J Plast Reconstr Aesthet Surg* 2012; 65(4): 530–532.)

stated, it is inadvisable to perform procedures on these patients since less than 10% will be satisfied with the results of medical or surgical interventions.

Selective serotonin reuptake inhibitors (SSRIs) and cognitive-behavioral psychotherapy remain the treatments of choice. Fluoxetine, fluvoxamine, and citalopram are the best studied agents, but recent evidence suggests that all SSRIs are probably effective. Higher dosing regimens than those used for depression are usually required. For example, fluoxetine and citalopram should be titrated to 60 mg per day while fluvoxamine should be increased to 300 mg per day at monthly intervals. Patients should receive a trial of 12–16 weeks before efficacy is assessed. If one agent fails, another should be substituted since some patients idiosyncratically respond more favorably to one agent over another. SSRIs appear to be more effective than antipsychotic agents despite the fact that BDD can involve severe distortions in self-perception to delusional proportion. Interestingly, only about 20% of patients will become free of their delusional thinking. However, the intrusiveness of the thoughts and distress will diminish sufficiently such that many patients will be able to resume some social and vocational functioning.

Cognitive-behavioral therapy (CBT) is a reality-based, in-the-present therapy that specifically focuses on the affected individual's cognitions and associated emotional experiences. The key elements are known as exposure, response prevention, perceptual retraining, and cognitive restructuring. Exposure consists of having patients expose the perceived defect in social and work situations. Response prevention techniques help patients avoid performance of their repetitive behaviors such as avoidance of others, excessive camouflage, picking, hyperventilating, etc. Perceptual retraining involves the development of a more holistic positive view of appearance. Cognitive restructuring helps patients challenge and eventually change their erroneous beliefs about their appearance. Ideally, treatment of BDD should encompass both CBT and an SSRI.

To initiate treatment or referral, suggest to the patient in a gentle manner that they may have a body image disorder called BDD. Convey your concern regarding the amount of their time being usurped by their preoccupation and their emotional distress. Psychiatric referral is preferable but often not feasible. Dermatologists are encouraged to align themselves, if possible, with mental health professionals who are experienced in treating this entity. Euphemisms for the psychiatric practitioner such as skin-emotion specialist may reduce the stigma of psychiatric referral and may

increase patient acceptance. If referral is not possible, treating with an SSRI may be successful. If suicidal ideation or intent are present, immediate hospitalization is recommended.

Specific Investigations

- Assess for potential suicide risk: emergent referral and appropriate notification if active ideation or intent
- Assess for any evidence of physical or emotional abuse
- Assess for evidence of substance abuse
- Assess for concomitant underlying psychiatric disease, i.e., depression/anxiety/OCD/psychosis, and make an appropriate psychiatric referral
- Appropriately diagnose and acknowledge genuine skin disease, i.e., hair loss, acne, rosacea, psoriasis, eczema, keratosis pilaris, seborrheic keratoses, or dyschromia, and offer legitimate therapies
- Investigate perceived skin changes appropriately to rule out atypical presentations of an underlying organic process if suspicion is present. Perform bacterial, viral, fungal cultures, skin biopsy, serologies, and imaging studies when deemed appropriate

Depression, anxiety, anger, and somatic symptoms in patients with body dysmorphic disorder. Phillips KA, Siniscalchi JM, McElroy SL. *Psychiatr Q* 2004; 75: 309–20.

Seventy-five patients with BDD completed a symptom questionnaire assessing depression, anxiety, somatic/somatization, and anger-hostility. Compared to normal controls, BDD subjects had markedly elevated scores on all four scales, indicating severe distress and psychopathology. When treated with fluvoxamine, all symptoms significantly improved.

Quality of life for patients with body dysmorphic disorder. Phillips KA. *J Nerv Ment Dis* 2000; 188: 170–5.

This is the only published study looking at quality of life (QOL) in BDD patients. These patients were found to have a poorer mental health QOL than has been reported for patients with other severe illnesses such type II diabetes, recent myocardial infarction, or depression. These findings highlight the dramatic impact of a non-disease.

Thirty-three cases of body dysmorphic disorder in children and adolescents. Albertini RS, Phillips KA. *J Am Acad Child Adolesc Psychiatry* 1999; 38: 453–9.

Thirty-three cases were examined. Onset was usually during adolescence but sometimes occurred in childhood. Earlier identification and treatment may avert unnecessary cosmetic and medical interventions as well as suicide.

Gender differences in body dysmorphic disorder. Phillips KA, Diaz S. *J Nerv Ment Dis* 1997; 185: 570–7.

This study looked at a large series of patients with DSM-4 defined BDD and found that one-quarter of patients had attempted suicide. Female patients with severe symptoms are at greater risk.

Body dysmorphic disorder. Ahmed I, Bowman D, Power A. *Medscape* October 3, 2019.

Excellent overview of entity and treatment strategies.

Suicide in dermatological patients. Cotterill JA, Cunliffe WJ. *Br J Dermatol* 1997; 137: 246–50.

Sixteen patients who had committed suicide are described. Most of these patients had acne or BDD. Females with facial complaints and men with facial scarring appeared more at risk for suicide. The authors relate these findings to the possible preventative benefits of early isotretinoin to prevent scarring in patients predisposed to BDD.

Diagnostic Aids

The body dysmorphic disorder symptom scale: development and preliminary validation of a self-report scale of symptom specific dysfunction. Body Image 2016; 17: 82–7. (Medline).

First-Line Therapies

- Selective serotonin reuptake inhibitors **A**
- Cognitive-behavioral therapy **B, C**

Treating body dysmorphic disorder with medication: evidence, misconceptions, and a suggested approach. Phillips KA, Hollander E. Body Image 2008; 5: 13–27.

SSRIs associated with improvement in core BDD symptoms, psychosocial functioning, QOL, suicidality, and other aspects of BDD.

Pharmacotherapy and psychotherapy for body dysmorphic disorder. Ipser JC, Sander C, Stein DJ. Cochrane Database Syst Rev 2009, Jan 21. CD005332.

Supports efficacy of SSRIs.

A randomized placebo-controlled trial of fluoxetine in body dysmorphic disorder. Phillips KA, Albertini RS, Rasmussen SA. Arch Gen Psychiatry 2002; 59: 381–8.

This is the only placebo-controlled BDD pharmacotherapy study. In the 74 patients studied, fluoxetine was significantly more effective than placebo, with a response rate of 53% versus 18%.

Pharmacotherapy relapse prevention in body dysmorphic disorder: a double-blind, placebo-controlled trial. Phillips KA, Keshaviah A, Dougherty DD, et al. Am J Psychiatry 2016; 173: 887–95.

In this trial, 100 BDD subjects were treated with citalopram for 14 weeks with 81% response rate; 58 responders were treated with additional citalopram or placebo for 6 months. The placebo group was 40% versus 18% for citalopram. Study supports ongoing maintenance therapy.

An open label study of venlafaxine in body dysmorphic disorder. Allen A, Hadley SJ, Kaplan A, et al. CNS Spectr 2008; 13: 138–44.

Seventeen patients enrolled, 11 completed 12–16 weeks of venlafaxine minimum 150 mg daily. All 11 patients significantly improved.

Clomipramine versus desipramine crossover trial in body dysmorphic disorder: selective efficacy of a serotonin reuptake inhibitor in imagined ugliness. Hollander E, Allen A, Kwon J, et al. Arch Gen Psychiatry 1999; 56: 1033–9.

This double-blind crossover study of 29 randomized patients found clomipramine (an SSRI) superior to desipramine (a non-SSRI tricyclic antidepressant).

Efficacy and safety of fluvoxamine in body dysmorphic disorder. Phillips KA, Dwight MM, McElroy SL. J Clin Psychiatry 1998; 59: 165–71.

Open-label study of fluvoxamine demonstrated good clinical response in 19 (63%) of 30 patients.

Delusionality and response to open-label fluvoxamine in body dysmorphic disorder. Phillips KA, McElroy SL, Dwight MM, et al. J Clin Psychiatry 2001; 62(2): 87–91.

In this open-label trial, 30 patients with BDD were treated with fluvoxamine for 16 weeks, with 63% of treated patients significantly improved. Important to note that both delusional and non-delusional patients responded similarly.

Change in psychosocial functioning and quality of life of patients with body dysmorphic disorder treated with fluoxetine: a placebo-controlled study. Phillips KA, Rasmussen SA. Psychosomatics 2004; 45: 438–44.

This was a 12-week placebo-controlled study of psychosocial functioning and mental health-related QOL in 60 patients. At baseline, the patients had impaired psychosocial functioning and markedly poor mental health-related QOL. A significant decrease in the severity of BDD was demonstrated along with improvement in functioning and QOL.

Modular cognitive behavioral therapy for body dysmorphic disorder: a randomized controlled trial. Wilhelm S, Phillips KA, Didie E, et al. Behav Ther 2014; 34: 314–27.

A group of 36 adults were treated with 22 sessions of modular CBT, with 81% achieving significant improvement in BDD symptoms, and high levels of satisfaction with treatment were reported.

Cognitive-behavioral body image therapy for body dysmorphic disorder. Rosen JC, Reiter J, Orosan P. J Consult Clin Psycho 1995; 63: 263–9.

Exposure with response prevention was effective in 77% of 27 women treated with cognitive-behavioral group therapy for 8 weeks. Subjects in the treatment group had greater improvement than those in the no-treatment waiting-list control group.

Cognitive-behavioral group therapy for body dysmorphic disorder: a case series. Behav Res Ther 1999; 37: 71–5.

In this case series, 13 BDD patients significantly improved after 12 group therapy sessions.

Body dysmorphic disorder: a cognitive behavioral model and pilot randomized controlled trial. Veale D, Gournay K, Dryden W, et al. Behav Res Ther 1996; 34: 717–29.

Nineteen patients were randomly assigned to CBT or a waiting-list control group. There was significantly greater improvement in BDD symptoms in the CBT group.

Second-Line Therapies

- Additional psychotropic agents and insight-oriented psychotherapy **D, E**
- Visual training programs **E**

Treating body dysmorphic disorder with medication: evidence, misconceptions, and a suggested approach. Phillips KA, Hollander E. Body Image 2008; 5: 13–27. doi: 10.1016/j.bodyim.2007.12.003.

Excellent review of alternative and concomitant psychotropic medications including clomipramine, venlafaxine, buspirone, and pimozide.

An open study of buspirone augmentation of serotonin-reuptake inhibitors in body dysmorphic disorder. Phillips KA. *Psychopharmacol Bull* 1996; 32(1): 175–80.

Thirteen patients with DSM-4 BDD who had not responded, or had responded only partially, to an SRI had buspirone added to the SRI. Six of these subjects (46%) improved. Three who decreased or discontinued buspirone experienced an increase in symptom severity.

The neurobiology of body dysmorphic disorder: a systematic review and theoretical model. Grace SA, Labuschagne I, Kaplan RA, et al. *Neurosci Biobehav Rev* 2017; 83: 83–96.

Nineteen studies utilizing fMRI studies of brain function in BDD patients demonstrated lower activity and poor connectivity between different regions of the occipital lobe for visual processing, suggesting possible opportunity for visual training interventions.

Modifying emotion recognition deficits in body dysmorphic disorder: an experimental investigation. Buhlmann U, Gleiss MJ, Rupf L, et al. *Depress Anxiety* 2011; 28(10): 924–31.

Thirty-four cases of BDD were examined in this study, looking at whether emotional recognition deficits can be improved through a training program. With respect to neutral and scared expressions, BDD participants improved significantly more in the training condition (emotional recognition program), relative to the non-training condition.

Third-Line Therapy	
• Future directions	E

Clinical and electrophysiological outcomes of deep TMS over the medial prefrontal and anterior cingulate cortices in OCD patients. Carmi L, Alyagon U, Barnea-Ygael N, et al. *Brain Stimul* 2018; 11(1): 158–65.

Transcranial magnetic stimulation has already been shown to reduce obsessive-compulsive severity. Obsessive-compulsive severity was believed to be reduced via activation of the medial prefrontal cortex.

Future direction may therefore look at this treatment in terms of BDD because of the shared clinical manifestations with OCD and recent DSM-5 inclusion of BDD under OCD.

Bowen disease and erythroplasia of Queyrat

Shareen Muthiah, Colin A. Morton

INTRODUCTION

Bowen disease (in situ squamous cell carcinoma [in situ SCC]) and erythroplasia of Queyrat (EQ) are forms of intraepidermal squamous cell carcinoma, with the latter located on the penis. Lesions typically present as well-demarcated, erythematous, hyperkeratotic plaques with an irregular border that are persistent and slowly enlarging. Plaques of EQ develop on the glans or inner aspect of the foreskin and can be smooth, scaly or warty. Risk factors for the development of Bowen disease and EQ vary according to site, but include sun exposure, human papilloma virus infection, arsenic exposure, radiation exposure, HIV, or other forms of immunosuppression.

DIAGNOSIS

An initial diagnostic biopsy is recommended, especially for EQ and atypical presentations of Bowen, but many dermatologists will initiate treatment of typical Bowen disease on the basis of clinical diagnosis, aided by dermoscopy.

The specific dermoscopic criteria of Bowen's disease. Zalaudek I, Di Stefani A, Argenziano G. *J Eur Acad Dermatol Venereol* 2006; 20: 361–2.

Dermoscopic features include irregular clusters of coiled 'glomerular vessels' together with a scaly surface characteristic, with

small, pigmented globules and/or homogeneous pigmentation present in pigmented variants.

MANAGEMENT STRATEGY

Curative therapy aims to prevent progression to invasive SCC. SCC arises in approximately 3–5% of typical Bowen disease and about 10% for EQ. Several treatment options are available, and evidence-based guidelines seek to balance efficacy, tolerability, and cosmesis with cost effectiveness. Sexual partners of patients with EQ should be screened for other forms of intraepithelial neoplasia caused by human papillomavirus (HPV) in the genital area.

British Association of Dermatologists' guidelines for the management of squamous cell carcinoma in situ (Bowen's disease) 2014. Morton CA, Birnie AJ, Eedy DJ. *Br J Dermatol* 2014; 170: 245–60.

Quality of evidence for reported treatments for Bowen disease and EQ was reviewed in detail. The strongest evidence was for topical photodynamic therapy (PDT), 5-fluorouracil, and imiquimod, as well as cryotherapy. Non-surgical options are increasingly used and offer advantages for large/multiple lesions. Surgical excision and curettage remain in common use, although with lower-quality evidence available. Similar therapeutic options are available for patients with EQ; however, treatment tolerability is a greater challenge.

Direct surgical excision can be considered if a lesion is small and well defined, especially if there is doubt over possible invasive SCC. Lesion ablation may also be achieved with electrodesiccation and curettage or cryotherapy. Mohs micrographic surgery (MMS) is the surgical treatment of choice in severe/recurrent cases of EQ and indicated for certain sites (e.g., digital Bowen disease) where tissue-sparing benefits are important. Laser and radiotherapy have a more limited evidence base, with poor healing reported after radiotherapy. Several treatment combinations are also reported in the literature but lack a substantial evidence base.

First-Line Therapies

• Photodynamic therapy	A
• Cryotherapy	A
• Electrodesiccation and curettage	B
• Standard excision	B

Interventions for cutaneous Bowen's disease. Bath-Hextall FJ, Matin RN, Wilkinson D, et al. *Cochrane Database Syst Rev* 2013; 6: CD007281.

Review of interventions for SCC in situ by the Cochrane Skin Group identified nine randomized, controlled trials but noted limited data for surgery and topical therapies. Methyl-aminolevulinic acid–photodynamic therapy (MAL-PDT) was shown to be more efficacious than cryotherapy, but equivalent to topical 5-fluorouracil.

ALA-PDT achieved a higher clearance rate compared with 5-fluorouracil, whereas 5-fluorouracil and cryotherapy showed similar efficacy.

Treatments for primary squamous cell carcinoma and squamous cell carcinoma in situ of the skin: a systematic review and network meta-analysis: summary of an agency for healthcare research and quality comparative effectiveness review. Drucker AM, Adam GP, Rofefer V, et al. *J Am Acad Dermatol* 2020; 82: 479–80.

MAL-PDT is more likely to achieve good or better observer-reported cosmesis than a physician's choice of cryotherapy or 5-fluorouracil. Laser plus MAL-PDT provided better clearance than PDT alone or a physician's choice of cryotherapy or topical 5-fluorouracil.

Comparison of topical methyl aminolevulinate photodynamic therapy with cryotherapy or fluorouracil for treatment of squamous cell carcinoma in situ. Morton C, Horn M, Leman J, et al. Arch Dermatol 2006; 142: 729–35.

Estimated complete response rates at 1 year were highest for MAL-PDT ($n\{ts\}=96$) at 80% (two treatments spaced 1 week apart, with the methyl-aminolevulinate applied for 3 hours before red light illumination) compared with cryotherapy ($n\{ts\}=96$) at 67% (a minimum 20-second freeze–thaw cycle) and 5% fluorouracil cream at 69% (4 weeks of treatment applied once a day for the first week, then twice a day), although the three therapies were equivalent at 24 months. MAL-PDT provided superior cosmesis. Given the smaller sample size of 30 lesions treated by 5-fluorouracil in this study where the comparator was chosen by clinician's preference and more limited study data elsewhere, topical 5-fluorouracil has been overall considered a second-line therapy in this chapter.

European guidelines for photodynamic therapy. Part 1: treatment delivery and current indications – actinic keratoses, Bowen's disease, basal cell carcinoma. Morton CA, Szeimies RM, Sidoroff A, et al. J Eur Acad Dermatol Venereol 2019; 33: 2225–38.

Review of the literature observing high efficacy (88–100%) of typical lesions of Bowen disease at 3 months after one or two cycles of MAL-PDT with sustained clearance of 68%–89% over periods of 17–50 months, equivalent to cryotherapy and topical 5-fluorouracil. PDT has been shown effective for large lesions over 3 cm in diameter, clearing 96%, as well as a tissue-sparing option for digital, subungual, and nipple lesions. Enhanced clearance rates have been reported by sequential use of PDT and imiquimod, or by ablative laser assisted MAL-PDT.

Methyl-aminolevulinate photodynamic therapy for the treatment of erythroplasia of Queyrat in 23 patients. Fai D, Romano I, Cassano N, et al. J Dermatolog Treat 2012; 23: 330–2.

Nineteen patients obtained complete clinical remission over an average posttreatment period of 18 months, although local adverse reactions were common during treatment.

Bowen's disease involving the urethra. Yasuda M, Tamura A, Shimizu A, et al. J Dermatol 2005; 32: 210–3.

A case report highlighting the importance of early and definitive surgical treatment of EQ, recognizing the limited options when EQ extends to include the urethral meatus.

Comparison of cryotherapy with curettage in the treatment of Bowen's disease: a prospective study. Ahmed I, Berth-Jones J, Charles-Holmes S, et al. Br J Dermatol 2000; 143: 759–66.

Eighty lesions were randomized to two groups, cryotherapy ($n=36$) or curettage ($n=44$), and followed for a median of 2 years. Curettage produced comparable cure rates with more rapid healing, less pain, and fewer skin complications.

Second-Line Therapies

• 5-Fluorouracil	B
• Imiquimod 5%	B
• Mohs micrographic surgery	B

Topical treatment of Bowen's disease with 5-fluorouracil. Bargman H, Hochman J. J Cutan Med Surg 2003; 7: 101–5.

Only two of 26 biopsy-confirmed lesions recurred up to 10 years after treatment.

Imiquimod 5% cream monotherapy for cutaneous squamous cell carcinoma in situ (Bowen's disease): a randomized, double-blind, placebo-controlled trial. Patel GK, Goodwin R, Chawla M, et al. J Am Acad Dermatol 2006; 54: 1025–32.

Seventy-three percent of 31 patients achieved clinical remission with no recurrence at the 9-month follow-up.

Treatment of Bowen's disease with topical 5% imiquimod cream: retrospective study. Rosen T, Harting M, Gibson M. Dermatol Surg 2007; 33: 427–31.

Forty-two of 49 patients (86%) treated with 5% imiquimod cream once daily for a mean of 9 weeks achieved complete clinical remission at 1.5-year follow-up.

Erythroplasia of Queyrat treated with imiquimod 5% cream. Micali G, Nasca MR, De Pasquale R. J Am Acad Dermatol 2006; 55: 901–3.

Case report of an elderly man with EQ treated with 5% imiquimod with clinical and histologically confirmed cure.

Cutaneous squamous carcinoma in situ (Bowen's disease): treatment with Mohs micrographic surgery. Leibovitch I, Huilgol SC, Selva D, et al. J Am Acad Dermatol 2005; 52: 997–1002.

A case series evaluating 270 cases of Bowen disease treated with MMS with 5-year follow-up demonstrating recurrence rates of approximately 6%. The majority of lesions treated were on the head and neck, and many were recurrent at the time of MMS.

Extensive Bowen's disease of the penile shaft treated with fresh tissue Mohs micrographic surgery in two separate operations. Moritz DL, Lynch WS. J Dermatol Surg Oncol 1991; 17: 374–8.

Third-Line Therapies

• Laser	C
• Radiotherapy	C

Bowen's disease treated by carbon dioxide laser. A series of 44 patients. Covadonga Martinez-Gonzalez M, del Pozo J, Paradelo S, et al. J Dermatolog Treat 2008; 19: 293–9.

A larger retrospective study that used a CO₂ laser in superpulsed mode (2W/cm²) to treat Bowen disease in 44 patients reported clearance after one treatment in 86% of patients.

Radiation therapy for Bowen's disease of the skin. Lukas VanderSpek LA, Pond GR, Wells W, et al. Int J Radiat Oncol Biol Phys 2005; 63: 505–10.

Forty-four cases of Bowen disease treated with radiation therapy were reviewed, demonstrating remission in 42 with three

recurrences at a median follow-up of 2.6 years. A broad range of radiation schedules were used and compared for efficacy and safety with no significant differences in disease remission or recurrence between low- and high-dose regimens.

Bullous pemphigoid

Asli Bilgiç, Dedee F. Murrell

Bullous pemphigoid (BP) is the most common autoimmune blistering disorder. The diagnosis is based on the combination of clinical, histopathological, and immunopathological findings. Currently, direct immunofluorescence (DIF) from perilesional skin (typically showing linear n-serrated deposits of IgG and/or C3 along the dermoepidermal junction) is regarded as the critical test for the diagnosis. However, enzyme-linked immunosorbent assay (ELISA) assessing serum concentrations of circulating auto-antibodies (especially anti-BP180 IgG) has increasing evidence for both diagnosis and monitoring the disease status and response to treatment. The Bullous Pemphigoid Disease Area Index (BPDAI) and the Autoimmune Bullous Skin Disorder Intensity Score (ABSIS) are outcome measures used for BP in clinical trials. There is increasing evidence for their use to determine disease severity in a standardized manner.

MANAGEMENT STRATEGY

Always recall that BP patients are generally elderly with comorbidities and all treatments need to be selected to first do no harm. The best evidence for treatment in clinical trials is for moderate-to-severe BP.

Current mortality of BP in non-selected patients is 25–35%; 40% for high-dose oral prednisone and 10% in trials in which over 80% of BP patients were excluded (tetracyclines, methotrexate (MTX) trials).

Superpotent topical corticosteroids have the best randomized controlled-trial (RCT) evidence. Over 1000 patients were reported in validated studies to prove the effectiveness of clobetasol propionate 0.05% cream, 30–40 g per day for severe BP and 20–30 g/day for moderate BP. It is important that the cream is applied all over the body except the face and genitalia, including the blistering and erosions and normal skin. The initial treatment is daily for the first month, every second day for the second month, twice a week for the third month, and once a week in the fourth month. After the fourth month, maintenance once weekly until months 9–12 or stop the treatment. However, due to problems of its practical use in extensive or severe disease, their usage is limited.

In localized or mild BP, superpotent topical steroids are an effective and safer treatment option for BP, as they cause less

serious adverse effects in comparison to high-dose systemic steroids. If topical steroids are not feasible, *oral corticosteroids* may be considered.

Medium doses of oral prednisone (0.5 mg/kg/day) are effective in mild BP with 95% remission rate by day 21. High-dose corticosteroids are effective but should be avoided due to high morbidity and mortality. Low-dose oral prednisone (<0.3 mg/kg) was ineffective for moderate-to-severe BP. If the disease is not controlled by medium-dose corticosteroids, steroid-sparing agents (for severe BP: MTX, azathioprine [AZA], mycophenolate mofetil [MMF]; for mild-to-moderate BP: tetracyclines or dapsone) may be added. *Tetracyclines* may be used initially for patients with many comorbidities or contraindications to conventional immunosuppressants in whom large amounts of potent topical steroids are not practical/affordable. Low doses of *methotrexate* (MTX) at 5 mg/week are ineffective alone or with low doses of prednisone. Median doses of MTX (12.5 mg/week) could be effective when added to potent topical steroids. However, serious side effects are more common when elderly patients are given MTX.

The evidence for adding MMF and AZA from RCTs was not compelling due to lack of statistical difference or insufficient power for demonstrating a steroid-sparing effect. In practice these are often still used for relapsing BP.

Specific Investigations

After the diagnostic lesional and perilesional skin biopsies and BP180/BP230 serology investigations, others to optimize management should be performed.

- Evaluation of medications to rule out drug-induced cases
- Complete physical examination for infections, comorbidities, and underlying malignancy
- Consider patient age and overall medical condition for therapeutic decision-making
- Dietary regulations for glucose intolerance, diabetes, hypertension, or any other metabolic problems
- Screening for tuberculosis, hepatitis B and C, and HIV serology
- Prophylactic vaccinations such as seasonal influenza and pneumococci
- Screening and prophylactic therapy for osteoporosis
- Pregnancy test if relevant prior to any treatment
- Testing glucose 6-phosphate dehydrogenase before dapsone treatment
- Testing thiopurine methyltransferase before azathioprine (AZA) treatment
- Testing serum IgA deficiency for intravenous immunoglobulin (IVIG) therapy

THERAPIES

First-Line Therapies

• Topical clobetasol propionate 0.05%	B
• Systemic corticosteroids	B
• Doxycycline	B
• Tetracycline and nicotinamide	B
• Minocycline	C
• Tetracycline	E

A comparison of oral and topical corticosteroids in patients with bullous pemphigoid. Joly P, Roujeau JC, Benichou J, et al. *N Engl J Med* 2002; 346: 321–7.

In a *non-blinded*, randomized, multicenter trial, Joly et al. enrolled 341 patients with BP. Patients either received topical clobetasol propionate 0.05% cream (a daily dose of 40g applied to the entire surface of the body in patients with extensive disease [bullae >10/day]; 20g/day <10 blisters/day) or oral prednisone (0.5mg/kg/day for moderate BP and 1mg/kg/day for those with extensive disease).

In those with extensive BP (188 patients), topical corticosteroids were superior to oral prednisone in terms of 1-year survival rate and the rate of disease control at 3 weeks.

A comparison of two regimens of topical corticosteroids in the treatment of patients with bullous pemphigoid: a multicenter randomized study. Joly P, Roujeau JC, Benichou J, et al. *J Invest Dermatol* 2009; 129: 1681–7.

In a multicenter, non-blinded, randomized, controlled trial, a total of 312 BP patients (134 moderate and 178 extensive patients) were randomly assigned either to the standard regimen (clobetasol propionate 0.05% cream, 40g per day initially, with corticosteroids [CS] tapering over 12 months) or the mild regimen (10–30g per day), with CS tapering over 4 months. A strong beneficial effect in terms of the risk of death or life-threatening adverse events was found in patients with moderate BP with the mild regimen relative to the standard regimen as well as allowing 70% reduction of the cumulative doses of CS and improved BP patients' outcome.

Treatment of bullous pemphigoid with prednisolone only: 0.75 mg/kg/day versus 1.25 mg/kg/day. A multicenter randomized study. Morel P, Guillaume JC. *Ann Dermatol Venerol* 1984; 11: 925–8.

A total of 46 patients with BP were included in this randomized study comparing the efficacy and safety of two dosages of prednisolone used as a single therapeutic agent: 0.75 mg/kg/day versus 1.25 mg/kg/day for 3 weeks. They found no difference in effectiveness in terms of active lesions after 51 days.

Doxycycline versus prednisolone as an initial treatment strategy for bullous pemphigoid: a pragmatic, non-inferiority, randomised controlled trial. Williams HC, Wojnarowska E, Kirtschig G, et al. *UK Dermatology Clinical Trials Network BLISTER Study Group. Lancet* 2017; 389(10079): 1630–8.

This multicenter, parallel-group, randomized, controlled, non-blinded trial examined the efficacy of doxycycline or prednisolone in adults with BP. Local application of adjuvant potent topical corticosteroids (<30g per week) were allowed during weeks 1–3; 132 patients were randomized to doxycycline (200 mg per day) and 121 to prednisolone (0.5 mg/kg/day) for 6 weeks to assess the primary effectiveness. The study concluded that doxycycline is a therapeutic option non-inferior to standard treatment with oral prednisolone in terms of achieving short-term blister control when used with topical steroids limited to the lesions (74% for doxy/91% pred) and significantly safer in terms of rate of serious adverse events and treatment-related death in the long term (56 weeks) (18% doxy vs. 34% pred). There has been significant controversy regarding the methodology because many in the doxycycline initial treatment group switched to the prednisolone group due to lack of efficacy but were analyzed as doxycycline treatment. Furthermore, patients were allowed to use topical steroids and the prednisolone group received an initial fixed prednisolone dose regardless of disease severity. Disease control assessment at 6 weeks was also rather a long time to assess response compared with previous BP studies, which used 3 weeks.

A randomised controlled trial to compare the safety, effectiveness and cost-effectiveness of doxycycline (200mg/day) with that of oral prednisolone (0.5mg/kg/day) for initial treatment of bullous pemphigoid: the Bullous Pemphigoid Steroids and Tetracyclines (BLISTER) trial. Chalmers JR, Wojnarowska E, Kirtschig G, et al. *Health Technol Assess* 2017; 21: 1–90.

A cost-effectiveness analysis of the previous study found no significant difference in terms of costs or quality-adjusted life-years (QALYs) per patient at 1 year between doxycycline-initiated therapy and prednisolone-initiated therapy in patients with low-to-moderate BP. However, prednisolone showed a better quality of life improvement and reduced costs in patients with severe BP.

Nicotinamide and tetracycline therapy of bullous pemphigoid. Fivenson DP, Breneman DL, Rosen GB, et al. *Arch Dermatol* 1994; 130: 753–8.

The efficacy of nicotinamide (500 mg three times daily) and tetracycline (500 mg four times daily) compared with prednisone therapy in 20 patients with BP in a randomized, open-label trial. The combination therapy was not significantly different in efficacy to prednisone and resulted in less toxicity, but the study was underpowered to detect significance, with many dropouts in the tetracycline arm.

Tetracycline, nicotinamide, and lesionally administered clobetasol as a therapeutic option to prednisone in patients with bullous pemphigoid: a comparative, retrospective analysis of 106 patients with long-term follow-up. Kalinska-Bienias A, Kowalczyk E, Jagielski P, et al. *Int J Dermatol* 2019; 58: 172–7.

In this retrospective 3-year clinical study, tetracycline 1.5g daily + nicotinamide 1.2g daily, and 0.05% lesionally administered clobetasol cream (TNC group) were compared with prednisone 0.5 mg/kg daily (P group). One hundred six patients with newly diagnosed BP were divided into two groups: 59 in TNC and 47 in P. TNC was an effective treatment with better survival rates compared with prednisone, especially in advanced-age patients with comorbidities.

Second-Line Therapies

• Azathioprine	B
• Mycophenolate mofetil	B
• Dapsone	B
• Methotrexate	C

An open, multicentre, randomized clinical study in patients with bullous pemphigoid comparing methylprednisolone and azathioprine with methylprednisolone and dapsone. Sticherling M, Franke A, Aberer E, et al. *Br J Dermatol* 2017; 177: 1299–305.

This study compared the efficacy and safety of oral methylprednisolone therapy (0.5 mg/kg/day) in combination with either AZA (1.5–2.5 mg/kg/day) or dapsone (1.5 mg/kg/day) in 54 patients with BP. The combination regimen of either drug with oral methylprednisolone was found to have a relatively low 1-year mortality. The time until complete tapering of methylprednisolone and the cumulative corticosteroid dose were not significantly different. The study was underpowered due to a low number of patients; dapsone was shown to have a higher corticosteroid-sparing potential than AZA.

A comparison of oral methylprednisolone plus azathioprine or mycophenolate mofetil for the treatment of bullous pemphigoid. Beissert S, Werfel T, Frieling U, et al. *Arch Dermatol* 2007; 143: 1536–42.

The efficacy and safety of oral methylprednisolone plus azathioprine 2 mg/kg/day (AZA group; 38 patients) or oral methylprednisolone plus mycophenolate mofetil 2 g/day (MMF group; 35 patients) in a prospective, multicenter, randomized, non-blinded clinical trial. Although MMF and AZA groups demonstrated similar efficacy and similar cumulative corticosteroid doses to control disease, AZA treatment was associated with faster remission and a lower cumulative dose of methylprednisolone. However, MMF showed a significantly lower liver toxicity profile than AZA.

Treatment of bullous pemphigoid with dapsone: retrospective study of thirty-six cases. Bouscarat F, Chosidow O, Picard-Dahan C, et al. *J Am Acad Dermatol* 1996; 34: 683–4.

In a retrospective study of 36 BP patients treated with dapsone, the response rate was 44% in patients treated with dapsone plus topical steroids versus 20% with dapsone alone. Thus, dapsone alone was less effective than a combination of dapsone and topical steroids.

Methotrexate is safe and efficient as long-term treatment for bullous pemphigoid. Delaunay S, Assikar S, Prudhomme R, et al. *Eur J Dermatol* 2019; 29: 217–8.

In this retrospective study, 51 patients received subcutaneous methotrexate (MTX) (dose range: 7.5–15 mg per week) after topical corticosteroids (clobetasol propionate every day for at least 3 months) out of 329 BP patients diagnosed between 2007 and 2017. Complete remission rate was 90% after 1 month of MTX, and 92% after 3 months. Thus, low-dose MTX with topical steroid can be beneficial for long-term treatment of BP leading to satisfactory control of the disease while being safe.

Combined treatment with low-dose methotrexate and initial short-term superpotent topical steroids in bullous pemphigoid: an open, multicentre, retrospective study. Du-Thanh A, Merlet S, Maillard H, et al. *Br J Dermatol* 2011; 165: 1337–43.

In a clinical record-based retrospective analysis, the effectiveness and safety of a combined regimen of initial short-term superpotent topical steroids and MTX followed by long-term MTX alone was evaluated in 70 BP patients. All patients showed complete clinical remission. Long-term disease control was achieved by 76%; however, 24% of patients experienced at least one relapse during subsequent treatment with MTX alone and 16% had drug-related adverse effects.

Third-Line Therapies

• Intravenous immunoglobulin (IVIG)	B
• Rituximab	C
• Omalizumab	C
• Chlorambucil + prednisolone	C
• Pulse intravenous corticosteroids	D
• Cyclophosphamide + pulse intravenous corticosteroids	D
• Dupilumab	D
• Cyclophosphamide	E
• Ciclosporin	E
• Dimethyl fumarate	E
• Etanercept	E
• Daclizumab	E
• Ustekinumab	E
• Secukinumab	E

A randomized double-blind trial of intravenous immunoglobulin for bullous pemphigoid. Amagai M, Ikeda S, Hashimoto T, et al. *Bullous Pemphigoid Study Group. J Dermatol Sci* 2017; 85: 77–84.

High-dose IVIG (IVIG; 400 mg/kg/day for 5 days) in resistant BP patients was assessed using a disease activity score (DAS) modified from the pemphigus disease area index (PDAI) on day 15. Twenty-nine patients were randomized to IVIG and 27 to placebo along with an oral steroid tapering. Although there was no significant difference between the IVIG and placebo groups, the IVIG group demonstrated lower scores than the placebo group at all observation points throughout the study period. Furthermore, a significant difference in the severe cases (DAS ≥ 40) between the treatment groups was shown during the early stages after treatment.

First-line combination therapy with rituximab and corticosteroids provides a high complete remission rate in moderate-to-severe bullous pemphigoid. Cho YT, Chu CY, Wang LF. *Br J Dermatol* 2015; 173: 302–4.

In a retrospective case-control study, patients with generalized BP (moderate to severe) treated with systemic treatments were evaluated. In the first-line combination therapy ($n=13$) (the regimen included four weekly infusions of 500 mg rituximab [RTX] and corticosteroids, with a starting dose of prednisolone of 0.5 mg/kg/day), the corticosteroids dose was tapered rapidly after the disease was controlled within a total duration of <6 months. The comparison group ($n=19$) consisted of patients from the same period receiving a similar starting dose of prednisolone for at least 6 months. This study was the first to use rituximab as a first-line treatment in BP and demonstrated a significantly better rate of complete remission than conventional steroid treatment. Results also showed similar and even lower rates of infection and mortality than conventional treatment although infection was the most important cause of mortality in the study. To conclude, the combination therapy of RTX and steroid is effective and relatively safe for moderate-to-severe BP.

Rituximab and omalizumab for the treatment of bullous pemphigoid: a systematic review of the literature. Kremer N, Snast I, Cohen ES, et al. *Am J Clin Dermatol* 2019; 20: 209–16.

A systematic review was carried out in order to evaluate the safety and efficacy of the use of RTX and omalizumab for the treatment of BP. Thirty-five publications including 84 patients (62 received rituximab and 22 received omalizumab) were analyzed. Complete response rates for RTX and omalizumab were compatible with the rates of 85% and 84%, respectively. Furthermore, there was no significant change in terms of adverse effects (24% in RTX and 20% in omalizumab). However, the RTX group had a lower (29%) relapse rate than with omalizumab (80%).

There are more than 11 case reports apart from this systematic review showing the efficacy of omalizumab.

Abdat R, Waldman RA, de Bedout V, et al. *J Am Acad Dermatol* 2020 [Epub ahead of print].

This recent multi-institutional study included 13 patients with BP who were treated with dupilumab (using the dosing regimen approved for atopic dermatitis: 600 mg SC initially followed by 300 SC every other week). They suggested that dupilumab might be an additional treatment for recalcitrant BP.

Daclizumab: a novel therapeutic option in severe bullous pemphigoid. Mockenhaupt M, Grosber M, Norgauer J. *Acta Dermatol Venereol* 2005; 85: 65–6.

Daclizumab (1 mg/kg per infusion given every 2 weeks) was used in a 52-year-old patient with diffuse BP who failed with combination treatment. The patient had six infusions of daclizumab and succeeded in complete resolution of lesions at week 2 and remained on prednisolone 5 mg/day and azathioprine 50 mg/day.

Treatment of bullous pemphigoid with low-dose oral cyclophosphamide: a case series of 20 patients. Gual A, Iranzo P, Mascaró JM Jr. *J Eur Acad Dermatol Venereol* 2014; 28: 814–8.

A retrospective study evaluated low-dose oral cyclophosphamide (50–100 mg/day) in refractory BP already taking systemic steroids; 11/19 (58%) had a complete response. Cyclophosphamide (CFM) was used as first-line corticosteroid-sparing treatment in 8/19 (40%) cases, as second-line treatment in eight (40%) patients, and as third-line therapy in the remaining three (15%) patients. Clinical remission was achieved in 8/19 and partial remission in 4/19 (21%). The main adverse effects were bone marrow suppression (in 12 patients), gastrointestinal intolerance (in one patient), and death because of heart failure (not attributed to CFM), and another patient developed acute myeloid leukemia 1.5 years after CFM therapy.

Cyclosporin in the treatment of bullous pemphigoid: preliminary study. Barthélémy H, Thivolet J, Cambazard F, et al. *Ann Dermatol Venereol* 1986; 113: 309–13.

Seven BP patients received cyclosporin (CyA) at 6 to 8 mg/kg/day. CyA was used alone in four patients, and used with a combination of steroids in three patients during relapses. Out of four patients using CyA alone, two had failures and two had successful outcomes. Researchers suggested that CyA had no beneficial effect in the acute phase and in the long term CyA could be potentially nephrotoxic in elderly people.

Successful management of bullous pemphigoid with dimethyl fumarate therapy: a case report. Bilgic-Temel A, Das S, Murrell DF. *Int J Womens Dermatol* 2019; 5: 179–80.

A 69-year-old woman affected by both multiple sclerosis for 35 years and BP (unsuccessful treatment with first-line therapies) was able to taper off corticosteroids with dimethyl fumarate (DMF) at

a dose of 120 mg twice per day for 7 days and then increased to 240 mg twice per day maintained for over a year. DMF is now under evaluation with an investigator-initiated prospective controlled trial in patients with BP to determine the efficacy and safety of adjuvant DMF (<http://www.erare.eu/financed-projects/dpem>).

Treatment of coexisting bullous pemphigoid and psoriasis with the tumor necrosis factor antagonist etanercept. Yam-auchi PS, Lowe NJ, Gindi V. *J Am Acad Dermatol* 2006; 54(3 Suppl 2): S121–2.

A 64-year-old man with psoriasis more than 12 years and coexisting BP was treated with etanercept 50 mg weekly with systemic prednisone after using mycophenolate mofetil (1 g twice daily) as initial therapy, then using prednisone alone at a dose of 60 mg daily. When the prednisone dose decreased to 20 mg/day, due to a flare, the etanercept dosage was increased to 50 mg twice weekly. BP lesions subsequently resolved, and prednisone was discontinued eventually.

A successful treatment with ustekinumab in a case of relapsing bullous pemphigoid associated with psoriasis. Loget J, Plée J, Antonicelli F, et al. *J Eur Acad Dermatol Venereol* 2017; 31: e228–30.

The patient had complete remission of recalcitrant BP and psoriasis after ustekinumab, an anti-IL 12/23 monoclonal antibody (45 mg subcutaneously at weeks 0 and 4, and then every 12 weeks). Although sparse psoriatic lesions persisted, complete remission was achieved, and serum anti-BP180 autoantibodies became negative.

Secukinumab decreased circulating anti-BP180-NC16a autoantibodies in a patient with coexisting psoriasis vulgaris and bullous pemphigoid. Kamata M, Asano Y, Shida R, et al. *J Dermatol* 2019; 46: 216–7.

A 69-year-old man with a 40-year history of psoriasis and recent diagnosis of BP who received secukinumab, an anti-interleukin (IL)-17 antibody, was shown to be effective in decreasing the required prednisolone dose and further decreased the anti-BP180-NC16a autoantibody level.

33

Burning mouth syndrome (glossodynia)

Ashley N. Privalle, Rochelle R. Torgerson

Primary burning mouth syndrome (BMS) is a rare, chronic, debilitating disease characterized by intraoral burning in the absence of systemic disease or identifiable abnormalities on physical examination and laboratory testing. Current evidence suggests that altered neurophysiology of the central or peripheral nervous system as well as immune-mediated, hormonal, and psychological factors may play an etiopathogenic role. The diagnosis of primary BMS is a clinical diagnosis of exclusion. Various medical conditions and medications can induce oral burning, a condition referred to as *secondary BMS*. Secondary BMS improves with treatment of the underlying condition(s).

MANAGEMENT STRATEGY

A detailed history and physical examination should be completed to identify all alternative or correctable causes of oral burning. Correctable, associated factors may be local, systemic, or psychological.

Local Factors

Local factors include xerostomia (age, medication, radiotherapy); direct irritation (oral care products, tobacco); mechanical trauma (rough dental restorations, poorly fitting dental prostheses); parafunctional habits (bruxism, tongue thrusting); microbial infection or colonization (candidiasis, herpetic, fusospirochetal); geographic or fissured tongue; mucocutaneous diseases (lichen planus, pemphigus, pemphigoid); and allergic or irritant contact stomatitis (flavorings, food additives, dental materials, cosmetic products).

Systemic Factors

Systemic factors include nutritional deficiency states; autoimmune disease (Sjögren syndrome); gastrointestinal disease (gastroesophageal reflux); neurologic disease (trigeminal neuralgia, acoustic neuroma, Parkinson disease, glossopharyngeal neuralgia); medication(s); and endocrinopathies (hypothyroidism, diabetes).

Psychological Factors

Psychological factors include anxiety (including cancerophobia), depression, adjustment disorder, and psychosocial stressors.

Specific Investigations

Laboratory evaluation should be directed by the history and physical examination findings. If burning persists after eliminating or treating potential local, systemic, and psychological factors, a working diagnosis of primary BMS is adopted. Although consensus on treatment for primary BMS is lacking, many have found success with multimodal approaches resembling those used for the treatment of chronic, neuropathic pain.

A population-based study of the incidence of burning mouth syndrome. Kohorst JJ, Bruce AJ, Torgerson RR, et al. *Mayo Clin Proc* 2014; 89(11): 1545–52.

Annual age- and sex-adjusted incidence of BMS of 11.4 per 100,000 person-years.

Burning mouth syndrome. Jaaskelainen SK, Woda A. *Cephalalgia* 2017; 37: 627–47.

A review of BMS including evidence of neurophysiologic alterations in the peripheral or central nervous system.

Psychiatric comorbidity in patients with burning mouth syndrome. Bogetto F, Maina G, Ferro G, et al. *Psychosom Med* 1998; 60: 378–85.

In a case-control study of 102 patients with BMS, 59.8% had concomitant psychiatric disorders.

Burning mouth syndrome. Torgerson RR. *Dermatol Ther* 2010; 23: 291–8.

Multiple possible etiologies of BMS, including neuropathic, exocrine dysfunction, taste disturbance, mucosal atrophy, and psychological illness are reviewed (Tables 33.1–33.3).

Burning mouth syndrome: a comparative cross-sectional study. Rabiei M, Leili EK, Alizadeh L. *Contemp Clin Dent* 2018; 9: S256–60.

Age and sex are significant risk factors for development of BMS. Menopause, candidiasis, psychological disorders, job status, dentures, and dry mouth were more common in patients with BMS.

Burning mouth syndrome. Bender SD. *Dent Clin North Am* 2018; 62: 585–96.

BMS is a multifactorial condition, including interaction of psychological and neurophysiologic factors.

Table 33.1 Specific investigations**History**

Oral symptoms	Timing, quality, duration, location, alleviating/exacerbating factors
Medications	Causative: efavirenz, ACE inhibitors, ARBs, omeprazole, topiramate, TNF- α inhibitors
Dental	Prostheses, recent procedures, dentifrices, topical medicaments, oral care products
Parafunctional habits	Bruxism, tongue thrusting
Review of symptoms	Weakness, headache, fatigue, concentration, sleep disturbance, arthralgia

Physical examination

Oral	Complete oral examination, including head and neck (remove any dental prostheses)
Nodal	Adenopathy
Musculoskeletal	Temporomandibular joint
Neurologic	Cranial nerve exam

Table 33.2 Laboratory evaluation

Hematologic	Complete blood count, ferritin, serum folate, cobalamin (+ methylmalonic acid, homocysteine)
Metabolic	Serum thiamine, riboflavin, pyridoxine, zinc (+ alkaline phosphatase), magnesium
Endocrinologic	Glycosylated hemoglobin, thyrotropin (+ free thyroxine)
Immunologic	Antinuclear factor (+ Ro/SSA, La/SSB)
Dermatologic	Biopsy (+ direct immunofluorescence) if visible abnormality on oral examination
Microbiology testing	Herpes simplex (polymerase chain reaction [PCR]); varicella zoster (PCR); candidiasis (swab from site of pain for direct examination and culture); human immunodeficiency virus screening

Table 33.3 Consultations

Otolaryngology	Nasopharyngoscopy
Gastroenterology	Esophagogastroduodenoscopy
Oral/maxillofacial	Periapical radiographs, magnetic resonance imaging
Mental health	Psychiatry consultation
Neurology	Neurologic examination, magnetic resonance imaging
Hypersensitivity testing	Epicutaneous patch testing (preservatives, oral flavors, metals, adhesives, food-related allergens)

First-Line Therapies

- Acknowledge and validate patient symptoms and experience; reassure **E**
- Avoid contact irritants (alcohol-based oral rinses, caustic mouthwashes, flavored dentifrices, acidic foods, carbonated beverages) **E**
- Treat xerostomia (sialagogues, artificial oral lubricants) **D**
- Discontinue or change causative medications (ACE inhibitor, ARB, selective serotonin reuptake inhibitor [SSRI], serotonin-norepinephrine reuptake inhibitor, benzodiazepine, non-nucleoside reverse-transcriptase inhibitor, PPI, anticonvulsant, anticholinergics, TNF- α inhibitors) **E**
- Replace thiamine, riboflavin, pyridoxine, folate, cobalamin, iron, zinc, ascorbic acid, magnesium **C**
- Manage concomitant psychiatric illness **C**
- Assess and address parafunctional habits (bruxism, tongue thrusting) **E**
- Assess oral prostheses and dental work **C**
- Imidazole/azole therapy (presence of functional pain) **C**
- Assess and address oral hygiene **E**
- Address sleep quality **B**

Patients complaining of a burning mouth. Further experience in clinical assessment and management. Main DM, Basker RM. Br Dent J 1983; 154: 206–11.

A high rate of intraoral burning attributable to shortcomings in denture design.

Glossodynia from Candida-associated lesions, burning mouth syndrome, or mixed causes. Terai H, Shimahara M. Pain Med 2010; 11: 856–60.

Seventy-two of 95 (75.7%) patients with functional glossodynia improved with imidazole therapy (25 mg gel four times a day for 2–4 weeks).

Drug-induced burning mouth syndrome: a new etiologic diagnosis. Salort-Llorca C, Minguez-Serra MP, Silvestre FJ. Med Oral Patol Oral Cir Bucal 2008; 13: E167–70.

Antihypertensive medications that interact with the renin-angiotensin system are the most frequent cause of drug-associated BMS. Efavirenz, clonazepam, venlafaxine, fluoxetine, and sertraline were also associated.

Proton pump inhibitors. Scully C. Br Dent J 2010; 208: 147.

A case report of BMS-like symptoms that resolved after discontinuing omeprazole.

Topiramate-induced burning mouth syndrome. Friedman DI. Headache 2010; 50: 1383–5.

A case report of BMS that resolved after discontinuing topiramate. Symptoms recurred upon rechallenge.

Burning mouth syndrome associated with tumor necrosis factor (TNF)- α inhibitor. Gambardella A, Licata G, De Rosa A, et al. Int J Dermatol 2020; 59: e70–1.

A case report of BMS following initiation of etanercept that resolved after discontinuation.

Burning mouth syndrome: results of screening tests for vitamin and mineral deficiencies, thyroid hormone, and glucose levels – experience at Mayo Clinic over a decade. Verenzuela CSM, Davis MDP, Bruce AJ, et al. *Int J Dermatol* 2017; 56: 952–6.

The most common laboratory abnormalities in patients with BMS included deficiencies in vitamins D₃, B₂, B₆, and B₁ and zinc and elevations of blood glucose and TSH.

The association between burning mouth syndrome and sleep disturbance: a case-control multicentre study. Adamo D, Sardella A, Varoni E, et al. *Oral Dis* 2018; 24: 638–49.

Seventy-nine percent of patients with BMS reported poor sleep quality. Anxiety and depression were strongly correlated with sleep quality.

Second-Line Therapies

• Topical capsaicin	A
• Topical clonazepam	B
• Low-dose clonazepam	A
• Amitriptyline	B
• Paroxetine	D
• Milnacipran	D
• Duloxetine	E
• Low-dose olanzapine	E
• Low-dose pregabalin	D
• Cognitive behavioral therapy	B
• Gabapentin	A
• Alpha lipoic acid (contradictory information)	A
• Bupivacaine lozenge	A

Application of a capsaicin rinse in the treatment of burning mouth syndrome. Silvestre FJ, Silvestre-Ranil J, Tamarit-Santafé C, et al. *Med Oral Patol Oral Cir Bucal* 2012; 17: e1–4.

A randomized, double-blind, crossover study of topical capsaicin rinse (0.02%) or placebo three times daily found reduced pain scores among capsaicin-treated, but not placebo-treated, patients with BMS.

Topical clonazepam in stomatodynia: a randomised placebo-controlled study. Gremeau-Richard C, Woda A, Navez ML, et al. *Pain* 2004; 108: 51–7.

Forty-eight patients with BMS received either 'suck and spit' clonazepam (1 mg) or placebo three times daily for 14 days. Patients receiving topical clonazepam had a greater reduction in pain scores.

Outcome predictors affecting the efficacy of clonazepam therapy for the management of burning mouth syndrome (BMS). Ko JY, Kim MJ, Lee SG, et al. *Arch Gerontol Geriatr* 2012; 55: 755–61.

One hundred patients with BMS took clonazepam (0.5 mg) once or twice daily for 4 weeks. Patients with fewer psychological symptoms, higher initial pain scores, and the presence of xerostomia or taste disturbance experienced greater therapeutic efficacy.

Therapeutic dose of amitriptyline for older patients with burning mouth syndrome. Suga T, Takenoshita M, Watanabe T, et al. *Neuropsychiatr Dis Treat* 2019; 15: 3599–607.

Seventy-six percent of 187 patients with BMS treated with amitriptyline (starting dose 5–10 mg/day increased by 5–10 mg weekly or biweekly, as tolerated) showed improvement in pain scores. Older patients required lower therapeutic doses.

An open-label, noncomparative, dose escalation pilot study of the effect of paroxetine in treatment of burning mouth syndrome. Yamazaki Y, Hata H, Kitamori S, et al. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 2009; 107: e6–11.

Out of 52 BMS patients, 42 (80.8%) responded to paroxetine (10–30 mg daily) over 12 weeks. Nineteen (70.4%) had a complete response by the end of the treatment period. The effects were dose dependent.

Milnacipran dose-effect study in patients with burning mouth syndrome. Kato Y, Sato T, Katagiri A, et al. *Clin Neuropharmacol* 2011; 34: 166–9.

An open-label, dose-escalation pilot study of milnacipran in 56 patients with BMS. The response rate was 67.9% and 50.8% for daily dosages of 90 mg and 60 mg, respectively.

Burning mouth syndrome responsive to duloxetine: a case report. Mignogna MD, Adamo D, Schiavone V, et al. *Pain Med* 2011; 12: 466–9.

Report of one case of BMS responsive to duloxetine (60 mg daily).

Two cases of burning mouth syndrome treated with olanzapine. Ueda N, Kodama Y, Hori H, et al. *Psychiatry Clin Neurosci* 2008; 62: 359–61.

Two cases of BMS responsive to olanzapine treatment (2.5–5.0 mg daily).

Five patients with burning mouth syndrome in whom an antidepressant (serotonin-noradrenaline reuptake inhibitor) was not effective, but pregabalin markedly relieved pain. Ito M, Tokura T, Yoshida K, et al. *Clin Neuropharmacol* 2015; 38: 158–61.

Pregabalin (50–150 mg/day) was effective in treating five patients who previously did not respond to SNRIs.

Cognitive therapy in the treatment of patients with resistant burning mouth syndrome: a controlled study. Bergdahl J, Anneroth G, Perris H. *J Oral Pathol Med* 1995; 24: 213–5.

A randomized trial in resistant BMS found cognitive therapy superior to an attention program.

Combination of alpha lipoic acid and gabapentin, its efficacy in the treatment of burning mouth syndrome: a randomized, double-blind, placebo controlled trial. López-D'alessandro E, Escovich L. *Med Oral Patol Oral Cir Bucal* 2011; 16: e635–40.

One hundred twenty patients with BMS were randomized to receive alpha lipoic acid (ALA) (600 mg/day), gabapentin (300 mg/day), or a combination of both reported improvement in 55%, 50%, and 70% of cases, respectively, compared with placebo (15%).

Alpha lipoic acid efficacy in burning mouth syndrome. A controlled clinical trial. Palacios-Sánchez B, Moreno-Lopez LA, Cerero-Lapiedra R, et al. *Med Oral Patol Oral Cir Bucal* 2015; 20: e435–40.

Sixty BMS patients were randomized to receive ALA 600 mg daily (200 mg every 8 hours) or placebo. ALA was statistically superior to placebo.

Alpha lipoic acid in burning mouth syndrome: a randomized double-blind placebo-controlled trial. Cavalcanti DR, da Silveira FR. *J Oral Pathol Med* 2009; 38: 254–61.

ALA failed to provide a therapeutic benefit.

Effect of a local anesthetic lozenge in relief of symptoms in burning mouth syndrome. Tredal C, Jacobsen CB, Mogensen S, et al. *Oral Dis* 2016; 22: 123–31.

A randomized, double-blinded control crossover trial of 18 patients with BMS demonstrated reduced pain with bupivacaine lozenges three times daily without improvement in taste alterations or xerostomia.

Third-Line Therapies	
• Avoid contact allergens	D
• Low-level laser therapy	B
• Mandibular nerve block	E

Type 3 burning mouth syndrome: psychological and allergic aspects. Lamey PJ, Lamb AB, Hughes A, et al. *J Oral Pathol Med* 1994; 23: 216–9.

In 33 patients with BMS and intermittent symptoms at atypical sites, 65% were found to have positive patch tests to food flavorings or additives. Symptoms improved in 80% with allergen avoidance.

Burning mouth syndrome and contact dermatitis. Powell A, Nelson KN, Awosika O, et al. *Dermatitis* 2020; 31: 238-43.

Addition of bakery and dental series will include allergens that may otherwise be missed in patients with type 3 BMS.

Low-level laser therapy in patients with burning mouth syndrome: a double-blind, randomized, controlled clinical trial. Spanemberg JC, Segura-Egea JJ, Rodriguez-de Rivera-Campillo E, et al. *J Clin Exp Dent* 2019; 11: e162–9.

Twenty-one BMS patients randomly assigned to twice-weekly sessions with low-level diode laser ($\lambda = 808 \text{ nm} \pm 5 \text{ nm}$; fluence = 1.97 J/cm^2 ; time = 15 seconds per spot) demonstrated significant improvement in pain scores compared to placebo.

Mandibular nerve block for long-term pain relief in a case of refractory burning mouth syndrome. Kassem H, Alexandre L, Urits I, et al. *Pain Ther* 2020 [Epub ahead of print].

One patient reported 70% improvement 1 month following therapeutic injection of the mandibular division of the left trigeminal nerve with a mixture of lidocaine and 10 mg/mL dexamethasone.

Calcinosis cutis

Jasmine Mann, Rabindranath Nambi, Ian H. Coulson

Calcinosis cutis is a rare disease of aberrant calcium deposition in the skin and subcutaneous tissue. There are five major types:

- Idiopathic: occurs without tissue injury or metabolic defect (e.g., idiopathic scrotal calcinosis)
- Dystrophic: (most common form) secondary to local tissue damage or alterations in collagen, elastin, or subcutaneous fat but normal calcium and phosphate levels (e.g., in autoimmune connective tissue diseases, post trauma or infection)
- Metastatic: abnormal calcium and/or phosphate metabolism leading to precipitation of calcium salts in normal tissue (hyperparathyroidism, sarcoidosis, chronic kidney failure, malignant neoplasms)
- Iatrogenic: secondary to a treatment or procedure (such as extravasation of calcium or phosphate infusions)
- Calciophylaxis: calcific vasculopathy that occurs in the setting of end-stage kidney disease

Other rare variants of calcinosis cutis that have been described include calcinosis cutis circumscripta, calcinosis universalis, tumoral calcinosis, transplant-associated calcinosis cutis, and milia-like idiopathic calcinosis cutis (usually associated with Down syndrome). Firm white or yellow dermal lesions may ulcerate and extrude a gritty material. It most commonly involves the extensor aspect of joints, particularly the fingers, but can also involve large areas of the body. Stiffening of the skin can limit joint mobility and function, and fingertip lesions may be painful.

MANAGEMENT STRATEGY

The first step in management is to identify any underlying cause, as the subtype influences the approach to treatment. Principles of treatment are to treat an underlying disease, reduce calcium deposits, minimize inflammation, and physical removal of deposits.

Dystrophic calcification occurs in approximately 25% of patients with systemic sclerosis (SSc) and 10%–40% of patients with juvenile dermatomyositis, but is rare in systemic lupus erythematosus. Examination and investigations for connective tissue disease are therefore strongly recommended. Skin

biopsy can help to distinguish cutaneous calcification from ossification.

Elevated interleukin-1 levels, along with interleukin-6, interleukin-1 β , and tumor necrosis factor- α (TNF- α), are found in patients with juvenile dermatomyositis. Mannose-binding lectin levels were significantly increased in SSc patients with calcinosis. It is positively associated with positive anticentromere, anti-PM/Scl, and anticardiolipin antibodies in SSc patients with calcinosis.

A number of malignancies have been implicated in causing metastatic calcification (e.g., leukemia and multiple myeloma). However, successful treatment of the underlying cause does not always have an impact on calcinosis cutis, which frequently requires other treatment modalities. There are no large studies for the treatment of calcinosis cutis, and most therapies are based on case reports or small case series.

Spontaneous extrusion of calcium salts may occur; this may need surgical encouragement. General measures to improve blood flow to extremities, such as avoiding smoking, stress, and cold exposure, are crucial. *Diltiazem*, *colchicine*, and *minocycline* have shown success, mostly in dystrophic calcinosis cutis associated with dermatomyositis. In particular, *colchicine* and *minocycline* have been reported to reduce the frequency of ulceration and inflammation associated with cutaneous calcinosis in patients with limited SSc. The mechanism of action may be mainly through inhibition of matrix metalloproteinases and antiinflammatory effects.

Other beneficial therapies for calcinosis cutis associated with connective tissue disease include: *intralesional corticosteroids*, *aluminum hydroxide supplements*, *bisphosphonates*, *probenecid*, *intravenous immunoglobulin*, *topical sodium thiosulfate*, *carbon dioxide laser vaporization*, and *extracorporeal shock wave lithotripsy*.

Warfarin has been advocated in both dermatomyositis and SSc-associated calcinosis for small, calcified deposits. *Topical sodium metabisulfite*, *infliximab*, and *apremilast* are recent approaches that have been tried. Surgical removal can be of benefit for idiopathic calcinosis cutis, large lesions, and lesions as a result of calciophylaxis.

Specific Investigations

- Full blood count
- Urea and creatinine
- Serum calcium and phosphate
- Parathyroid hormone levels
- Vitamin D levels
- Serum electrophoresis
- Muscle enzymes: creatine kinase, lactate dehydrogenase (LDH), aldolase
- Connective tissue disease screen: antinuclear antibodies (ANAs) and other autoantibodies
- Skin biopsy
- Plain radiographs
- Bone scintigraphy
- Computed tomography and magnetic resonance imaging (MRI)

First-Line Therapies

• No treatment/self-healing	E
• Diltiazem	C
• Intralesional corticosteroid/oral prednisolone	E

Self-healing dystrophic calcinosis following trauma with transepidermal elimination. Pitt AE, Ethington JE, Troy JL. *Cutis* 1990; 45: 28–32.

A case of dystrophic calcinosis after trauma that resolved over 8 weeks with spontaneous transepidermal elimination.

Calcinosis cutis: part II. Treatment options. Reiter N, El-Shabrawi L, Leinweber B, et al. *J Am Acad Dermatol* 2011; 65: 15–22.

Calcinosis cutis in dermatomyositis has been successfully treated with diltiazem (2–4 mg/kg/day), with lower doses being ineffective. Surgical excision or curettage is the treatment of choice in idiopathic calcinosis cutis, especially scrotal calcinosis. It is also effective for small, digital calcified skin lesions. A 16-year-old boy with morphea profunda developed small, calcified deposits on both arms, his chest, and left thigh. He was treated with ceftriaxone 2 g/day intravenously for 20 days, and the calcification diminished within weeks.

A case of juvenile dermatomyositis with severe calcinosis and successful treatment with prednisone and diltiazem. Jiang X, Yi Q, Liu D, et al. *Int J Dermatol* 2011; 50: 74–7.

A 12-year-old boy with calcinosis secondary to juvenile dermatomyositis received diltiazem at a dose of 30 mg/day, resulting in obvious softening and radiologic regression and functional improvement at 4 months.

Calcinosis cutis occurring in association with autoimmune connective tissue disease: the Mayo Clinic experience with 78 patients, 1996 to 2009. Balin SJ, Wetter DA, Andersen LK, et al. *Arch Dermatol* 2012; 148: 455–62.

Nine of 17 patients with autoimmune connective tissue disorders showed partial response to treatment with diltiazem at the dose of <480 mg/day. This is recommended as first-line treatment. Eight patients were treated with colchicine (<1.2 g/day), resulting in one patient showing complete response and two patients showing partial response. Six patients received minocycline (200 mg/day). Only one patient showed partial response, two patients did not respond, and the response was unknown in three patients. Four patients were treated with warfarin with only one patient partially responding. Out of the 11 patients who received surgical excision alone, all 11 responded, with eight having a complete response. Another 17 patients had surgical and medical treatment with complete response in 14 patients, partial response in two patients, and no response in one patient.

Localized calcinosis in juvenile dermatomyositis: successful treatment with intralesional corticosteroids injection. Al-Mayouf SM, Alsonbul A, Alismail K. *Int J Rheum Dis* 2010; 13: e26–8.

A 10-year-old boy with juvenile dermatomyositis had calcinosis of his left elbow. It was treated with Depo-Medrol 80 mg and xylocaine 1% under ultrasound guidance with significant improvement.

Severe calcinosis cutis with cutaneous ulceration in juvenile dermatomyositis. Meher BK, Mishra P, Sivaraj P, et al. *Indian Pediatr* 2014; 51: 925–7.

A 7-year-old girl with severe calcinosis cutis with ulceration improved, with healing of the ulcer and resolution of nodules, after 1 month of oral prednisolone (1 mg/kg/day) and methotrexate (10 mg/week).

Second-Line Therapies

• Colchicine	E
• Minocycline	E
• Bisphosphonates	D
• Probenecid	E
• Aluminum hydroxide	D

Treatment of cutaneous calcinosis in limited systemic sclerosis with minocycline. Robertson LP, Marshall RW, Hickling P. *Ann Rheum Dis* 2003; 62: 267–9.

In an open-label study, eight out of nine patients with limited cutaneous SSc prescribed minocycline 50 mg or 100 mg daily showed definite improvement. The frequency of ulceration and inflammation associated with the calcinosis deposits decreased with treatment. A reduction in calcinosis size was evident but less dramatic, with improvement occurring by 5 months. The mean duration of treatment was 3.5 years.

See also Balin et al. earlier regarding colchicine and minocycline.

Dramatic improvement of subcutaneous calcinosis by intermittent, high-dose etidronate plus cimetidine in a patient with juvenile dermatomyositis. Wakabayashi T, Sasaki N, Chinen N, et al. *Case Rep Rheumatol* 2015, Article ID 817592, 3 pages, 2015.

A 17-year-old boy with juvenile dermatomyositis and bilateral extensive lower limb calcinosis extending into the subcutaneous tissue and muscle showed marked improvement with intermittent six monthly high-dose etidronate (800 mg/day for 3 months) and cimetidine for over 5 years.

Effectiveness of the treatment with intravenous pamidronate in calcinosis in juvenile dermatomyositis. Marco Puche A, Calvo Penades I, Lopez Montesinos B. *Clin Exp Rheumatol* 2010; 28: 135–40.

Three children with juvenile dermatomyositis received treatment with intravenous pamidronate at 1 mg/kg/day on 3 consecutive days every 3 months. In all three cases calcinosis significantly decreased and even totally cleared in one of them.

Improvement of calcinosis using pamidronate in a patient with juvenile dermatomyositis. Martillotti J, Moote D, Zemel L. *Pediatr Radiol* 2014; 44: 115–8.

A 7-year-old girl with juvenile dermatomyositis developed severe calcinosis, despite an extensive medication regimen. Three administrations of intravenous pamidronate (1 mg/kg/dose every month for 3 months) produced significant improvement in calcinosis, pain, and function, leading to remission less than 1 year after induction of therapy.

Efficacy of probenecid for a patient with juvenile dermatomyositis complicated with calcinosis. Nakamura H, Kawakami A, Ida H, et al. *J Rheumatol* 2006; 33: 1691–3.

An 11-year-old boy with juvenile dermatomyositis developed calcinosis of both legs. Probenecid was used to reduce calcinosis, resulting in remarkable improvement of calcinosis accompanied by normalization of serum phosphorus level.

Large subcutaneous calcification in systemic lupus erythematosus: treatment with oral aluminium hydroxide administration followed by surgical excision. Park YM, Lee SJ, Kang H, et al. *J Korean Med Sci* 1999; 14: 589–92.

A 22-year-old woman with systemic lupus erythematosus developed soft tissue calcification with ulceration, infection, and abscess formation. She was treated with aluminum hydroxide 600 mg three times a day with reduction in size and softening of the deposits after 9 months.

Calcinosis cutis in juvenile dermatomyositis responsive to aluminum hydroxide treatment. Nakagawa T, Takaiwa T. *J Dermatol* 1993; 20: 558–60.

A case of calcinosis cutis in juvenile dermatomyositis was successfully treated with oral aluminum hydroxide; near-complete clearance was observed after 8 months of therapy.

The use of these agents in patients with renal insufficiency may result in aluminum toxicity.

Third-Line Therapies

• Warfarin	D
• Ceftriaxone	E
• Rituximab	E
• Intravenous immunoglobulin	D
• Intralesional sodium thiosulfate	D
• Topical sodium thiosulfate	D
• Topical sodium metabisulfite	E
• Surgery	C
• Carbon dioxide laser	E
• Extracorporeal shock wave lithotripsy	D
• Infliximab	D
• Apremilast	E

Low dose warfarin treatment for calcinosis in patients with systemic sclerosis. Cukierman T, Elinav E, Korem M, et al. *Ann Rheum Dis* 2004; 63: 1341–3.

Three patients with disseminated subcutaneous calcinosis were treated with low doses of warfarin (1 mg/day) for 1 year. Two patients (relatively small lesions up to 2 cm in diameter) had complete resolution within 2 months. The other patient (larger and longer-standing lesions reaching up to 5 cm) did not respond to treatment. None of the patients showed a prolongation of prothrombin time, partial thromboplastin time, or an increased tendency for bleeding.

See also Reiter et al. earlier regarding ceftriaxone.

Rituximab-induced regression of CREST-related calcinosis. de Paula DR, Klem FB, Lorencetti PG, et al. *Clin Rheumatol* 2013; 32: 281–3.

A 54-year-old woman with limited cutaneous scleroderma and calcinosis in her hands had complete resolution 7 months after the first infusion of rituximab (four weekly infusions 375 mg/m²).

Treatment of systemic sclerosis-associated calcinosis: a case report of rituximab-induced regression of CREST-related calcinosis and review of the literature. Daoussis D, Antonopoulos I, Liossis SN, et al. *Semin Arthritis Rheum* 2012; 41: 822–9.

This patient with frequently ulcerating and painful extensive CREST-related calcinosis received two rituximab courses (consisting of four weekly infusions, 375 mg/m² each); calcinosis significantly improved and pain disappeared.

Intravenous immunoglobulin for treatment of dermatomyositis-associated dystrophic calcinosis. Galimberti F, Li Y, Fernandez AP. *J Am Acad Dermatol* 2015; 73: 174–6.

In a retrospective analysis of dermatomyositis-associated calcinosis in an institution, five out of eight patients showed clinical improvement of calcinosis after IV immunoglobulin (1–3 g/kg over 2 days monthly).

Calcinosis cutis associated with amyopathic dermatomyositis: response to intravenous immunoglobulin. Peñate Y, Guillermo N, Melwani P, et al. *J Am Acad Dermatol* 2009; 60: 1076–7.

A 55-year-old female with amyopathic dermatomyositis and progressive dystrophic calcinosis on the limbs with ulceration and pain failed to respond to various immunosuppressants and diltiazem. She had treatment with intravenous immunoglobulin (IVIG) (2 g/kg/month) at a dose of 0.4 g/day for 5 consecutive days, in combination with a reduced dose of prednisolone. After five courses of IVIG the dermal calcifications reduced, both clinically and radiologically, and became asymptomatic.

Intralesional sodium thiosulfate treatment for calcinosis cutis in the setting of lupus panniculitis. Gunasekera NS, Maniar LE, Lezcano C, et al. *JAMA Dermatol* 2017; 153(9): 944–5.

A 40-year-old female with systemic lupus erythematosus with calcified subcutaneous nodules on her abdomen, arms, and legs was treated with intralesional sodium thiosulfate solution at a concentration of 12.5 g/50 mL, injected into individual calcified lesions, using 0.5 mL/cm(diameter) and injecting every 5–10 mm. After this treatment was repeated one or two times per lesion at subsequent appointments, the patient noticed softening and decreased size of the lesions over the next 16 months, with no new inflammatory lesions, and resolution of deep calcified lesions.

Treatment of skin calcifications with intra-lesional injection of sodium thiosulphate: a case series. Baumgartner-Nielsen J, Olesen AB. *Acta Derm Venereol* 2016; 96: 257–8.

A case series of six consecutive patients with calcifications due to systemic sclerosis or nephrogenic systemic fibrosis were treated with intralesional injections of sodium thiosulfate, 150 mg/mL. A total of eight lesions on the extremities in six female patients were treated with a total of 21 injections of sodium thiosulfate for up to a 4-week period, using doses ranging from 12.5 mg to 275 mg at each treatment. The size of the lesions was, on average, reduced by 67% by week 4 and by 90% by week 12. Complete remission was obtained in 50% of patients by week 12 and 80% reduction in baseline lesion size was achieved in the remaining 50% by week 12.

Topical sodium thiosulfate for calcinosis cutis associated with autoimmune connective tissue diseases: the Mayo Clinic experience, 2012–2017. Ma JE, Ernste FC, Davis MD, et al. *Clin Exp Dermatol* 2019; 44: 189–92.

A case series of 28 patients showed clinical improvement in 19 patients. Two had unknown response and seven had no response. One patient had pain with application and two had skin irritation but, overall, it was relatively well-tolerated.

Topical sodium metabisulfite for the treatment of calcinosis cutis: a promising new therapy. Del Barrio-Díaz P, Moll-Manzur C, Álvarez-Veliz S, et al. *Br J Dermatol* 2016; 175: 608–11.

Four female patients with calcinosis cutis showed decrease in size, erythema, and pain after 6 weeks of topical 25% sodium metabisulfite twice daily.

See also Reiter et al earlier regarding surgical excision.

High-speed burr debulking of digital calcinosis cutis in scleroderma patients. Lapner MA, Goetz TJ. *J Hand Surg Am* 2014; 39(3): 503–10.

A retrospective analysis of nine patients with scleroderma who underwent debulking surgery using a high-speed micro-burr to soften and express calcific material in digits was performed. After 2 years' follow-up, four patients were very or somewhat satisfied with the procedure and two patients had no recurrence, but there were seven cases of recurrence. Patient satisfaction appeared inversely correlated to the number of digits involved.

Scrotal calcinosis: two case reports. Karray O, Dhaoui A, Boulma R, et al. *J Med Case Rep* 2017; 11(1): 312.

Case reports of two North African patients with scrotal calcinosis. Complete excision resulted in good aesthetic and functional outcomes and, 5 years postoperatively, patients have no sign of recurrence.

Surgical debridement of painful fingertip calcinosis cutis in CREST syndrome. Saddic N, Miller JJ, Miller OF 3rd, et al. *Arch Dermatol* 2009; 145: 212–3.

A 58-year-old woman with CREST syndrome underwent 2-mm curettage. There was immediate pain relief, and 7 months after the procedure, calcinosis had not recurred.

See also Balin et al. earlier. Surgical excision of large, discrete, and symptomatic lesions can be beneficial to patients.

A dystrophic calcinosis cutis case treated with CO₂ laser. Kutlubay Z, Yardimci G, Gokler G, et al. *J Cosmet Laser Ther* 2014; 16: 144–6.

A 12-year-old boy with 2- to 4-mm calcinosis on his right knee was treated with eight to 10 passes with a CO₂ laser (Candela CO2RE) at a wavelength of 10,600 nm, in classical mode, 3- to 5-mm spot size, fluence of 5 mJ, and pulse duration of 0.104 ms. There was resolution and no recurrence after 3 months.

Therapy of calcinosis cutis using erbium-doped yttrium aluminum garnet laser treatment. Meissner M, Ochsendorf F, Kaufmann R. *Dermatol Surg* 2010; 36: 727–8.

Patients with subcutaneous nodules smaller than 2 cm in diameter were given local anesthesia, then the skin over the mass was opened using a focused erbium-doped yttrium aluminum garnet (Er:YAG) beam (5 J/cm², 5 mm diameter, 5 Hz). The chalky material was then removed with a swab or curette. Reepithelialization and cosmetic recovery were seen at 2–3 weeks and 14 weeks, respectively.

Treatment of calcinosis cutis by extracorporeal shock-wave lithotripsy. Sultan-Bichat N, Menard J, Perceau G, et al. *J Am Acad Dermatol* 2012; 66: 424–9.

A single center study, including eight consecutive patients (with 10 calcinosis cutis lesions) who underwent three extracorporeal shock wave lithotripsy sessions at 3-week intervals for 6 months. At the end of this treatment period the median area had decreased by more than 50% in three calcinosis cutis lesions, with pain scores decreasing significantly in five patients and analgesia consumption decreasing in three patients, with no difference in results according to the underlying causal disease.

Effectiveness of infliximab in the treatment of refractory juvenile dermatomyositis with calcinosis. Riley P, McCann LJ, Maillard SM, et al. *Rheumatology* 2008; 47: 877–80.

Intravenous infliximab was initially given at a dose of 3 mg/kg to five patients with dermatomyositis-associated calcinosis. Further doses were then given at weeks 2, 6 and every 8 weeks thereafter. Between 8 and 30 months after starting infliximab, improvements were seen in all five patients, as shown by positive changes in physician visual analog scale, Childhood Myositis Assessment Score (CMAS), Childhood Health Assessment Questionnaire (CHAQ), joint range of movement, and, in some, regression of calcinosis and skin signs.

Apremilast as an adjuvant therapy for calcinosis cutis. Qiblawi SH, Fivenson DP. *JAAD Case Reports* 2019; 874–6.

Two patients with calcinosis cutis resistant to multiple treatments started on apremilast, with improvement after 2 months. One had recurrent infections on apremilast and had to stop; the other remained on treatment for over 16 months and continued to have slow improvement of deep ulcerated lesions on the legs.

Calciphylaxis

Kevin Young Chao, Reid Oldenburg, Taraneh Paravar

From Weenig RH. Pathogenesis of calciphylaxis: Hans Selye to nuclear factor kappa-B. J Am Acad Dermatol 2008; 58(3): 458–471.

Calciphylaxis (or calcific uremic arteriolopathy) is a life-threatening condition, which most often occurs in patients with end-stage renal disease, although non-uremic calciphylaxis also occurs. It is characterized by calcification of the medial layer of arterioles and subintimal fibrosis, which progresses to thrombotic occlusion and cutaneous necrosis. Calciphylaxis presents with tender purpuric retiform plaques, nodules, or ulcers most commonly on the lower extremities.

MANAGEMENT STRATEGY

Calciphylaxis has a mortality of up to 80%, which underscores the importance of early diagnosis via skin biopsy and aggressive treatment. The pillars of treatment for calciphylaxis are monitoring for infection, aggressive wound care, calcium chelation, and addressing underlying metabolic imbalance.

Sepsis is the leading cause of death in calciphylaxis, which necessitates consistent surveillance for wound infection including consideration of tissue and wound cultures, *monitoring for systemic signs of infection*, and prompt initiation of *antibiotics when necessary*. Early and aggressive *debridement of necrotic tissue* is important to remove a potential nidus of infection.

Intravenous sodium thiosulfate (STS) is used to remove calcium deposits by chelation. STS is currently considered a standard of care. *Intralesional STS* has also been used.

Addressing the underlying metabolic dysregulation is critical. Serum calcium should be decreased by *discontinuing calcium and vitamin D supplementation*. Hyperphosphatemia must be reduced with dietary phosphorus restriction and usage of non-calcium-based phosphate binders. *Discontinuation of vitamin K antagonists (VKA)* such as warfarin is critical to promote vitamin K-dependent production of matrix Gla protein, a potent inhibitor of arterial calcification. In renal failure, the use of *low-calcium dialysate* to

solubilize calcium into the intravascular space is helpful. *Bisphosphonates* can be used to decrease arterial calcification.

Hyperparathyroidism may be treated with *cinacalcet* with continued surveillance of parathyroid hormone levels. *Parathyroidectomy* is an option for recalcitrant hyperparathyroidism, but risks and benefits of surgery must be weighed.

Patients should be evaluated for hypercoagulability and autoimmune conditions. Hyperbaric oxygen therapy and negative pressure wound therapy also have potential utility.

Multi-interventional therapy is important in calciphylaxis management.

Specific Investigations

- Skin biopsy
- Serum calcium, phosphorus, parathyroid hormone, 25-hydroxyvitamin D, vitamin K, albumin
- Wound/tissue cultures
- Hypercoagulation evaluation (PT, PTT, protein C/S, antithrombin III, and antiphospholipid antibodies)
- Bone scintigraphy

Calciphylaxis: risk factors, diagnosis, and treatment. Nigwekar SU, Kroshinsky D, Nazarian RM, et al. Am J Kidney Dis 2015; 66: 133–46.

Literature review of calciphylaxis.

The role of bone scintigraphy in the diagnosis of calciphylaxis. Paul S, Rabito CA, Vedak P, et al. JAMA Dermatol 2017; 153: 101–3.

In a retrospective case-control study of calciphylaxis and control patients, bone scintigraphy had a sensitivity of 89% and a specificity of 97%.

First-Line Therapies

• Debridement of necrotic tissue and aggressive wound care	C
• Discontinuation of calcium and vitamin D supplementation	C
• Decrease serum phosphorus	C
• Discontinue vitamin K antagonists (VKA)	C
• Treatment of low serum albumin	C
• IV sodium thiosulfate (STS)	C
• Cinacalcet	C
• Pamidronate	D
• Monitoring for infection	C

Calciphylaxis epidemiology, risk factors, treatment and survival among French chronic kidney disease patients: a case-control study. Gaisne R, Péré M, Menoyo V, et al. BMC Nephrol 2020; 21: 63.

Retrospective cohort study of 89 calciphylaxis patients (70 dialysis and 19 non-dialysis). Higher serum albumin, surgical debridement, treatment with STS, treatment with sevelamer, and VKA discontinuation were associated with better survival.

A nationally representative study of calcific uremic arteriopathy risk factors. Nigwekar S, Zhao S, Wenger J, et al. J Am Soc Nephrol 2016; 27: 3421–9.

Retrospective review of 1030 patients found diabetes, high body mass index (BMI), hypercalcemia, hyperphosphatemia, vitamin D treatment, and warfarin were associated with increased odds of developing calciphylaxis.

Multi-intervention management of calcific uremic arteriopathy in 24 patients. Harris C, Kiaii M, Lau W, et al. Clin Kidney J 2018; 11: 704–9.

Retrospective analysis of 24 patients with calciphylaxis, all of whom received IV STS (12.5–25 g three times weekly), intensive hemodialysis, wound care, and medication discontinuation, some of whom received hyperbaric oxygen and cinacalcet. The majority showed complete or partial response to therapy and seven showed no response.

Use of sodium thiosulfate in a multi-interventional setting for the treatment of calciphylaxis in dialysis patients. Emanuel Z, Matthias K, Andreas V, et al. Nephrol Dial Transplant 2013; 28: 1232–40.

Retrospective cohort study of 27 calciphylaxis patients that were treated with STS. Complete or partial remission was achieved in 70%.

The effect of cinacalcet on calcific uremic arteriopathy events in patients receiving hemodialysis: The EVOLVE Trial. Floege J, Kubo Y, Floege A, et al. Clin J Am Soc Nephrol 2015; 10: 800–7.

Randomized placebo-controlled study of cinacalcet with conventional therapies for chronic kidney disease-mineral and bone disorder found that prophylactic cinacalcet (30–180 mg daily) resulted in 69%–75% risk reduction in calciphylaxis.

The use of cinacalcet for the treatment of calciphylaxis in patients with chronic kidney disease: a comprehensive review. Deen J, Schaidler H. Australas J Dermatol 2019; 60: e186–94.

Review of 41 patients from 26 publications. Of these patients, 12 received cinacalcet monotherapy and 29 received combination therapy. Combination therapy yielded complete response in 18 of 29 cases and partial response in six of 29 cases, with a total response rate of 82.8%. Monotherapy yielded similar results.

Non-uraemic calciphylaxis successfully treated with pamidronate infusion. Truong D, Riedhammer MM, Zinszer K. Int Wound J 2019; 16: 250–5.

This is one of several reports of the successful use of pamidronate as calciphylaxis therapy. Pamidronate disodium 30 mg infusions every 2 weeks for a total of four infusions led to resolution in a patient with calciphylaxis over 6 months.

Second-Line Therapies	
• Intralesional sodium thiosulfate (STS)	D
• Parathyroidectomy (for patients with elevated parathyroid hormone)	C
• Hyperbaric oxygen therapy	C
• Low-calcium dialysate	D
• Negative pressure wound therapy	E
• Vitamin K supplementation in patients who are deficient	E

Intralesional sodium thiosulfate for the treatment of calciphylaxis. Strazzula L, Nigwekar SU, Steele D, et al. JAMA Dermatol 2013; 149: 946–9.

Four patients with calciphylaxis treated with 1–4 mL of intralesional STS (250 mg/mL) in areas of clinically active disease had complete resolution of ulcers with only transient localized discomfort during injection. This and other cases utilized 1–4 mL every 1–2 weeks.

Survival, risk factors, and effect of treatment in 101 patients with calciphylaxis. McCarthy JT, El-Azhary RA, Patzelt MT, et al. Mayo Clin Proc 2016; 91: 1384–94.

Calciphylaxis patients with hyperparathyroidism treated with subtotal parathyroidectomy had improved 6-month and overall survival. Surgical debridement was also associated with improved survival.

Hyperbaric oxygen in the treatment of calciphylaxis: a case series and literature review. An J, Devaney B, Ooi KY, et al. Nephrology (Carlton) 2015; 20: 444–50.

Retrospective analysis of patients with calciphylaxis associated with renal disease. In total, 34 received a full course of hyperbaric oxygen therapy with or without parathyroidectomy or STS, with 58% showing improvement and over half demonstrating complete healing.

Successful treatment of severe calciphylaxis in a hemodialysis patient using low-calcium dialysate and medical parathyroidectomy: case report and literature review. Wang HY, Yu CC, Huang CC. Ren Fail 2004; 26: 77–82.

This and other cases report successful calciphylaxis treatment with low-calcium dialysate.

Nonuraemic calciphylaxis: response to treatment with pamidronate and negative pressure therapy. Lorriaux A, Chaby G, Dhaille F, et al. Clin Exp Dermatol 2015; 40: 52–5.

Two cases of non-uraemic calciphylaxis responded to IV pamidronate 30 mg every 2 weeks with negative pressure therapy with improvement in wounds and pain after several months.

Calciphylaxis in a dialysis patient successfully treated with high-dose vitamin K supplementation. Christiadi D, Singer R. Clin Kidney J 2018; 11: 528–9.

Case report of a hemodialysis patient with calciphylaxis and undetectable vitamin K levels who received vitamin K supplementation with lesion resolution.

Third-Line Therapies	
• Rheopheresis	D
• Myo-inositol hexaphosphate	C
• Prednisone (for patients without ulcerations only)	C
• Renal transplantation	E
• Heparin	D
• Tissue plasminogen activator	D

Rheopheresis: a new therapeutic approach in severe calciphylaxis. Robert T, Lionet A, Bataille S, et al. Nephrology (Carlton) 2020; 25: 298–304.

Retrospective study of eight cases of calciphylaxis that failed STS and VKA discontinuation and were treated with 2–3 weekly sessions of rheopheresis with hemodialysis. Complete remission was obtained in five patients over 114–196 days.

Improvement in wound healing, pain, and quality of life after 12 weeks of SNF472 treatment: a phase 2 open-label study of patients with calciphylaxis. Brandenburg VM, Sinha S, Torregrosa JV, et al. *J Nephrol* 2019; 32: 811–21.

Open-label, single-arm study of 14 calciphylaxis patients who received standard care and intravenous myo-inositol hexaphosphate, which inhibits formation of hydroxyapatite crystals, three times per week for 12 weeks. Seven of nine patients with ulcerated lesions improved.

Calciphylaxis is usually nonulcerating: risk factors, outcome and therapy. Fine A, Zacharias J. *Kidney Int* 2000; 61: 2210–7.

Review of 36 patients who presented with calciphylaxis without ulcerations demonstrated improvement from steroid therapy (prednisone 30–50 mg orally daily for 3–8 weeks) in 80% of cases. Contraindications to steroid therapy include ulceration anywhere or high risk of infection.

Resolution of calciphylaxis after urgent kidney transplantation in 3 patients with end-stage kidney failure. Nordheim E, Dahle DO, Syse IM, et al. *Transplant Direct* 2016; 2: e113.

Three case reports of patients with prior failed kidney transplants demonstrate complete resolution of calciphylaxis within 4 months of receiving kidney transplantation.

Calciphylaxis with evidence of hypercoagulability successfully treated with unfractionated heparin: a multidisciplinary approach. Carter A, Ortega-Loayza AG, Barrett J, et al. *Clin Exp Dermatol* 2016; 41: 275–8.

This and other case reports note successful use of unfractionated heparin or low molecular weight heparin for calciphylaxis.

Retrospective analysis of tissue plasminogen activator as an adjuvant treatment for calciphylaxis. el-Azhary RA, Arthur AK, Davis MDP, et al. *JAMA Dermatol* 2013; 149: 63–7.

Retrospective study of calciphylaxis treated with adjunctive low-dose tissue plasminogen activator suggests benefit. Bleeding was a complication.

Capillaritis (pigmented purpuric dermatoses, purpura pigmentosa)

Cord Sunderkötter, Thomas A. Luger

Capillaritis (a generic term for the various pigmented purpuric dermatoses) presents with the common feature of orange-red macules with peripheral purpuric spots resembling grains of cayenne pepper. As they progress, the macules partially coalesce and acquire a yellowish-brown color. Also called Schamberg purpura, capillaritis is a chronic dermatosis with relapses and remissions. Pigmented purpuric dermatoses are characterized histologically by erythrocyte extravasation and perivascular infiltration with T lymphocytes. Lesions develop a characteristic brown to orange color due to hemosiderin deposits in macrophages. These conditions may also present with additional, distinctive, and sometimes overlapping morphological patterns, which have given rise to several descriptive or eponymous names: papules in pigmented purpuric lichenoid dermatosis (of Gougerot and Blum) or in the rarely described granulomatous pigmented purpura (non-necrotizing granulomata with concomitant lymphocytic infiltrate); eczematous spongiosis with pruritus in eczematoid-like purpura; annular forms with telangiectases and central clearing in purpura annularis telangiectodes (Majocchi disease); and often solitary, ochre-golden plaques or patches with band-like infiltrates including a grenz zone in lichen aureus. Sites of predilection are mostly both lower extremities. A form of unilateral linear capillaritis or involvement of other areas of the skin are rare. Pigmented purpuric dermatoses also occur in children, albeit less frequently than in adults.

The etiology of capillaritis is not known. The reason for extravasation of erythrocytes is not an inflammatory fibrinoid necrosis of vessel walls (no vasculitis). Possible pathophysiological factors that can be addressed therapeutically are recruitment or activation of lymphocytes, increased venous pressure, increased vascular permeability, or vascular fragility due to subtle defects in the extracellular matrix.

MANAGEMENT STRATEGY

Diagnostic hallmarks are the yellow-brown or orange patches with superimposed pinpoint cayenne pepper spots, which represent petechiae and persist with diascopy. Thus, biopsies are warranted when in doubt.

Dermoscopic examination shows a coppery-red to brownish diffuse coloration of the background, round to oval red dots, globules or patches, and gray dots (probably accumulation of hemosiderin-containing macrophages) and a partial network of interconnected pigmented lines.

The main differential diagnoses are petechiae in thrombocytopenia ($<10.000\text{--}20.000/\text{mm}^3$) and small vessel vasculitis; a discerning criterion from the latter would be a palpable infiltrate (palpable or retiform purpura) when present, but there are courses or variants of small vessel vasculitis with petechial maculae only (e.g., IgA vasculitis or recurrent macular vasculitis in hypergammaglobulinemia [hypergammaglobulinemic purpura of Waldenström]).

Thus, biopsies are warranted when in doubt. Allergic contact dermatitis (e.g., in response to textile or azo dyes) may be purpuric or hemorrhagic, but with intense pruritus. The pigmented purpuric dermatitis-like variant of mycosis fungoides also needs to be excluded. Suspicion would be raised by poikiloderma, pruritus, coalescing plaques, and a duration of more than 1 year. Exclusion of mycosis fungoides may require repeated biopsies. Linear morphea was seen to develop in the same anatomic distribution as prior lichen aureus, warranting follow-up especially in pediatric patients.

Capillaritis has a benign course and therefore must be differentiated from these more serious diseases.

Usually there is no need for treatment unless the patient has pruritus or suffers from cosmetic disfigurement.

Detection and avoidance of possible eliciting agents should always be attempted. Reported causes include:

- Drugs (14% in one series), e.g., non-steroidal antiinflammatory drugs (NSAIDs) (acetaminophen, acetylsalicylic acid), bromine-containing drugs, carbamazepine, meprobamate, chlorthalidone, furosemide, nitroglycerine, interferon- α , raloxifene (selective estrogen receptor modulator), thiamine (vitamin B1), sildenafil, or topical 5-fluorouracil. As a rule, drug-induced capillaritis is more generalized and does not usually present with epidermal involvement or lichenoid infiltrate; its onset is around 10 days after intake of the suspected drug.
- Dietary supplements or ingredients: reported triggers include creatine or coca cola and apple-cherry fruit spritzer, as well as ingredients of an energy drink (vitamin B complex, caffeine, taurine).
- Chronic infections such as viral hepatitis B or C (though relation is questionable) or odontogenic infections.

When the etiology remains obscure, therapy has to be empirical. Local corticosteroids, calcineurin inhibitors, or ultraviolet (UV) 311 nm (preferred to psoralen plus UVA [PUVA]) have been tried. Increased venous pressure (particularly in the legs) or exercise are not direct causes but can aggravate capillaritis. In these cases, compression stockings may be helpful.

There is some evidence for increased vascular permeability or vascular fragility due to subtle defects in the extracellular matrix. This may explain reported responses to *bioflavonoids* (which may be due to inhibition of elastase and hyaluronase and of leukocyte activation), *ascorbic acid* (antioxidant effects and perhaps reduction of vascular permeability), and *calcium dobesilate* (reduction of microvascular permeability in part by antioxidant properties).

Specific Investigations

- Careful drug history
- Look for signs of chronic infection or rheumatoid arthritis
- Exclude chronic venous insufficiency and purpuric contact eczema (e.g., by modified patch test performed at the site of skin lesions to look after a petechial reaction to, e.g., azo dyes)
- Dermoscopy
- Hematology (complete blood count)
- C-reactive protein
- Optional: immunoglobulins, protein electrophoresis
- Histology
- In granulomatous variant: triglycerides and cholesterol

Purpura simplex (inflammatory purpura without vasculitis): a clinicopathologic study of 174 cases. Ratnam KV, Su WP, Peters MS. *J Am Acad Dermatol* 1991; 25: 642–7.

A retrospective review of 174 cases. A correlation between purpuric reaction and drugs was observed in 14%. Of the 87 patients who were followed up, 67% appeared to eventually have clearing of lesions.

Pigmented purpuric dermatosis: clinicopathologic characterization in a pediatric series. Coulombe J, Jean SE, Hatami A, et al. *Pediatr Dermatol* 2015; 32: 358–62.

A retrospective chart review of 17 children. Pigmented purpuric dermatosis resolved in 13 cases with a median duration <1 year, in five of them without treatment; those cases treated with topical corticosteroids improved in 75% and those with narrowband ultraviolet B in 100%. No associated disease or drug exposure were found.

The pathological spectrum and clinical correlation of pigmented purpuric dermatosis – a retrospective review of 107 cases. Huang Y-K, Lin C-K, Wu Y-H. *J Cutan Pathol* 2018; 45: 325–32.

This study described the wide pathological spectrum of pigmented purpuric dermatosis among Asians.

Progression of pigmented purpura-like eruptions to mycosis fungoides: report of three cases. Barnhill RL, Braverman IM. *J Am Acad Dermatol* 1988; 19: 25–31.

Initial eruptions, resembling pigmented purpuric dermatitis both clinically and histologically, developed into histologically definite mycosis fungoides in a follow-up period averaging 8.4 years.

Drug-induced purpura simplex: clinical and histological characteristics. Pang BK, Su D, Ratnam KV. *Ann Acad Med Singapore* 1993; 22: 870–2.

A prospective study of 183 patients with purpura simplex was carried out. Of these, 27 cases were confirmed to be drug induced as the purpura cleared within 4 months of withdrawal of medications. NSAIDs, diuretics, meprobamate, and ampicillin were the commonest offenders.

Pigmented purpura dermatosis and viral hepatitis: a case-control study. Ehsani AH, Ghodsi SZ, Nourmohammad-Pour P, et al. *Australas J Dermatol* 2013; 54: 225–7.

A prospective case-control study with 60 pigmented purpuric dermatosis (PPD) patients and 230 randomly selected controls. The prevalence of hepatitis B surface antigen (HBsAg) in PPD patients and the controls were 3% and 4.3%, respectively; the prevalence of hepatitis C virus (HCV) was 1.7% vs. 1.3%. Thus, direct involvement of hepatitis B (HBV) or HCV in pathogenesis of PPD is not certain.

Chronic pigmented purpura associated with odontogenic infection. Satoh T, Yokozeki H, Nishioka K. *J Am Acad Dermatol* 2002; 46: 942–4.

Appearance of purpuric spots in five patients ceased after treatment for periodontitis, pulpitis, or both.

Capillaritis associated with interferon-alfa treatment of chronic hepatitis C infection. Gupta G, Holmes SC, Spence E, et al. *J Am Acad Dermatol* 2000; 43: 937–8.

Pigmented purpuric dermatosis after taking a dietary supplement. Unal E, Ergül G. *Cutan Ocul Toxicol* 2015; Nov 10: 1–3.

Dermoscopic finding in pigmented purpuric lichenoid dermatosis of Gougerot-Blum: a useful tool for clinical diagnosis. Park MY, Shim WH, Kim JM, et al. *Ann Dermatol* 2018; 30: 245–7.

Nomenclature of Cutaneous Vasculitis: Dermatologic Addendum to the 2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitides. Sunderkötter C, Zelger B, Chen KR, et al. *Arthritis Rheumatol* 2018; 70(2): 171–84.

Capillaritis or pigmented purpura dermatosis are no genuine vasculitis (and would also not present a so-called lymphocytic vasculitis if it exists).

Linear morphea overlying site of previous lichen aureus in a pediatric patient. Johnston M, Benson P, Morley K. *Pediatr Dermatol* 2019; 36(4): e91–2.

First-Line Therapies

• Oral bioflavonoids and ascorbic acid	C
• Local corticosteroids initially in cases of pruritus/eczematoid or itching purpura	D
• Narrowband UVB (or PUVA)	D
• Calcium dobesilate	D
• Compression stocking when aggravated by increased venous pressure	E

We recommend rutoside and ascorbic acid as our therapy of choice, because it is efficacious especially in early disease and because it has fewer potential side effects than UV light or topical corticosteroids.

Early treatment with rutoside and ascorbic acid is highly effective for progressive pigmented purpuric dermatosis. Schober SM, Peitsch WK, Bonsmann G, et al. *J Dtsch Dermatol Ges* 2014; 12: 1112–9.

A retrospective review on 35 patients treated with 1000 mg ascorbic acid and 2 × 50 mg rutoside (a form of bioflavonoid,

often available without prescription). The mean treatment duration was 8.2 months: 71.4% of the participants experienced complete clearance and 20.0% an improvement of more than 50%. Nine (25.1%) relapsed after discontinuation; in seven treatment was successfully reinitiated. Only three participants reported mild adverse effects. Participants with shorter disease duration showed better and faster therapeutic success, and lower risk of recurrence.

Treatment of progressive pigmented purpura with oral bioflavonoids and ascorbic acid: an open pilot study in 3 patients. Reinhold U, Seiter S, Ugurel S, et al. *J Am Acad Dermatol* 1999; 41: 207–8.

First report on this treatment; complete clearance of skin lesions after 4 weeks of treatment.

Venoprotective drugs in pigmented purpuric dermatoses: a case report. Gupta A, Sardana K, Kishan Gautam R. *A case report. J Cosmet Dermatol* 2019 [Epub ahead of print].

Successful treatment with a fixed dose combination of diosmin 450 mg, hesperidin 50 mg (micronized purified flavonoid fraction [MFPP]), *Euphorbia prostrata* extract 100 mg, and calcium dobesilate 500 mg once a day. Relapse after discontinuation was responsive to the same medication.

PUVA therapy in lichen aureus. Ling TC, Goulden V, Goodfield MJ. *J Am Acad Dermatol* 2001; 45: 145–6.

One case of lichen aureus that responded dramatically to photochemotherapy (PUVA).

Treatment of pigmented purpuric dermatoses with narrow-band UVB: a report of six cases. Fathy H, Abdelgaber S. *J Eur Acad Dermatol Venereol* 2011; 25: 603–6.

Successful treatment was achieved in all six patients after 24–28 treatments and maintenance of nine treatments. Two patients who showed flare of their lesions were efficiently controlled with further 14 treatments.

Calcium dobesilate (Cd) in pigmented purpuric dermatosis (PPD): a pilot evaluation. Agrawal SK, Gandhi V, Bhattacharya SN. *J Dermatol* 2004; 31: 98–103.

Nine male patients (seven with Schamberg disease and one each with lichenoid dermatosis of Gougerot and Blum and lichen aureus) were given calcium dobesilate 500 mg twice daily for 2 weeks initially, and then 500 mg once daily for 3 months. No new lesions occurred within 2 weeks, and itching ceased in all patients. The improvement of existing lesions 1 year after cessation of therapy was moderate in 11.11% and mild in 66.67% of cases; 22.22% did not show any improvement.

Second-Line Therapies

• Pentoxifylline	E
• Topical calcineurin inhibitors	E
• Advanced fluorescence technology (AFT) of broadband pulsed light	D

Successful treatment of Schamberg's disease with pentoxifylline. Kano Y, Hirayama K, Orihara M, et al. *J Am Acad Dermatol* 1997; 36: 827–30.

Three patients with Schamberg disease were treated with pentoxifylline 300 mg daily for 8 weeks. A significant response was observed within 2–3 weeks. One patient had recurrence after discontinuation, but promptly responded to resumption of therapy.

Resolution of lichen aureus in a 10-year-old child after topical pimecrolimus. Böhm M, Bonsmann G, Luger TA. *Br J Dermatol* 2004; 150: 519–20.

A 10-year-old boy with lichen aureus, resistant to topical corticosteroids for 4 months. A significant improvement was observed within 3 weeks of treatment with pimecrolimus cream twice daily.

Unlike topical corticosteroids, topical immunomodulators do not cause fragility of blood vessels, which is an advantage when treating this group of diseases.

Treatment of Schamberg's disease with advanced fluorescence technology. Manolagos DA, Weiss J, Glick B, et al. *J Drugs Dermatol* 2012; 11: 528–9.

Favorable treatment of five patients with Schamberg disease using AFT pulsed light, a broadband pulsed light platform device as used for non-ablative treatment of, for example, photodamaged skin.

Third-Line Therapies

• Colchicine	E
• Ciclosporin	E
• Methotrexate	E

The authors would recommend neither ciclosporin nor methotrexate because of the severity of possible adverse events or side effects and because of the benign nature of capillaritis.

Schamberg's disease: case report with therapeutic success by using colchicine. Cavalcante MLLL, Masuda PY, Brito FF, et al. *An Bras Dermatol* 2017; 92(2): 246–8.

Capillaritis improved after 2 months of colchicine 0.6 mg twice daily and cleared after 4 months.

Cat scratch disease

Floriane Kouby, Olivier Chosidow

Cat scratch disease (CSD) is a benign, usually self-limited disease caused by *Bartonella henselae* (formerly *Rochalimaea henselae*), a Gram-negative pleomorphic rod. The primary lesion consists of a 0.5- to 1-cm papule or pustule, which may undergo ulceration, and adjacent unilateral lymphadenopathy is the hallmark of the disease. Atypical manifestations, including retinitis/neuroretinitis, Parinaud syndrome (granulomatous conjunctivitis and preauricular adenopathy), neuritis, encephalitis, hepatosplenic disease, osteomyelitis, erythema nodosum, and endocarditis, develops in 5%–20% of patients with the disease.

Atypical manifestations of cat-scratch disease, United States, 2005–2014. Nawrocki C, Max R, Marzec N, et al. Emerg Infect Dis. 2020; 26: 1438–46.

Using US nationwide insurance claims data, authors identified and characterized 224 atypical cases of cat scratch disease during 2005–2014 and estimated an average annual incidence of 0.7 cases/100,000 population. Ocular (48.7%), hepatosplenic (24.6%), and neurologic (13.8%) manifestations were common. Atypical cat scratch occurred most often in females 10–14 years of age.

MANAGEMENT STRATEGY

As there is a paucity of data showing a clear benefit of antimicrobial therapy in the treatment of patients with mild-to-moderate CSD, these patients should be managed with *conservative, symptomatic treatment*. The lymphadenopathy associated with CSD is self-limiting and resolves in 2–4 months; therefore, most patients can be managed with *observation* until involution of the node.

For patients with systemic symptoms and/or complications, antibiotic therapy should be instituted. *Azithromycin* (500 mg on day 1, followed by 250 mg on days 2–5) is the only antibiotic that has been shown in a double-blind, placebo-controlled evaluation to be beneficial to immunocompetent patients with CSD. In a retrospective analysis of 202 patients with CSD who had been on at least 3 days of antimicrobial therapy, only four antibiotics

(rifampin, ciprofloxacin, gentamicin, and trimethoprim-sulfamethoxazole) provided clinical benefit.

In immunosuppressed patients, infection with the CSD bacillus can produce a spectrum of disease, from classic CSD to bacillary angiomatosis, peliosis, or septicemia (see Chapter 21, Bacillary angiomatosis). Antimicrobial treatment for such patients is beneficial and clearly indicated. Lesions and symptoms respond rapidly to erythromycin 500 mg four times daily or doxycycline 100 mg twice daily. In patients with AIDS, therapy should be administered for at least 3 months.

Of note, *B. henselae* has rarely been isolated from patients with CSD; however, patients who are immunosuppressed may be culture positive. A single dose of oral antibiotics will rapidly sterilize blood and lesional cultures.

Specific Investigations

- Serology
- Polymerase chain reaction (PCR)-based techniques
- Histopathology
- Culture

CSD may be diagnosed presumptively in patients with typical signs and symptoms and a compatible exposure history. The *Bartonella* species are difficult to culture, and serology is the best initial test and can be performed by indirect fluorescent assay or enzyme-linked immunosorbent assay. Although more sensitive than culture, serologic tests lack specificity because many asymptomatic persons may have positive serology because of previous (often asymptomatic) exposure. *B. henselae* DNA may be detected by PCR or culture of lymph node aspirates or blood. Lymph node biopsy is not indicated routinely but should be considered if the diagnosis is unclear.

Evaluation of sensitivity, specificity and cross-reactivity in *Bartonella henselae* serology. Vermeulen MJ, Verbakel H, Notermans DW, et al. J Med Microbiol 2010; 59: 743–5.

The combined use of (Houston strain) indirect fluorescence antibody assay (IFA), IgM, and IgG improves sensitivity with significant reduction of specificity. Erroneous diagnosis of CSD can have a major impact for the patient, so IgG results must be interpreted with caution.

Development of a specific and sensitive enzyme-linked immunosorbent assay as an in vitro diagnostic tool for detection of *Bartonella henselae* antibodies in human serum. Jost M, Latz A, Ballhorn W, et al. J Clin Microbiol 2018; 56: e01329–e18.

The authors report the development of enzyme-linked immunosorbent assay (ELISA)-detecting human anti-*B. henselae* antibodies from serum samples. By the use of well-characterized human sera from the strictly quality-controlled serum library of the German National Consiliary Laboratory for *Bartonella* infections, the sensitivity of this ELISA was 100% for PCR-proven infections and 76% for clinically-suspected infections with a specificity of 93%.

***Bartonella henselae* DNA in seronegative patients with cat-scratch disease.** Yanagihara M, Tsuneoka H, Tanimoto A, et al. Emerg Infect Dis 2018; 24: 924–5.

Real-time PCR was used to detect *Bartonella henselae* DNA in 7.9% (5/63) of blood specimens from seronegative patients suspected of cat scratch disease. The combined use of serologic tests and real-time PCR to analyze blood specimens is recommended.

Bartonella-associated infections. Spach DH, Koehler JE. Infect Dis Clin North Am 1998; 12: 137–55.

Early in the disease course, lymphoid hyperplasia and arteriolar proliferation are prominent. Subsequently, granulomas appear. Late in the disease, multiple stellate microabscesses are prominent.

Combined application of immunohistochemistry and Warthin–Starry silver stain on the pathologic diagnosis of cat scratch disease. Peng J, Fan Z, Zheng H, et al. Appl Immunohistochem Mol Morphol 2020.

In this review of 46 cases of paraffin-embedded lymphadenitis with histologic and/or clinical suspicion of CSD, 80.4% of cases were positive for *B. henselae* by immunohistochemistry (IHC) and 52.5% by the Warthin–Starry silver stain (WS) method. Moreover, a positive percentage of *B. henselae* was 97.8%, which was detected by the combined application of IHC and WS. The combination of IHC and WS exhibited high sensitivity (97.8%) with good concordance (86.5%).

First-Line Therapy

- Symptomatic treatment

A

Treatment outcomes of human bartonellosis: a systematic review and meta-analysis. Prutsky G, Domecq JP, Mori L, et al. Int J Infect Dis 2013; 17: e811–9.

Two studies evaluating antibiotic therapy in CSD. The first was a randomized controlled trial comparing azithromycin with placebo, and the second was a non-randomized observational study comparing trimethoprim-sulfamethoxazole, ciprofloxacin, gentamicin, and rifampin with no treatment. These two studies did not show a statistically significant effect in terms of cure rate or time to achieve cure.

Second-Line Therapy

- Azithromycin

A

Prospective randomized double blind placebo-controlled evaluation of azithromycin for treatment of cat-scratch disease. Bass JW, Freitas BC, Freitas AD, et al. Pediatr Infect Dis J 1998; 17: 447–52.

Seven of 14 azithromycin-treated patients (500 mg on day 1, followed by 250 mg on days 2–5) showed an 80% reduction in initial lymph node volume compared with one of 15 placebo-treated controls during the first 30 days of observation. After 30 days there was no significant difference in resolution rates.

This is the only controlled clinical trial of an antibiotic for the therapy of CSD; the use of all other antibiotics is based on anecdotal reports.

Third-Line Therapies

- Erythromycin
- Doxycycline
- Rifampin
- Ciprofloxacin
- Gentamicin
- Trimethoprim-sulfamethoxazole
- Surgical intervention

C
C
C
C
C
C
C

Antibiotic therapy for cat-scratch disease: clinical study of therapeutic outcome in 268 patients and a review of the literature. Margileth AM. Pediatr Infect Dis J 1992; 11: 474–8.

In 60 patients with CSD with systemic symptoms, one of four antibiotics was effective at least 72% of the time. Patients who received rifampin (10–20 mg/kg daily for 7–14 days), ciprofloxacin (20–30 mg/kg daily for 7–14 days), gentamicin (5 mg/kg daily intravenously in divided doses every 8 hours for at least 3 days), or trimethoprim-sulfamethoxazole (6–8 mg/kg of trimethoprim component 2–3 times daily for 7 days) had a shorter mean duration of posttreatment illness than those who received either no antibiotics or antibiotics thought to be ineffective.

Recommendations for the treatment of human infections caused by *Bartonella* species. Rolain JM, Brouqui P, Koehler JE, et al. Antimicrob Agents Chemother 2004; 48: 1921–33.

Even if azithromycin is the authors' first-line treatments for CSD, combination of doxycycline (10 mg twice daily) with rifampin (300 mg twice daily) could be an alternative. This combination has been successful in treating patients with retinitis or central nervous system disease.

When CSD lymph nodes suppurate, needle aspiration results in rapid pain alleviation.

Effectiveness of antibiotic therapy in pediatric patients with cat scratch disease. Shorbatli LA, Koranyi KI, Nahata MC. Int J Clin Pharm 2018; 40:1458–61.

In a group of 175 children, 102 were treated with azithromycin and 18 with trimethoprim-sulfamethoxazole (TMP-SMX). There was no statistically significant difference in the effectiveness based on CSD resolution or improvement between azithromycin and TMP-SMX groups ($p=0.56$).

Cat-scratch disease of the head and neck in a pediatric population: surgical indications and outcomes. Munson PD, Boyce TG, Salomao DR, et al. Otolaryngol Head Neck Surg 2008; 139: 358–63.

In children, failure of medical therapy in cases that presented as persistent lymphadenopathy often were accompanied by violaceous skin changes, extreme tenderness to palpation, and even chronic drainage. In this subgroup of patients the benefit of surgical intervention and concurrent tissue examination outweighed the risk.

Acknowledgments

The authors thank Bryan A. Selkin and George J. Murakawa for writing the previous version of this chapter.

Cellulite

Doris M. Hexsel, Bruce E. Katz, Camile L. Hexsel

Cellulite consists of surface relief alterations with depressed and raised areas, located mainly on the thighs and buttocks but also on other areas. Depressed lesions are due to the presence of fibrous septa that pull the skin surface down; raised areas result from the projection of underlying fat to the skin surface. In addition, cellulite is aggravated by progressive skin laxity, localized fat deposition, and obesity. Treatments do not cure cellulite but can improve its appearance. Unfortunately, some studies lack blinding or controls and objective measurements.

MANAGEMENT STRATEGY

Diagnosis: Clinical

Specific Treatments

- Subcision, which targets the subcutaneous septa that pull the skin down and addresses cellulite depressions
- Devices and treatments that target the dermis and thus improve flaccidity and projection of fat and devices that target localized fat
- Weight control to a normal body mass index (BMI)
- Oral and topical treatments

Specific Investigations

- Physical examination: patient in standing position with relaxed gluteus muscles. Determine morphologic characteristics to help guide treatment option selection:
 - Presence and depth of cellulite depressions
 - Presence of localized fat and obesity
 - Presence of flaccidity and fat herniation
- Pretreatment and posttreatment photographs (relaxed gluteus muscles)
- Scales: a validated photonumeric scale, cellulite severity scale (CSS), and dimple scales for pre- and posttreatment objective assessment
- Preoperative investigations for subcision: prothrombin time (PT), partial thromboplastin time (PTT), and international normalization ratio (INR); history of coagulation disorders; use of medications that alter blood coagulation

A validated photonumeric cellulite severity scale. Hexsel DM, Dal'forno T, Hexsel CL. *J Eur Acad Dermatol Venereol* 2009; 23: 523–8.

A validated photonumeric severity quantitative and qualitative scale of five key morphologic aspects of cellulite. Each item is graded from 0 to 3; their sum allows a final classification of cellulite as mild, moderate, and severe.

Validated assessment scales for cellulite dimples on the buttocks and thighs in female patients. Hexsel D, Fabi SG, Sattler G, et al. *Dermatol Surg* 2019; 45 (Suppl 1): S2–11.

The cellulite dimple grading scales provide 5-point photonumeric assessments of cellulite severity at rest and in a dynamic state. Overall inter-rater reliability and intra-rater reliability of the scales were both 'almost perfect' (at rest) and 'substantial' (dynamic).

Side-by-side comparison of areas with and without cellulite depressions using magnetic resonance imaging. Hexsel DM, Abreu M, Rodrigues TC, et al. *Dermatol Surg* 2009; 35: 1471–7.

Cellulite depressions were associated to the presence of underlying fibrous septa perpendicular to the skin surface ($n=30$).

First-Line Therapies

• Subcision	B
• Devices	B
• Weight control	B

Effect of weight loss on cellulite: gynoid lipodystrophy. Smalls LK, Hicks M, Passeretti D, et al. *Plast Reconstr Surg* 2006; 118(2): 510–6.

Twenty-eight subjects with visible cellulite recruited from a weight loss program and eight weight-stable subjects without visible cellulite completed a study in which 17 subjects' cellulite improved and nine worsened.

Subcision: a treatment for cellulite. Hexsel DM, Mazzuco R. *Int J Dermatol* 2000; 39: 539–44.

Based on clinical assessment of pre- and posttreatment standardized photographs on 232 patients, subcision was shown to be efficacious in the treatment of high-grade cellulite. It specifically targets major cellulite depressions by sectioning the underlying fibrous septa and consequently forming new connective tissue.

Magnetic resonance imaging of cellulite depressed lesions successfully treated by subcision. Hexsel D, Dal Forno T, Hexsel C, et al. *Dermatol Surg* 2016; 42: 693–6.

A 7-month follow-up of moderate-to-severe cellulite-depressed lesions treated with subcision showing evident reduction in CSS grading (number and depth of the treated lesions) in the two assessed patients. The subdermal portion of the septum underlying the treated lesion was absent after subcision.

A multicenter pivotal study to evaluate tissue stabilized-guided subcision using the Cellfina device for the treatment of cellulite with 3-year follow-up. Kaminer MS, Coleman WP 3rd, Weiss RA, et al. *Dermatol Surg* 2017; 43(10): 1240–8.

Fifty-five women with moderate-to-severe cellulite underwent one treatment with a vacuum-assisted tissue stabilized-guided subcision (TS-GS). Assessments by subject photographs, CSSs, GAIS (Global Aesthetic Improvement Scale), and subject satisfaction showed significant improvements lasting up to 1 year; 94% of subjects had at least 1-grade improvement in the CSS (mean change of 2 points; $p < 0.0001$). At 3 years posttreatment, more than 91% of patients sustained improvement.

Multicenter study of vacuum-assisted precise tissue release for the treatment of cellulite in a cohort of 112 Italian women assessed with cellulite dimples scale at rest. Stefania G, Bruno B, Luigi CP, et al. *J Cosmet Laser Ther* 2019; 21(7–8): 404–7.

A retrospective study of one treatment with TS-GS for cellulite ($n = 122$). The mean score of Merz Aesthetics cellulite dimple grading scale decreased from 2.6 ± 0.9 to 0.9 ± 0.6 ($n = 112$; $p < .01$) after 1 year, and 96.4% of the subjects improved at least 1 point in cellulite dimple scale.

Treatment of dimpling from cellulite. Amore R, Amuso D, Leonardi V, et al. *Plast Reconstr Surg Glob Open* 2018; 6(5): e1771.

Multicenter observational study ($n = 200$) of one treatment with manual subcision with Celluerase, a microsurgical blade with two cutters and a gauge of 19 G $\times$ 30 mm. Results were assessed by two physicians using a scale from 0 to 10 where 0 is 'no result at all' and 10 is 'the best result achievable'. The average score was 8.1 and the subjective improvement average score 7.8.

Collagenase Clostridium histolyticum for the treatment of edematous fibrosclerotic panniculopathy (cellulite): a randomized trial. Sadick NS, Goldman MP, Liu G, et al. *Dermatol Surg* 2019; 45(8): 1047–56.

A collagenase *Clostridium histolyticum* (CCH) is thought to enzymatically disrupt fibrous septae. A double-blind placebo-controlled multicenter trial, in which 843 women received three injection sessions to the buttocks at 3-week intervals. CCH significantly improved cellulite compared to placebo considering a two-level composite response in the photonumeric cellulite severity scale (PCSS) assessment. Significant subject satisfaction on the GAIS was also observed.

Treatment of cellulite using a 1440-nm pulsed laser with one-year follow-up. DiBernardo BE. *Aesthet Surg J* 2011; 31: 328–41.

Ten women with cellulite on their thighs received a single treatment with a 1440-nm pulsed laser. Mean skin thickness (as shown by ultrasound) and skin elasticity increased. Subjective physician evaluations indicated improvement in the appearance of cellulite.

Quantitative and qualitative evaluation of efficacy of a 1440 nm Nd:YAG laser with novel bi-directional optical fiber in the treatment of cellulite as measured by 3-dimensional surface imaging. Katz BE. *J Drugs Dermatol* 2013; 12: 1224–30.

Fifteen women with cellulite were treated with a 1440-nm pulsed laser with side-firing fiber. There was improvement in cellulite in 68% of subjects on photographic evaluation by two independent observers, revealing good-to-excellent results, and significant improvement in 65% of subjects assessed by three-dimensional surface imaging.

Microfocused ultrasound with visualization and calcium hydroxylapatite for improving skin laxity and cellulite appearance. Casabona G, Pereira G. *Plast Reconstr Surg Glob Open* 2017; 5(7): e1388.

Twenty women with skin laxity and moderate-to-severe cellulite on the buttocks and thighs were treated with MFU-V using 4 MHz and 7 MHz transducers (25 lines/transducer/site) and immediately followed by subdermal calcium hydroxylapatite injection (1 mL/buttock or thigh). Two blinded evaluators reported improvements compared with baseline for each item on the cellulite severity scale ($p < 0.001$) with a 4.5-point improvement in mean overall score ($p < 0.001$).

Effectiveness of the electromagnetic shock wave therapy in the treatment of cellulite. Modena DAO, Nogueira da Silva C, Delinocente TCP, et al. *Dermatol Res Pract* 2019; 2019: 8246815.

Comparative and prospective longitudinal study ($n = 27$) showed significant improvement in CSS between baseline and after 10 treatments, and follow-up of 3 months for gluteus (7.2 ± 2.8 to 6.6 ± 2.7 and 5.5 ± 2.2 to 5.3 ± 1.6 ; $p < 0.0087$) and posterior thigh (7.2 ± 2.9 to 6.4 ± 2.6 and 5.7 ± 2.3 to 5.2 ± 1.5 ; $p < 0.0031$).

Acoustic wave therapy for cellulite, body shaping and fat reduction. Hexsel D, Camozzato FO, Silva AF, et al. *J Cosmet Laser Ther* 2017; 19(3): 165–73.

Prospective, single-center, open study ($n = 25$). The mean CSS grading reduced from 11.1 at baseline to 9.5 at 12 weeks ($p < 0.001$) posttreatment.

The effectiveness of anticellulite treatment using tripolar radiofrequency monitored by classic and high-frequency ultrasound. Mlosek RK, Woźniak W, Malinowska S, et al. *J Eur Acad Dermatol Venerol* 2012; 26: 696–703.

Randomized, controlled study in which 28 women with cellulite grade I to III underwent eight treatments with radiofrequency; 17 women were in the placebo group. Nürnberger–Müller scale was reduced in 89.3% in the treatment group and no statistically significant changes were observed in the placebo group.

Unipolar radiofrequency treatment to improve the appearance of cellulite. Alexiades-Armenakas M, Dover JS, Arndt KA. *J Cosmet Laser Ther* 2008; 10: 148–53.

Randomized, blinded, split-design study ($n = 10$) of excessive localized fat and cellulite (grades II–IV) on the thighs evaluated up to six unilateral treatments (number of treatments at the investigator's discretion; mean: 4.22, range: 3–6) at 2-week intervals.

with unipolar RF. Blinded photographic evaluations of a quantitative four-point cellulite grading scale demonstrated improvements in mean grading scores for the treated leg versus the control side: 11.2% in dimple density, 10.7% in dimple distribution, 2.5% in dimple depth, and $8 \pm 2.8\%$ mean score improvement.

A multicenter study of cellulite treatment with a variable emission radio frequency system. Van der Lugt C, Romero C, Ancona D, et al. *Dermatol Ther* 2009; 22: 74–84.

The buttocks of 50 patients were treated with bipolar RF technology at $6\text{ J}/\text{cm}^2$ for 12 weekly sessions on each buttock, with the treatment end point of 42°C external skin temperature. Based on the photography at baseline and at the 2-month assessment, the blinded independent clinicians' assessment of the cellulite appearance demonstrated that results were apparent in 66% of patients.

Reduction in thigh circumference and improvement in the appearance of cellulite with dual-wavelength, low-level laser energy and massage. Gold MH, Khatri KA, Hails K, et al. *J Cosmet Laser Ther* 2011; 13: 13–20.

In this controlled, multicenter study, 83 subjects with mild-to-moderate cellulite received eight treatments with a device comprising a low-level, dual-wavelength diode laser (650 nm and 915 nm), combined with heat induction and mechanical massage by suction, in one thigh with the untreated contralateral thigh serving as a control. There was subjective clinical improvement of the appearance of cellulite when comparing pretreatment and posttreatment photographs.

A single center, randomized, comparative, prospective clinical study to determine the efficacy of the VelaSmooth system versus the Triactive system for the treatment of cellulite. Nootheti PK, Magpantay A, Yosowitz G, et al. *Lasers Surg Med* 2006; 38: 908–12.

Twenty female patients were treated biweekly for 6 weeks with randomization to infrared (IR) light (680–1550 nm) with bipolar radiofrequency (RF) and mechanical massage by vacuum suction on one side, and diode lasers (808/810 nm) combined with mechanical massage, suction, and localized cooling on the other side. In both treatment groups, 25% of the patients had improvement in the appearance of cellulite. The rates of improvement in roughness and of perceived change in cellulite grade were not statistically different ($p > 0.05$) between the two treatment arms.

Prospective multicenter clinical trial of a temperature-controlled subcutaneous microneedle fractional bipolar radiofrequency system for the treatment of cellulite. Alexiades M, Munavalli G, Goldberg D, et al. *Dermatol Surg* 2018; 44(10): 1262–71.

Open clinical trial to assess the effects of minimally invasive bipolar fractional RF system ($n = 50$). Blinded physician evaluations revealed a procedural success rate of 93% at 6-month follow-up.

Second-Line Treatments

• Mesotherapy	B
• Carboxytherapy	B
• Mesolipolysis	B

Efficacy of intradermal mesotherapy in cellulite reduction – conventional and high-frequency ultrasound monitoring results. Sylwia M, Krzysztof MR. *J Cosmet Laser Ther* 2017; 19(6): 320–24.

Twenty-one women received six treatments with polyaminoacidic gel, $\alpha\text{-D-(+)}$ glucopyranose, 1-4 glycosidic, ethylenediaminetetraacetic sodium, amino acid buffer system with bicarbonate-sodium corrector, osmolarity regulator at 6–7-day intervals. Improvements: Nürnberger–Müller's scale ($p = 0.002$); reduction in thigh circumference, subcutaneous tissue thickness, and surface area of a subcutaneous tissue fascicle ($p \leq 0.0005$).

Evaluation and efficacy of carbon dioxide therapy (carboxytherapy) versus mesolipolysis in the treatment of cellulite. Eldsouky F, Ebrahim HM. *J Cosmet Laser Ther* 2018; 20(5): 307–12.

Randomized blind study of one group receiving carboxytherapy and the other mesolipolysis using phosphatidylcholine for 6 weeks, one weekly session. Improvement in cellulite grading scale ($p < 0.001$) were observed in both groups. Results persisted for 6 months in 66.7% of cases treated with carboxytherapy and in 65.8% treated with mesolipolysis. Regression of results occurred in 33.3% and 34.2% of the cases, respectively.

Third-Line Therapies

• Topical retinol, caffeine, and ruscogenin	B
• Occluded topical caffeine with extracts of green tea, black pepper seed, citrus, ginger, and cinnamon	B
• Topical retinol	C
• Topical caffeine	B
• Topical phosphatidylcholine gel and light-emitting diode (LED)	C

A double-blind evaluation of the activity of an anticellulite product containing retinol, caffeine, and ruscogenin by a combination of several noninvasive methods. Bertin C, Zunino H, Pittet JC, et al. *J Cosmet Sci* 2001; 52: 199–210.

A placebo-controlled, double-blind study ($n = 46$) evaluated a topical anticellulite product that combined *retinol* microcapsules, *caffeine*, *Centella asiatica*, *L-carnitine*, *Esculoside*, and *ruscogenin*. The product was more effective than placebo in reducing cellulite appearance.

A two-center, double blinded, randomized trial testing the tolerability and efficacy of a novel therapeutic agent for cellulite reduction. Rao J, Gold MH, Goldman MP. *J Cosmet Dermatol* 2005; 4: 93–102.

In this placebo-controlled study, 34 women with moderate cellulite used a cream (caffeine, green tea extract, black pepper seed extract, citrus extract, ginger root extract, cinnamon bark extract, and capsicum annum resin) under occlusion with bio-ceramic-coated neoprene shorts. Dermatologists noted greater improvement in the treated group in 68% of subjects (prestudy vs. poststudy photographs).

Topical retinol improves cellulite. Kligman AM, Pagnoni A, Stoudmayer T. *J Dermatol Treat* 1999; 10: 119–25.

This placebo-controlled study ($n = 19$) demonstrated improvement in cellulite on the side treated with topical *retinol* 0.3% on the thighs for 6 months in 63.1% of the patients compared with the untreated side by clinical dermatologic evaluation.

The effectiveness and safety of topical PhotoActiv phosphatidylcholine-based anticellulite gel and LED (red and near-infrared) light on grade II–III thigh cellulite: a randomized,

double-blinded study. Sasaki GH, Oberg K, Tucker B, et al. J Cosmet Laser Ther 2007; 9: 87–96.

Placebo-controlled, double-blinded study. Nine subjects with grade II–III thigh cellulite were randomly treated twice daily with a phosphatidylcholine-based anticellulite gel on one thigh. Twice weekly, each thigh was exposed for a 15-minute treatment with LED array (660nm and 950nm) for 24 treatments; 89% of the treated thighs were downgraded to a lower cellulite grade by clinical examination, digital photography, and pinch test assessment. After 18 months, 63% of responsive thighs reverted back to baseline grading.

Cellulite reduction by modified Thai herbal compresses: a randomized double-blind trial. Ngamdokmai N, Waranuch N, Chootip K, et al. J Evid Based Integr Med 2018; 23: 2515690X18794158.

Double-blind, randomized, placebo-controlled paired trial. Twenty-one women received both herbal and placebo compress treatments for cellulite in one or other leg for 8 weeks. The actively treated leg presented significant reduction in CSS grading. Significant difference between the CSS scores (active vs. placebo) was observed. At week 11, the CSS score increased ($p=0.001$ vs. previous visit) and treatment effects dissipated.

39

Cellulitis and erysipelas

Colleen Gabel, Lauren Ko, Daniela Kroshinsky

Cellulitis is an infection of the deep dermis and subcutaneous tissue thought to occur after pathogen entry into the dermis through breaks in the skin. In erysipelas, superficial infection gives rise to an edematous, palpable, well-demarcated, often advancing, edge. These infections are often grouped together and included in the larger category of skin and skin-structure infections (SSSIs). The causative organism is commonly group A streptococcus, though many organisms have been isolated, including *Staphylococcus*, *Haemophilus influenzae*, and, more rarely, *Aeromonas hydrophila*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa*, as well as fungi and Gram-negative rods. Fulminating and necrotic cellulitis and fasciitis may occur rarely, usually in relation to immunosuppression or atypical organisms, and are accompanied by a high mortality rate.

MANAGEMENT STRATEGY

The management of SSTIs should initially assess illness severity and determine the appropriate treatment setting (i.e., outpatient vs. hospital), identifying the organism responsible when indicated, and then directing antimicrobial therapy. Underlying and predisposing conditions should be treated to prevent recurrence.

In the United States, the Infectious Diseases Society of America (IDSA) has published treatment guidelines for non-purulent and purulent SSTIs; however, there is little agreement on regimen. As published by Raff and Kroshinsky (2016), the following is derived in combination from the IDSA 2014 guidelines, Johns Hopkins antibiotic guidelines, and results from the literature for non-purulent cellulitis (Box 39.1) and purulent cellulitis (Box 39.2). Systemic inflammatory response syndrome (SIRS) is identified by two or more symptoms including fever or hypothermia, tachycardia, tachypnea, and change in blood leucocyte count.

For both non-purulent and purulent cellulitis, the following definitions apply:

- Mild cellulitis – cellulitis without systemic signs of infection
- Moderate cellulitis – cellulitis in a patient who meets 1 point of the following criteria: heart rate greater than 90/min; temperature greater than 38°C or lower than 36°C; respiratory rate greater than 20/min; or white blood cell count greater than 12,000 cells/mm³ or fewer than 4000 cells/mm³

- Severe cellulitis – cellulitis in a patient with any of the moderate cellulitis criteria and hypotension, rapid progression, or immunocompromise

Mild non-purulent cellulitis should be treated with amoxicillin/clavulanate, cephalexin, dicloxacillin, penicillin VK, or, in cases of true penicillin allergy, clindamycin to provide antistreptococcal coverage.

The same agents used for mild cellulitis may be used in cases of moderate cellulitis. Intravenous antibiotics such as cefazolin, ceftriaxone, and penicillin G should be considered in patients who fail oral therapy or meet two or more SIRS criteria. Clindamycin may be used in penicillin allergy.

Patients with severe non-purulent cellulitis should receive broad coverage therapy. Intravenous vancomycin with piperacillin/tazobactam, imipenem, or meropenem may be used. If necrotizing infection is suspected, urgent surgical evaluation

Box 39.1 Non-purulent cellulitis

Mild – Oral therapy with amoxicillin/clavulanate, cephalexin, dicloxacillin, penicillin VK

Moderate – If 1 SIRS criterion present, oral antibiotics as for mild cellulitis. If ≥ 2 SIRS criteria or treatment failure with oral antibiotics, intravenous cefazolin, ceftriaxone, penicillin G

Severe – Intravenous vancomycin plus piperacillin/tazobactam, imipenem, or meropenem. Consider surgical evaluation for necrotizing process with culture and sensitivity. If *S. pyogenes* or methicillin-susceptible *Staphylococcus aureus* (MSSA) is suspected, intravenous cefazolin, cefotaxime, ceftriaxone, or penicillin G. If treatment failure or suspected methicillin-resistant *Staphylococcus aureus* (MRSA), intravenous vancomycin, clindamycin, linezolid, daptomycin, ceftaroline, telavancin, or tigecycline

Box 39.2 Purulent cellulitis (purulent drainage or pustules in the absence of an abscess)

For all, perform I&D.

Mild – If suspected MSSA, oral cephalexin, dicloxacillin, or amoxicillin/clavulanate. If suspected MRSA, oral TMP-SMX, doxycycline, or minocycline. Cover with cephalexin or penicillin if streptococcal coverage also needed

Moderate – If 1 SIRS criteria present, as above for suspected MSSA or suspected MRSA. If ≥ 2 SIRS criteria and suspected MSSA, intravenous oxacillin, nafcillin, or cefazolin. If ≥ 2 SIRS criteria and suspected MRSA, intravenous vancomycin, clindamycin, or linezolid

Severe – Culture and sensitivity plus consideration of surgical evaluation for necrotizing disease with culture and sensitivity of any surgically obtained tissue. Empiric broad coverage with intravenous vancomycin, clindamycin, linezolid, daptomycin, ceftaroline, telavancin, or tigecycline. If MSSA culture positive, deescalate to intravenous oxacillin, nafcillin, cefazolin, or ceftriaxone. If MRSA culture positive, continue broad-spectrum coverage

Adapted from Raff AB, Kroshinsky D. Cellulitis: a review. JAMA 2016;316(3):3253–7.

with cultures and sensitivities should be sought. If streptococcal toxic shock syndrome is suspected, penicillin G and clindamycin should be used.

Other risk factors that should prompt broad-spectrum coverage with vancomycin or linezolid include cases secondary to penetrating trauma, active injection drug use, or evidence of MRSA infection or colonization. Patients who cannot receive vancomycin may be treated with oral linezolid. Severely immunocompromised patients should receive broad-spectrum coverage.

Purulent cellulitis should be accompanied by culture and sensitivity testing. Cases of purulent cellulitis are more likely to be *S. aureus*, and patient risk factors for MRSA may guide empiric antibiotic choice. Risk factors for MRSA include athletes, children, men who have sex with men, prisoners, military recruits, residents of long-term care facilities, individuals with previous MRSA exposure, and intravenous drug use.

Mild purulent cellulitis therapy is based on suspicion for methicillin-sensitive *S. aureus* (MSSA) versus MRSA. If MSSA is suspected, consider cephalexin, dicloxacillin, amoxicillin/clavulanate, or clindamycin if there is a penicillin allergy. If MRSA is suspected, trimethoprim-sulfamethoxazole, doxycycline, or minocycline should be used. If both streptococcal and staphylococcal organisms are suspected, cephalexin or penicillin should be added to therapy, with clindamycin or linezolid for penicillin-allergic patients.

Moderate purulent cellulitis in patients meeting only one SIRS criterion may be treated with the same initial therapy as mild non-purulent disease, with empiric therapy selected based on suspicion for MSSA versus MRSA. Intravenous antibiotics should be considered if patients meet two or more SIRS criteria. For suspected MSSA, agents of choice include cefazolin, oxacillin, or nafcillin. For suspected MRSA, vancomycin, clindamycin, or linezolid should be used.

Empiric MRSA coverage with intravenous vancomycin, clindamycin, linezolid, daptomycin, or ceftaroline should be used in patients with severe cellulitis. If necrotizing cellulitis is suspected, surgical evaluation with culture and sensitivity should be obtained.

Newer antibiotic agents include telavancin, tedizolid, dalbavancin, and oritavancin. These agents may be considered; however, they currently have limited clinical applications. Second-line therapies for cellulitis discussed below are limited in clinical practice due to cost and concern for adverse effects.

Sites of entry for infection should be sought and should be treated, such as tinea pedis and chronic skin ulcers. Lymphedema can be associated with recurrence of cellulitis and so should be managed with long-term compression and elevation, when possible.

The use of long-term antibiotics for the prevention of recurrent cellulitis has produced conflicting evidence but may be considered for at least 3–4 recurrent cases/year once underlying risk factors have been mitigated. There are no supporting data for antibiotic prophylaxis for MRSA cellulitis.

Specific Investigations

- Blood cultures – not routinely done in uncomplicated patients due to low yield
- Swabs of any purulent exudate, pustules, or wounds
- Ultrasound to assess for a drainable fluid collection if clinical exam indeterminate for abscess
- Skin scrapings for mycology

The IDSA recommends against performing routine blood or tissue cultures, except in cases of malignancy on chemotherapy, severe cell-mediated immunodeficiency, neutropenia, animal bites, or immersion injuries. Routine use of procalcitonin to diagnose or evaluate cellulitis is not recommended.

Ultrasound may be helpful in identifying abscesses.

In the case of SSTIs of the lower leg, skin scrapings from toe web spaces, sides of feet, or toenail subungual debris may be taken for mycologic examination. Facial erysipelas should warrant sinus radiographs to exclude underlying sinusitis. Crepitus should prompt the clinician to the presence of either *Clostridia* or non-spore-forming anaerobes, either alone or mixed with other organisms, and warrants surgical consultation and/or imaging.

Procalcitonin and cellulitis: correlation of procalcitonin blood levels with measurements of severity and outcome in patients with limb cellulitis. Brindle RJ, Ijaz A, Davies P. *Biomarkers* 2019; 24(2): 127–30.

Procalcitonin levels are not recommended in the evaluation or confirmation of limb cellulitis and is a poor predictor of improvement.

Clinical practice. Skin and soft-tissue infections caused by methicillin-resistant *Staphylococcus aureus*. Daum RS. *N Engl J Med* 2007; 357(4): 380–90.

In cases of purulent cellulitis, culture and sensitivity testing should be performed to guide therapy, with empirical antibiotic selection based on patient risk factors for MRSA infection.

Clinical usefulness of imaging and blood cultures in cellulitis evaluation. Ko L, Garza-Mayers AC, St. John J, et al. *JAMA Intern Med* 2018; 178(7): 994–6.

Radiologic imaging and blood cultures are not recommended for routine use in evaluation and treatment of cellulitis and may contribute significant cost to the healthcare system.

Methicillin-resistant *S. aureus* infections among patients in the emergency department. Moran GJ, Krishnadasan A, Gorwitz RJ, et al. *N Engl J Med* 2006; 355: 666–74.

A study of 422 patients in the United States who presented with purulent SSTIs found that swabs showed 59% had MRSA, 17% had methicillin-sensitive *S. aureus*, and 2.9% had β -hemolytic *Streptococcus*, demonstrating importance of swabs in such cases.

Clinical practice. Skin and soft-tissue infections caused by methicillin-resistant *Staphylococcus aureus*. Daum RS. *N Engl J Med* 2007; 357(4): 380–90.

Risk factors for MRSA colonization include household and day-care contacts of a patient with MRSA infection, children, soldiers, incarceration, men who have sex with men, athletes, infectious drug use, and previous MRSA infection.

Effect of dermatology consultation on outcomes for patients with presumed cellulitis: a randomized clinical trial. Ko LN, Garza-Mayers AC, St. John J, et al. *JAMA Dermatol* 2018; 154(5): 529–36.

This randomized clinical trial demonstrated that inpatient dermatology consultation may improve outcomes by identifying misdiagnosed cases of cellulitis and decreasing length of antibiotic treatment, improving antibiotic stewardship.

First-Line Empiric Therapies for Mild, Non-Purulent Cellulitis

• Cephalexin	A
• Dicloxacillin	A
• Penicillin VK	A
• Amoxicillin with clavulanic acid	A
• Clindamycin	B

First-Line Therapies for Mild Purulent Cellulitis – MSSA

• Cephalexin	A
• Dicloxacillin	A
• Amoxicillin with clavulanic acid	A
• Clindamycin	B

First-Line Therapies for Mild Purulent Cellulitis – MRSA

• TMP-SMX	A
• Doxycycline	A
• Minocycline	A
• Clindamycin	B
• Linezolid	B

Cellulitis. Fabre V, Bartlett, JC. Johns Hopkins ABX Guide, The Johns Hopkins University, 2019. Johns Hopkins Guide: www.hopkinsguides.com/hopkins/view/Johns_Hopkins_ABX_Guide/540106/all/Cellulitis.

Informs the above treatment recommendations for purulent and non-purulent cellulitis.

The course, costs and complications of oral versus intravenous penicillin therapy of erysipelas. Jorup-Ronstrum C, Britton S, Gavlevik A, et al. *Infection* 1984; 12: 390–4.

In this study of 60 patients there appeared to be no appreciable benefit from intravenous rather than oral therapy with penicillin for erysipelas, and so oral therapy is recommended if there are no associated complications with the infection.

Interventions for cellulitis and erysipelas. Kilburn SA, Featherstone P, Higgins B, et al. *Cochrane Database Syst Rev* 2010; 16: CD004299.

A Cochrane review in 2010 could not recommend any particular antibiotic regimen for cellulitis and erysipelas due to the large variation in treatment regimens studied.

Efficacy of oral beta-lactam versus non-beta-lactam treatment of uncomplicated cellulitis. Madaras-Kelly KJ, Remington RE, Oliphant CM, et al. *Am J Med* 2008; 121(5): 419–25.

A multicenter, retrospective cohort study of outpatients treated for uncomplicated cellulitis found no significant difference in failure rates when comparing oral beta-lactams with non-β-lactams, with increased discontinuation in the non-β-lactam group because of adverse events.

Effect of cephalexin plus trimethoprim-sulfamethoxazole vs. cephalexin alone on clinical cure of uncomplicated cellulitis:

a randomized clinical trial. Moran GJ, Krishnadasan A, Mower WR, et al. *JAMA* 2017; 317(20): 2088–96.

In this multicenter, double-blind, randomized superiority trial in five US emergency departments of uncomplicated cellulitis treatment, clinical resolution of cellulitis was not significantly different in patients treated with cephalexin plus trimethoprim-sulfamethoxazole compared to cephalexin alone.

Clinical trial: comparative effectiveness of cephalexin plus trimethoprim-sulfamethoxazole versus cephalexin alone for treatment of uncomplicated cellulitis: a randomized controlled trial. Pallin DJ, Binder WD, Allen MB, et al. *Clin Infect Dis* 2013; 56(12): 1754–62.

A multicenter, double-blind, randomized controlled trial comparing the use of cephalexin to cephalexin and trimethoprim-sulfamethoxazole for cases of non-purulent, uncomplicated cellulitis demonstrated no benefit to the addition of antibiotics against community-acquired MRSA.

Risk factors for nonpurulent leg cellulitis: a systematic review and meta-analysis. Quirke M, Ayoub F, McCabe A, et al. *Br J Dermatol* 2017; 177(2): 382–94.

A systematic literature search revealed increased risk of non-purulent cellulitis associated with previous cellulitis, wounds, current leg ulcers, lymphedema, excoriation, tinea pedis, and obesity.

Cellulitis: a review. Raff AB, Kroshinsky D. *JAMA* 2016; 316: 325–37.

A review article from 2016 advises the above treatment regime based on the IDSA guidelines and Johns Hopkins Guidelines, as well as randomized controlled trials.

Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. Stevens DL, Bisno AL, Chambers HF, et al. *Clin Infect Dis* 2014; 59(2): 147.

These updated guidelines serve as a basis for the antibiotic regimes suggested above.

Management of invasive group A streptococcal infections. Waddington CS, Snelling TL, Carapetis JR. *J Infect* 2014; 69(Suppl 1): S63–9.

Patients with cellulitis and signs of shock should receive penicillin G and clindamycin for potential streptococcal toxic shock syndrome.

Second-Line Therapies

• Linezolid	A
• Daptomycin	A
• Vancomycin	A
• Oritavancin	B
• Telavancin	B
• Tedizolid	B
• Dalbavancin	B
• Imipenem/cilastatin	B

ATLAS trials: efficacy and safety of telavancin compared with vancomycin for the treatment of skin infections. Barriere SL. *Future Microbiol* 2010; 5(12): 1765–73.

Telavancin is FDA-approved for the treatment of complicated SSTIs caused by susceptible Gram-positive bacteria, including

MRSA. Telavancin 10 mg/kg once daily is non-inferior to vancomycin; however, there is a risk of nephrotoxicity.

Single-dose oritavancin in the treatment of acute bacterial skin infections. Corey GR, Kabler H, Mehra P, et al. *N Engl J Med* 2014; 370(23): 2180–90.

A single dose of oritavancin has been shown to be as effective as twice-daily intravenous vancomycin administered for 7–10 days.

Tedizolid phosphate vs linezolid for treatment of acute bacterial skin and skin structure infections: The ESTABLISH-1 Randomized Trial. Prokocimer P, De Anda C, Fang E, et al. *JAMA* 2013; 309(6): 559–69.

A once-daily oral dose of 200 mg tedizolid phosphate for 6 days was non-inferior to 600 mg oral linezolid every 12 hours for 10 days in early clinical response at 48–72 hours.

Twice daily intramuscular imipenem/cilastatin in the treatment of skin and soft tissue infections. Sexton DJ, Wlodaver CG, Tobey LE, et al. *Chemotherapy* 1991; 37: 26–30.

Of 102 patients enrolled in this study with mild to moderately severe SSTIs, 74 were evaluable, with 20 having cellulitis, 23 wound infections, and 31 abscesses. Imipenem/cilastatin was given intramuscularly using doses of 500 mg or 750 mg 12-hourly. In this study there was no assessment by type of infection, but 82% were cured and 16% improved. Eight patients reported minor side effects.

Randomized comparison of linezolid (PNU-100766) versus oxacillin-dicloxacillin for treatment of complicated skin and soft tissue infections. Stevens DL, Smith LG, Bruss JB, et al. *Antimicrob Agents Chemother* 2000; 12: 3408–13.

Hospitalized adult patients were randomized to receive linezolid (600 mg intravenously) every 12 hours or oxacillin (2 g intravenously) every 6 hours; after sufficient clinical improvement, patients were switched to the respective oral agents (linezolid 600 mg orally every 12 hours or dicloxacillin 500 mg orally every 6 hours). The clinical cure rates were 88.6% and 85.8%, respectively.

Comparative efficacy of antibiotics for the treatment of acute bacterial skin and skin structure infections (ABSSSI): a systematic review and network meta-analysis. Thom H, Thompson JC, Scott DA, et al. *Curr Med Res Opin* 2015; 31: 1539–51.

This meta-analysis of 52 trials concluded that there is equivalence of clinical efficacy between vancomycin, daptomycin, linezolid, and the novel antimicrobial agent oritavancin. However, they noted the heterogeneity of the available evidence and the need for further research.

Linezolid versus vancomycin for skin and soft tissue infections. Yue J, Dong BR, Yang M, et al. *Cochrane Database Syst Rev* 2013; 7(7): CD008056.

A 2013 Cochrane review comparing oral linezolid with intravenous vancomycin for the treatment of SSTIs demonstrated that linezolid had better clinical and microbiological cure rates overall as well as for MRSA infections.

Prophylaxis

• Low-dose oral penicillin	A
• Intramuscular weekly penicillin	C
• Treatment of predisposing factors	E

The experience of intramuscular benzathine penicillin for prophylaxis of recurrent cellulitis: a cohort study. Chen HM, Li YL, Liu YM, et al. *J Microbiol Immunol Infect* 2017; 50(5): 613–8.

A retrospective study of 72 patients with a history of recurrent cellulitis who had received intramuscular benzathine penicillin at a 4-week interval demonstrated a reduced incidence rate of recurrent cellulitis.

Interventions for the prevention of recurrent erysipelas and cellulitis. Dalal A, Eskin-Schwartz M, Mimouni D, et al. *Cochrane Database Syst Rev* 2017; 6.

A total of six trials were assessed in this systematic review, concluding that antibiotics may be effective in reducing recurrence, incidence, and time to next episode of lower limb cellulitis (moderate-certainty evidence) for the duration that the antibiotic is prescribed (low-certainty evidence).

Cellulitis and erysipelas. Morris A. *Clin Evid* 2004; 12: 2268–74.

Although there is a consensus that successful treatment of predisposing factors such as leg edema, tinea pedis, and traumatic wounds reduces the risk of developing cellulitis, there are no randomized controlled trials or observational studies to support this.

Antibiotic prophylaxis for preventing recurrent cellulitis: a systematic review and meta-analysis. Oh CC, Ko HC, Lee HY, et al. *J Infect* 2014; 69: 26.

This meta-analysis concluded that antibiotic prophylaxis can prevent recurrent cellulitis but that further research is needed to establish indication, choice of drug, and dosage regimens.

Penicillin to prevent recurrent leg cellulitis. Thomas KS, Crook AM, Nunn AJ, et al. *N Engl J Med* 2013; 368(18): 1695–703.

A double-blind, randomized, controlled trial of 274 patients treated either with low-dose oral penicillin (250 mg twice daily) or placebo for 12 months, finding a reduced recurrence risk during the time of prophylaxis administration, but not in subsequent no-prophylaxis follow-up.

Chancroid

Iris A. Hagans, Glenn C. Newell

Chancroid is an ulcerative disease of the skin caused by the Gram-negative, facultative, anaerobic coccobacillus *Haemophilus ducreyi*. Chancroid is typically considered a sexually transmitted genital ulcer disease; however, it is increasingly identified as a cause of non-genital ulcerative skin lesions, especially in endemic areas. The incidence is decreasing worldwide; however, chancroid should be suspected in any ulcerative skin lesion especially in travelers returning from high-risk areas, including Africa, the Caribbean basin, and Southwest Asia.

Chancroid typically presents as a painful, ragged, deep ulcer 3–20 mm in diameter without induration, often beginning with papules that may pustulate and subsequently break down into the classic ulcer. There may be surrounding erythema, and the base is often covered with a yellow-gray exudate.

Genital lesions may be single, but can be multiple as a result of autoinoculation (kissing lesions). Painful lymphadenitis occurs in 30%–60% of genitally infected patients, and approximately one quarter of patients with lymphadenopathy may develop a suppurative bubo.

DIAGNOSIS AND MANAGEMENT STRATEGY

Diagnosis on clinical criteria alone is difficult. The painful genital ulcer of chancroid can easily be confused with genital herpes or secondarily infected syphilis, and non-genital ulcerative lesions have been misdiagnosed as yaws in both adults and children.

A presumptive diagnosis of chancroid can be made with consistent epidemiologic history, one or more painful genital or skin ulcers with negative laboratory tests for herpes simplex virus (HSV) and syphilis. In genital lesions, coinfection with either of these diseases occurs in as many as 10% of patients, further complicating diagnosis.

A definitive diagnosis may be made by culturing the exudates from the ulcer base or by aspiration of a bubo. Gram stain of the ulcer base in chancroid may show Gram-negative coccobacilli in a 'school of fish' appearance. Special culture media should be used, and the specimen should be handled by laboratories familiar with *H. ducreyi*. It should be noted that sensitivity of culture as shown by DNA amplification techniques can be as low as 75%.

Nucleic acid amplification tests (NAATs) show higher positivity rates than culture and do not depend on live bacteria, making the test especially useful. However, only a few laboratories have established NAATs for the diagnosis of chancroid. Polymerase chain reaction testing has the advantage of simultaneous testing of *H. ducreyi* along with *T. pallidum* and HSV.

Concurrent HIV infection can alter the manifestations of chancroid. HIV prolongs the incubation period of *H. ducreyi* and prevents proper healing of the ulcers. As HIV can increase the number of genital ulcers and non-genital ulcers are frequently found, the diagnosis is often confused with HSV. Treatment guidelines for patients coinfecting with HIV are the same as for those without HIV, but closer follow-up and a potentially longer course of therapy may be recommended, as there are increased treatment failures with HIV coinfection. Additionally, chancroid has been noted to increase the susceptibility to HIV, probably by disrupting mucosal integrity. Patients should be tested for HIV at the time of chancroid diagnosis and should be retested for HIV 3 months after the diagnosis of chancroid if initial testing was negative.

Treatment should be started once a presumptive diagnosis is made and it is not necessary to wait for laboratory confirmation. Single-dose azithromycin or ceftriaxone are considered the preferred treatment regimens. These offer the advantage of improved adherence rates, though there is a scarcity of data regarding treatment success and antimicrobial resistance, in part due to limited testing and most cases occurring in resource-poor areas. Improvement occurs rapidly with a decrease in symptoms typically noted within 3 days and visual ulcer healing beginning within 7 days, though scarring can occur. Of note, uncircumcised men may have a higher risk of infection and may take longer to cure. Patients should be reevaluated within a week of treatment and if no improvement is noted the diagnosis should be reconsidered and adherence should be assessed. Additionally, HIV coinfection should be ruled out and consideration regarding antimicrobial resistance should be made. Patients should abstain from sexual contact and sexual partners should also be examined and treated.

Specific Investigations

- Gram stain of ulcer base or bubo aspirate
- Culture of ulcer base or bubo aspirate
- NAATs
- Syphilis serology
- HIV serology

First-Line Therapies

• Azithromycin 1 g orally (one dose)	A
• Ceftriaxone 250 mg intramuscularly (one dose)	A

2017 European guideline for the management of chancroid. Lautenschlager S, Michael Kemp M, Christensen JJ, et al. Int J STD AIDS 2017; 28: 324–9.

A comprehensive review of chancroid diagnosis and management. The authors note that while the first-line therapies above have generally acceptable response rates, treatment failures have been noted in HIV positive patients.

Macrolides for treatment of *Haemophilus ducreyi* infection in sexually active adults. Romero L, Huerfano C, Grillo-Ardila CF. Cochrane Database Syst Rev 2017(12): CD012492.

A systematic review of seven randomized, controlled studies to evaluate the effectiveness of macrolides for the treatment of

H. ducreyi infections. The authors determined that, based on low quality evidence, azithromycin can be considered a first-line therapy for the treatment of *H. ducreyi* infections due to its single-dose administration compared with erythromycin, which requires a longer course. There was little data regarding the safety and effectiveness of using macrolides to treat *H. ducreyi* in patients with HIV.

Single-dose azithromycin for the treatment of *Haemophilus ducreyi* skin ulcers in Papua New Guinea. González-Beiras C, Kapa A, Vall-Mayans M, et al. Clin Infect Dis 2017; 65: 2085–90.

A community-based cohort study on a single island in Papua New Guinea, in which 246 patients with skin or genital ulcers were tested for *H. ducreyi* and *Treponema pallidum* subspecies *pertenue* (the causative agent of yaws) via lesional polymerase chain reaction (PCR) swab and given 1 g of azithromycin orally. Ulcers were examined 14 days later. Healing rates were 88.5% in the *H. ducreyi* group, 78.4% in the yaws group, and 74.4% in the PCR-negative group. Of the patients with *H. ducreyi*-positive lesions, 94.7% had improved ulcers and all patients with non-healed *H. ducreyi* lesions converted to *H. ducreyi* PCR negative.

Second-Line Therapies

- Ciprofloxacin 500mg orally twice a day for 3 days **B**
- Erythromycin 500mg orally three times a day for 7 days **B**

Epidemiology of *Haemophilus ducreyi* infections. González-Beiras C, Marks M, Chen CY, et al. Emerg Infect Dis 2016; 22: 1–8.

This is a systematic review to assess the global epidemiology of *H. ducreyi* infections between 1980 and 2014. There was a clear decrease in the percentage of genital ulcers caused by *H. ducreyi* during this time, though several studies demonstrated that it is a significant cause of chronic skin ulceration.

Incision and drainage versus aspiration of fluctuant buboes in the emergency department during an epidemic of chancroid. Ernst AA, Marvez-Valls E, Martin DH. Sex Transm Dis 1995; 22: 217–20.

Evacuation of buboes has historically been recommended to prevent fistula formation, and needle aspiration was previously the procedure of choice. This study compared incision and drainage with packing with needle aspiration of suppurative buboes during an epidemic in Louisiana. No difference in cure rate was seen; however, aspirated buboes required reaspiration in six out of 15 patients. As such, the authors recommended considering incision and drainage as an alternative to needle aspiration.

***Haemophilus ducreyi*: from sexually transmitted infection to skin ulcer pathogen.** Lewis DA, Mitjá O. Curr Opin Infect Dis 2016; 29: 52–7.

The authors of this review discuss recent investigations discerning yaws from chancroid as the culprit for chronic skin ulceration in endemic countries. They suggest that chancroid should be considered in the evaluation of chronic limb ulceration.

***Haemophilus ducreyi* as a cause of skin ulcers in children from a yaws-endemic area of Papua New Guinea: a prospective cohort study.** Lancet Glob Health 2014; 2: e235–41

This study evaluated the prevalence and characteristics of chancroid and yaws on an island in Papua New Guinea and compared the characteristics of the skin lesions of these two diseases. *H. ducreyi* lesions tended to be larger and more superficial whereas yaws and yaws/chancroid coinfections tended to present with more circular lesions with central granulating tissue and indurated edges.

Class I *Haemophilus ducreyi* strain containing a class II *hgbA* allele is partially attenuated in humans: implications for HgbA vaccine efficacy trials. Leduc I, Fortney KR, Janowicz DW, et al. Infect Immun 2019; 87:e00112–9.

H. ducreyi was shown to colonize 20% of asymptomatic children in an endemic area and has been detected on flies and fomites. These environmental reservoirs are thought to contribute to the development of non-genital *H. ducreyi* skin lesions and have subsequently made *H. ducreyi* a target for vaccination. Preliminary studies are being performed to explore models for *H. ducreyi* vaccine development.

Chilblains

Antonios Kanelleas, Spyridon Schoinas

Chilblains (synonyms: *perniosis*, *pernio*) are localized, inflammatory lesions that are caused by exposure to cold, damp, non-freezing conditions. The pathogenesis is unknown, but chilblains are thought to represent an abnormal inflammatory response of vascular origin (vasospasm) to cold.

The onset is usually in the autumn or winter, with women, children, and the elderly being most frequently affected.

Lesions occur acutely as single or multiple erythematous to blue-violaceous macules, papules, or nodules. They are usually accompanied by pruritus, burning sensation, or pain and rarely in severe cases may blister or ulcerate. The lesions are often symmetrical with a predilection for fingers, toes, heels, nose, and ears.

Chilblains usually resolve spontaneously within 1–3 weeks, although they may be prolonged in elderly patients.

Perniosis may be idiopathic or represent a clinical manifestation of systemic diseases (connective tissue disorders, cold-induced syndromes, hematological malignancies) or eating disorders (anorexia nervosa, poor nutrition). During the COVID-19 pandemic pernio-like lesions, called ‘Covid toes’, occurred and were attributed to an associated coagulopathy.

MANAGEMENT STRATEGY

Clinical findings and history suggest the diagnosis and further investigations are seldom required. However, in patients with atypical and/or persistent lesions and in the elderly, investigations should be performed for underlying causes. The condition must be distinguished from *chilblain lupus*, a form of cutaneous lupus in which lesions develop in cold but tend to persist and ulcerate, and from *lupus pernio*, which is a form of cutaneous sarcoidosis that usually affects the face/nose.

The treatment of perniosis remains unsatisfactory.

For chilblains with no underlying pathology, preventive measures such as adequate clothing and heating and insulation, avoidance of cold, and avoidance of smoking are important.

Treatment includes use of vasodilator *calcium channel blockers* (*nifedipine* 20–60 mg daily, *diltiazem* 60–120 mg TID), which have been shown to be effective in the treatment and

prophylaxis of perniosis in patients with idiopathic acral perniosis and in those with low body weight. *Pentoxifylline* provides a safe alternative approach. A range of *topical vasodilators* and other treatments have been deployed with a largely anecdotal evidence base.

Specific Investigations

Investigations are not routinely required in typical cases, but consider:

- CBC
- Autoimmune profile (ANA, complement)
- Antiphospholipid antibodies
- Cryoglobulins
- Cold agglutinins
- Cryofibrinogen
- Histology and immunofluorescence
- Vascular assessment in the elderly
- Serum protein electrophoresis

Chilblains. Nyssen A, Benhadou F, Magnée M, et al. *Vasa* 2020; 49(2): 133–40.

A comprehensive literature review regarding differential diagnosis and management of chilblains.

Chilblain lupus erythematosus – a review of literature. Hedrich CM, Fiebig B, Hauck FH, et al. *Clin Rheumatol* 2008; 27: 949–54.

This article reviews the clinical presentation, pathogenesis, diagnosis, and management of chilblain lupus erythematosus.

Pernio as the presenting sign of blast crisis in acute lymphoblastic leukemia. Park KK, Tayebi B, Uihlein L, et al. *Pediatr Dermatol* 2018; 35(1): e74–5.

A case of a 5-year-old girl with pernio as the presenting symptom of acute B-cell lymphoblastic leukemia.

Anorexia nervosa associated with acromegaloïd features, onset of acrocyanosis and Raynaud’s phenomenon and worsening of chilblains. Rustin MH, Foreman JC, Dowd PM. *J Roy Soc Med* 1990; 83: 495–6.

Two patients are reported who developed severe perniosis in association with anorexia nervosa.

Acute perniosis in elderly people: a predictive sign of systemic disease? Guadagni M, Nazzari G. *Acta Derm Venereol*. 2010; 90(5): 544–5.

In this letter to the editor, the authors present seven cases of elderly patients in which perniosis was associated with an underlying disease in six out of the seven patients.

Childhood pernio and cryoproteins. Weston WL, Morelli JG. *Pediatr Dermatol* 2000; 17: 97–9.

A 10-year retrospective study in a pediatric clinic identified eight patients with perniosis, four of whom had cryoglobulins or cold agglutinins and two who had positive rheumatoid factor.

First-Line Therapies

• Conservative management	C
• Avoidance of further cold injury	E
• Calcium channel blockers	B

Clinical characteristics, etiologic associations, laboratory findings, treatment, and proposal of diagnostic criteria of perniosis (chilblains) in a series of 104 patients at Mayo Clinic, 2000 to 2011. Cappel JA, Wetter DA. Mayo Clin Proc 2014; 89: 207–15.

Conservative treatments (e.g., warming, drying, and smoking cessation) provided complete response in 23 (82%) of the 28 patients for whom follow-up data were available.

The treatment of chilblains with nifedipine: the results of a pilot study, a double-blind placebo-controlled randomized study and a long-term open trial. Rustin MH, Newton JA, Smith NP, et al. Br J Dermatol 1989; 120: 267–75.

Ten patients with severe recurrent acral perniosis were treated with 20 mg of nifedipine or placebo daily in a double-blind, crossover trial for 12 weeks total. No patients developed new lesions while on treatment, and 70% were clear after a mean of 8 days. In the open study, 34 patients received up to 60 mg of nifedipine daily for 2 months; this was shown to be effective in reducing the healing time and symptoms of lesions.

Diltiazem vs. nifedipine in chilblains: a clinical trial. Patra AK, Das AL, Ramadasan P. Indian J Dermatol Venereol Leprol 2003; 69: 209–11.

The authors compared two groups of patients with chilblains. Group A (12 patients) was treated with diltiazem 60 mg TID and group B (24 patients) with nifedipine 10 mg TID until complete relief and then 20 mg twice daily for maintenance. They concluded that nifedipine has greater efficacy than diltiazem (80%–90% of patients from group B showed relief by the 14th day of treatment).

Nifedipine vs placebo for treatment of chronic chilblains: a randomized controlled trial. Souwer IH, Bor JH, Smits P, et al. Ann Fam Med 2016; 14(5): 453–9.

Contrary to other papers the authors could not confirm that nifedipine was superior to placebo.

Assessing the effectiveness of topical betamethasone to treat chronic chilblains: a randomised clinical trial in primary care. Souwer IH, Bor JH, Smits P, et al. Br J Gen Pract 2017; 67(656): e187–93.

The authors concluded that there was no clinically or statistically significant difference between treatment with topical betamethasone valerate cream and placebo. Therefore, topical steroids *cannot be recommended* in the treatment of chronic chilblains.

Second-Line Therapies

• Topical nitroglycerine	C
• Pentoxifylline	A
• Topical 2% hexyl nicotinate cream	E
• Minoxidil 5% lotion	E
• Acidified nitrate cream	E
• Tamoxifen	E

Topical nitroglycerine in perniosis/chilblains. Verma P. Skinmed 2015; 13: 176–7.

An uncontrolled study on 0.2% nitroglycerine ointment: 18 of 22 patients had regression of lesions within a week.

Treatment of primary perniosis with oral pentoxifylline (a double-blind placebo-controlled randomized therapeutic trial). Al-Sudany NK. Dermatol Ther 2016; 29: 263–8.

Pentoxifylline 400 mg TID for 3 weeks proved superior to placebo in a double-blind trial undertaken in Iraq.

Treatment of perniosis with oral pentoxifylline in comparison with oral prednisolone plus topical clobetasol ointment in Iraqi patients. Noaimi AA, Fadheel BM. Saudi Med J 2008; 29: 1762–4.

Forty patients with chilblains were randomly divided into two equal groups. Group A received oral prednisolone 0.5 mg/kg/day BD and topical clobetasol ointment for 2 weeks. Patients in group B received pentoxifylline tablets 400 mg TID for 2 weeks. In group B, 5 of 9 patients (55.5%) who completed the study showed a significant improvement, compared with 3 of 11 patients (27.2%) in group A.

Chilblains. Dowd PM, Blackwell V. In: Lebowitz M, Heymann W, Berth-Jones J, et al., eds. Treatment of Skin Disease: Comprehensive Therapeutic Strategies, 2nd edn. Chicago: Mosby, 2006; 39–40.

These authors reported use of 2% hexyl nicotinate in aqueous cream preparation and minoxidil 5% lotion applied three times a day in patients with chilblains and Raynaud phenomenon, and acidified nitrite cream (3% salicylic acid and 3% potassium nitrate) TID in patients with chilblains intolerant of calcium channel blockers. Low-dose (5 mg daily) tamoxifen proved useful in anorexia-associated perniosis.

Third-Line Therapies

• Non-steroidal antiinflammatory drugs	E
• Prednisolone	E
• Hydroxychloroquine	E
• Intense pulsed light	E

Major cluster of chilblain cases in a cold dry Western Australian winter. Larkins N, Murray KJ. J Paediatr Child Health 2013; 49: 144–7.

Thirty-two patients with perniosis are described. Most received some form of treatment including non-steroidal antiinflammatory drugs, prednisolone, or nifedipine, but most improved spontaneously with warmer weather or responded to cold protection advice.

Successful treatment of perniosis with hydroxychloroquine. Yang X, Perez OA, English JC 3rd. J Drugs Dermatol 2010; 9: 1242–6.

In this retrospective study, hydroxychloroquine improved symptoms in four out of five patients with perniosis.

Chondrodermatitis nodularis helicis chronicus

Walayat Hussain

Chondrodermatitis is a benign condition; the chief indication for treatment is pain causing sleep disturbance. Asymptomatic areas of chondrodermatitis do not require active intervention. The use of a pressure-relieving sponge or cushion can provide a good first-choice alternative to surgery.

MANAGEMENT STRATEGY

Chondrodermatitis usually occurs on the lateral portion of the ear on the preferred sleeping side. It is generally caused by the weight of the head on the pillow causing direct pressure and frictional irritation of the cartilage of the ear. Surgery or injury to the ear may leave irregular spicule(s) of cartilage that become a focus for sleep-related pressure. Chondrodermatitis affects the most protuberant part of the ear – most frequently the helix in men and the antihelix in women. Individuals who can only adopt one sleeping position due to arthritis or vertigo, for example, are particularly vulnerable. Requests for patients to ‘change their sleeping position’ are therefore impractical. Patients should be reassured that chondrodermatitis is not skin cancer. If there is any diagnostic uncertainty, a biopsy is warranted. Conservative treatment, such as lidocaine (lignocaine) gel, nitroglycerin gel, a potent topical corticosteroid, self-adhesive foam dressing, or a pressure-relieving cushion may be tried. If sleep is unaffected, further intervention is not necessary unless cosmesis is a concern.

Numerous surgical strategies have been described to treat chondrodermatitis. Whichever surgical technique is adopted, unless the subsequent underlying area of cartilage is smooth, without protuberant foci, the condition will inevitably recur. Although there is no ‘need’ for skin or ulcer excision, this is often undertaken as part of the chosen technique. Other destructive therapies have been advocated but tend to be less effective.

Specific Investigations

- None required
- Biopsy only if diagnostic uncertainty exists (specifically to exclude skin cancer)

First-Line Therapies

- Reassurance that chondrodermatitis is not skin cancer **B**
- Conservative management **B**
- Pressure-relieving cushion or sponge **B**
- Topical corticosteroids **B**
- Intralesional corticosteroids **B**
- Topical nitroglycerin **C**

Treatment of chondrodermatitis nodularis helicis and conventional wisdom? Beck MH. Br J Dermatol 1985; 113: 504–5.

Topical corticosteroids (betamethasone valerate 0.1% and 3% clioquinol cream) used twice a day for up to 6 weeks resolved the condition in all patients.

This was a small case series of only five patients, with limited (eight week) follow-up only.

Intralesional triamcinolone for chondrodermatitis nodularis: a follow-up study of 60 patients. Cox NH, Denham PF. Br J Dermatol 2002; 146: 712–3.

A retrospective analysis of 60 patients with chondrodermatitis nodularis helicis (CNH) treated with 0.1 mL intralesional triamcinolone acetonide 10 mg/mL or triamcinolone hexacetonide 5 mg/mL showed good response on 43% of helix and 31% of antihelix lesions.

This author's experience is that topical or intralesional steroids provide only temporary benefit in a minority of patients. Although their use is still advocated by clinicians, this author has stopped using this approach in favor of topical nitroglycerin or surgery.

The usefulness of 0.2% topical nitroglycerin for chondrodermatitis nodularis helicis. Sanz-Motilva V, Martorell-Calatayud A, Gutiérrez García-Rodrigo C, et al. Actas Dermosifiliogr 2015; 106: 555–61.

Ninety-three percent of 29 patients treated showed clinical improvement with a mean follow-up of 5.9 months. There were fewer side effects using the 0.2% preparation compared with the original 2% ointment.

Perichondrial arteriolar constriction inducing ischemia is implicated in the etiology of chondrodermatitis. This author has found the use of nitroglycerin ointment (0.2%) to be very effective in managing the condition non-surgically. Side effects such as headache are rare with the 0.2% preparation. Asking patients solely to not sleep on the affected side is impractical as a chronic, underlying condition often necessitates that the patient ends up on the side of the chondrodermatitis. The use of a pressure-relieving device as an adjunct to any intervention is of benefit to lessen the chances of recurrence.

Auricular pressure relieving cushions for chondrodermatitis nodularis helix. Allen DL, Swinson PA, Arnstein PM. J Maxillofac Prosthet Tech 1998; 2: 5–10.

Thirty-five of 46 patients treated in this way had complete resolution of their symptoms.

Effective treatment of chondrodermatitis nodularis chronica helix using a conservative approach. Moncrieff M, Sassoon EM. Br J Dermatol 2004; 150: 892–4.

A simple-to-construct ear cushion design was used, made up of a bath sponge with the center removed and held in place with a head band. Thirteen out of 15 patients followed for 1 month responded.

The author (no conflicts of interest) has directed patients to use a similar pressure-relieving device, which is commercially available (CNH ear protector, Delasco.com), with good results.

Management of chondrodermatitis nodularis chronica helix using a “doughnut pillow”. Sanu A, Koppa R, Snow DG. J Laryngol Otol 2007; 121: 1096–8.

Patients used a doughnut-shaped pillow made of orthopedic ‘memory foam’. This distributes the weight of the recumbent head more evenly and is designed to relieve the pressure on the affected ear. Thirteen of 23 (56%) patients treated remained pain free after a 1-year follow-up.

Management of chondrodermatitis nodularis helix by auricular pressure-relieving device: a retrospective study. Belgi A, Logan RA. Br J Dermatol 2007; 157(Suppl 1): 68.

Seventy-eight patients with CNH used a custom-made ear pressure-relieving device designed and built by the local maxillofacial technicians. Of these, 48 patients responded to a questionnaire examining the outcome. Only 7 found it helpful (15%); 20 reported no benefit (42%) and 20 reported some benefit (42%).

Management of chondrodermatitis helix by protective padding: a series of 12 cases and a review of the literature. Timoney N, Davison PM. Br J Plast Surg 2002; 55: 387–9.

Fourteen patients with CNH were prospectively enrolled and used protective padding of the ear at night. Most patients were rapidly relieved of their symptoms, although healing was frequently prolonged.

Chondrodermatitis nodularis chronica helix: a conservative therapeutic approach by decompression. Kuen-Spiegel M, Ratzinger G, Sepp N, Fritsch P. J Dtsch Dermatol Ges 2011; 9: 292–6.

Using a self-made bandage of foam plastic applied during the night, 11 out of 12 patients reported substantial reduction of pain within the first month and were pain free after an average of 1.75 months.

Self-adhering foam: a simple method for pressure relief during sleep in patients with chondrodermatitis nodularis helix. Travelute CR. Dermatol Surg 2013; 39: 317–9.

An inexpensive method using a self-adhering foam sponge (Reston Foam 3M, St Paul, MN) placed on the back of the ear and used nightly for several months was described as effective for helix and antihelix lesions.

Various types of ear cushions are described. They all share the same aim, that is, to transfer the weight of the sleeping head from the ear to the surrounding scalp. Authors report a wide range of benefits with between 15% and 80% of patients not requiring surgery. This author advocates the use of some form of pressure relief as an adjunct to any

non-surgical approach as in his experience the outcomes are favorable, and the benefits of treatment maintained.

Second-Line Therapy

- Surgical excision of cartilage

B

The treatment of chondrodermatitis nodularis with cartilage removal alone. Lawrence CM. Arch Dermatol 1991; 127: 530–5.

Cartilage excision without skin removal resulted in cure rates of 84% for helix and 75% for antihelix lesions. Local anesthesia with lidocaine and epinephrine (adrenaline) reduced bleeding and improved the visibility without ear skin necrosis. On the helix, the skin was reflected back from a helix rim incision to expose the cartilage. On the antihelix, a medially based skin flap was raised to expose cartilage. After exposed cartilage excision, all remaining cartilage edges were left smooth and gently shelving up to the uninvolved cartilage to prevent recurrences that may develop on rough or protuberant cartilage edges. Cartilage excision alone is not disfiguring, and further cartilage edges can be removed if recurrences occur.

This comprehensive article laid the foundation for cartilage excision (without skin removal) in the surgical management of chondrodermatitis of the helix and antihelix.

Treatment of chondrodermatitis nodularis with removal of the underlying cartilage alone: retrospective analysis of experience in 37 lesions. de Ru JA, Lohuis PJ, Saleh HA, et al. J Laryngol Otol 2002; 116: 677–81.

Most otolaryngologists treat patients with chondrodermatitis nodularis by wedge excision. This can leave the patient with an asymmetric, deformed ear. The authors described their results after changing to removal of cartilage alone. In a mean follow-up of 30 months, all 34 patients remained symptom free, and only one required revisional surgery.

Wedge excision should not be used in the surgical management of chondrodermatitis – it is unnecessarily destructive and results in marked unwarranted ear asymmetry.

Twelve years’ experience of simplified surgical treatment of chondrodermatitis nodularis by cartilage trimming and sutureless skin closure. Hussain W, Chalmers RJ. Br J Dermatol 2009; 160: 116–8.

After skin incision, mosquito forceps were used to ‘nibble’ away fragments of cartilage to leave a smooth cartilage contour without the need for full exposure of the cartilage edge. Skin nodules or ulcers are not excised but are left to resolve spontaneously. Tape strips were used for skin closure. Thirty-two of 34 (94%) patients with chondrodermatitis, 7 on the antihelix and 27 on the helix, showed no discomfort or clinical recurrence 4 months after this procedure.

Chondrodermatitis nodularis chronica helix et antihelix. Munnoch DA, Herbert KJ, Morris AM. Br J Plast Surg 1996; 49: 473–6.

In total, 54 chondrodermatitis lesions (36 helix, 18 antihelix), including 23 recurrent after previous surgery, were treated by minimal skin excision combined with extensive cartilage resection. There were no recurrences and minimal postoperative deformity.

Narrow elliptical skin excision and cartilage shaving for chondrodermatitis nodularis. Rex J, Ribera M, Bielsa I, et al. Dermatol Surg 2006; 32: 400–4.

A narrow elliptical excision of the papule followed by a slice of the underlying cartilage was taken and trimmed carefully to remove any cartilage spikes. Good cosmetic results were obtained in all 74 patients retrospectively analyzed. The recurrence rate ranged from 10% for helical and 37% for antihelical lesions after a median follow-up of 54 and 50 months, respectively.

Modified surgical excision for the treatment of chondrodermatitis nodularis. Ormond P, Collins P. *Dermatol Surg* 2004; 30(2 Pt 1): 208–10.

Excision of the cartilage alone is therapeutically and cosmetically effective. To simplify the surgical procedure, a narrow ellipse of skin over the nodule was excised and cold steel dissection of the adjacent skin replaced by hydrodissection to create a plane of cleavage between the skin and cartilage. These two refinements maintained the clinical and cosmetic efficacy and simplified the surgical technique.

All these techniques are based on removal of damaged cartilage and avoidance of leaving irregular cartilaginous fragments, which act as a focus for recurrence. Treatment outcome is operator dependent. Skin excision is often included as it makes the procedure easier to perform but it is not a prerequisite for surgical success.

Third-Line Therapies

• Curettage	B
• Punch and graft	B
• Intralesional hyaluronic acid	B
• CO ₂ /argon laser ablation	C
• Collagen injections	D
• Photodynamic therapy	D
• Cryotherapy	E
• Incision and cartilage curettage	E

Chondrodermatitis nodularis chronica heliis treated with curettage and electrocauterization: follow-up of a 15-year material. Kromann N, Hoyer H, Reyman F. *Acta Derm Venerol* 1983; 63: 85–7.

In total, 142 cases of chondrodermatitis were principally treated by curettage followed by electrocauterization. Seventy-eight patients were reexamined after an average interval of 7.1 years. This simple surgical technique produced a relapse rate of 31%.

The surgical management of chondrodermatitis nodularis chronica heliis. Coldiron BM. *J Dermatol Surg Oncol* 1991; 17: 902–4.

An ellipse of skin is removed around the ulcerated area. The central necrotic or damaged cartilage is removed using a curette and the skin edges sutured. A series is not reported.

Chondrodermatitis nodularis chronica heliis. Successful treatment with the carbon dioxide laser. Taylor MB. *J Dermatol Surg Oncol* 1991; 17: 862–4.

The CO₂ laser was used to vaporize the cutaneous nodules and involved cartilage. The wounds were allowed to heal with only

minimal care using hydrogen peroxide cleansing and applications of topical antibiotic ointment. Twelve lesions have been treated with no recurrences after 2–15 months.

Argon laser therapy for chondrodermatitis nodularis chronica heliis. Hesse G, Schmoeckel C, Wichmann-Hesse A. *Hautarzt* 1994; 45: 222–4.

A small case series of nine patients in whom a 56% cure was seen.

The punch and graft technique: a novel method of surgical treatment for chondrodermatitis nodularis heliis. Rajan N, Langtry JA. *Br J Dermatol* 2007; 157: 744–7.

Twenty-three lesions (15 helix, 3 antihelix, 5 not recorded) were treated by punch removal of the nodule and underlying cartilage. The small defect was closed with a full-thickness skin graft taken from behind the ear using the same punch.

This 'punch and graft' technique contradicts the dogma about the necessity of leaving smooth cartilage margins after any surgical approach. Although the authors state a cure rate of 83%, the author's experience has been that of ultimate recurrence in the short- to medium-term with this technique.

Intralesional hyaluronic acid injection for chondrodermatitis nodularis heliis: a novel treatment for rapid relief of pain and healing of ulcerations. Carey W. *Dermatol Surg* 2021; 47: 373–376.

In this series, 24 patients were injected with 0.2 to 0.3mL of hyaluronic acid and followed up in 2 to 4 weeks intervals. Symptom benefit and improvement in clinical appearance was seen in 23 patients treated after 1 or 2 injections.

The treatment of chondrodermatitis nodularis chronica heliis with injectable collagen. Greenbaum SS. *Int J Dermatol* 1991; 30: 291–4.

Five patients treated with collagen to relieve pressure on the affected cartilage reportedly all gained benefit.

Chondrodermatitis nodularis heliis successfully treated with photodynamic therapy. Gilaberte Y, Frias MP, Perez-Lorenz JB. *Arch Dermatol* 2010; 146: 1080–2.

Retrospective review of five patients with an 80% reported success rate but confounded by prior use of curettage.

Chondrodermatitis nodularis chronica heliis and photodynamic therapy: a new therapeutic option? Pelligrino M, Taddeucci P, Mei S, et al. *Dermatologic Therapy* 2011; 24: 144–7.

A case report of two patients in whom photodynamic therapy was reportedly successful.

Cryotherapy has been advocated but, other than a single case report, no published outcome data exist.

Chromoblastomycosis

Wanda S. Robles, Mahreen Ameen

Chromoblastomycosis is a chronic fungal infection of cutaneous and subcutaneous tissues prevalent in tropical and subtropical climates including Central and South America, Africa, Asia (highest incidence in Japan), and Oceania (first described in Australia), with cases also reported from New Zealand and Solomon Islands. Most cases reported outside the tropical areas, particularly in Europe, are considered imported dermatoses. It is caused by the traumatic cutaneous implantation of dimorphic pigmented (dematiaceous) fungi, classified in the order *Chaetothyriales*. These produce characteristic thick-walled sclerotic bodies (also known as *muriform fumagoid* or *Medlar bodies*) in infected tissues. The most common etiologic agents are *Fonsecaea pedrosoi*, *Phialophora verrucosa* and *Cladophialophora carrionii*. Clinically, chromoblastomycosis presents as plaques, nodules, tumors, cicatricial or verrucous exophytic lesions, which are commonly located on the feet and lower legs. Lesions are indolent and slow growing; over years they extend centrifugally, leaving central areas of scarring. Disease is commonly localized but can spread through autoinoculation or lymphatic dissemination, producing metastatic lesions away from the primary site. Complications include ulceration, secondary bacterial infection, and lymphedema. Rarely, malignant transformation (squamous cell carcinoma) in chronic lesions and systemic involvement have been reported.

MANAGEMENT STRATEGY

Chromoblastomycosis is a difficult-to-treat mycosis characterized by low cure and high rates of relapse, particularly in chronic and extensive disease. There are no clinical trials that determine the best therapeutic approach. Studies report highly variable rates of clinical and mycological cure, ranging from 15% to 80%. The choice of treatment and outcome depend on the etiologic agent, severity and extent of the lesions, clinical topography, and the presence of complications (dermal fibrosis and edema may reduce tissue antifungal drug levels). *F. pedrosoi* is the most common etiologic agent but has the lowest sensitivity to the major systemic antifungal agents. *C. carrionii* and *P. verrucosa* are much more sensitive and have been found to respond more favorably to treatment.

Surgical excision may be successful for small and localized lesions. It is performed with wide surgical margins and is usually accompanied by chemotherapy in order to reduce the risk of recurrence. Curettage and electrodesiccation is not recommended because it may promote lymphatic spread. Other physical modalities include cryotherapy with liquid nitrogen, as well as thermotherapy (applying local heat to produce controlled temperatures ranging from 42°C to 45°C, which inhibit fungal growth) using a variety of methods, including benzene pocket warmers and pocket-handkerchief-type warmers. Cryosurgery and thermotherapy have the advantage that they are relatively inexpensive treatment options.

There are no comparative trials of antifungal chemotherapy for chromoblastomycosis. Itraconazole (100–400 mg daily) and terbinafine (250–500 mg daily) are considered first-line treatments, with both drugs having shown high in vitro activity against the causative agents of chromoblastomycosis. They are typically given for long periods at high doses. Dual therapy with itraconazole and terbinafine is recommended if it is affordable and tolerated. It is not uncommon for more than one treatment modality to be used, such as oral antifungals combined with surgery, cryotherapy, or thermotherapy. For example, itraconazole and/or terbinafine combined with cryosurgery is advocated for extensive disease. The antifungal is given first until there is a maximum reduction in lesion size, which usually requires 6–12 months of chemotherapy. The lesions then require several treatments with cryosurgery.

Of the other antifungal agents, ketoconazole is not recommended due to toxicity at high doses. Despite a few cases in the early literature reporting success with fluconazole, it too is not recommended as in vitro studies have shown that it has little activity against black fungi. Flucytosine (converted into 5-fluorouracil in fungal cells) was an early treatment that demonstrated some degree of efficacy. It is associated with a high risk of developing resistance, but this can be overcome if it is used in combination with another antifungal. It is also hepatotoxic and myelotoxic, requiring regular monitoring of serum levels. It is rarely used now except for resistant cases. Amphotericin B (AmB) monotherapy is ineffective, and even in combination with other antifungals, results are generally poor. However, AmB and flucytosine dual therapy has demonstrated efficacy, with in vitro studies having demonstrated synergistic activity between the two drugs. The new second-generation azoles, such as posaconazole and voriconazole, have shown acceptable results in case reports, but experience to date is limited mainly due to high costs in endemic areas.

Other modalities of treatment, including imiquimod, conventional photodynamic therapy, and carbon dioxide laser photocoagulation, are mainly anecdotal.

Specific Investigations

- Direct microscopy
- Culture
- Histopathology

A positive direct examination of scrapings in 10% potassium hydroxide will demonstrate thick-walled, brown sclerotic cells that are pathognomonic of chromoblastomycosis, irrespective of the causative species. Specimens are more likely to yield a positive result if they include the 'black dots' visible on the surface of the lesion. Culture enables the identification of the causative agent. It is a slow-growing fungus and culture may be inconclusive due to poor morphologic differentiation. Polymerase chain reaction (PCR) has been developed for the identification of *Fonsecaea* and *C. carrionii*. Serologic tests such as enzyme-linked

immunosorbent assay (ELISA) can be useful in evaluating therapy response, but like PCR they are not widely available in most endemic settings. A biopsy demonstrates the typical sclerotic bodies in a granulomatous lesion that may be accompanied by trans-epithelial elimination.

First-Line Therapies

• Itraconazole	B
• Terbinafine	B
• Combined	B

Treating chromoblastomycosis with systemic antifungals. Bonifaz A, Paredes-Solis V, Saul A. Expert Opin Pharmacother 2004; 5: 247–54.

A review article highlighting the difficulties in treating this condition. The authors state that the best results for therapy have been obtained with the combination and use of high-dose itraconazole and terbinafine for a minimum treatment period of 6–12 months.

Chromoblastomycosis. Lopez-Martinez R, Mendez Tovar LJ. Clin Dermatol 2007; 25: 188–94.

A comprehensive review article. Itraconazole is considered the treatment of choice in combination with surgery in some cases.

Chromoblastomycosis: an overview of clinical manifestations diagnosis and treatment. Queiroz-Telles F, Esterre P, Perez-Blanco M, et al. Med Mycol 2009; 47: 3–15.

The authors state that there is no treatment of choice but rather several treatment options: they suggest that physical therapies should enhance chemotherapy and that systemic combination therapies may increase cure rate but may be associated with a higher risk of adverse effects.

Pulse itraconazole 400 mg daily in the treatment of chromoblastomycosis. Ungpakorn R, Reangchainam S. Clin Exp Dermatol 2006; 31: 245–7.

In this small study, six cases of *F. pedrosoi* infection in Thailand were treated with pulse itraconazole 400 mg daily, for one week each month. All achieved clinical and mycological cure. Four patients were cured after 12 pulses of treatment, and one after 15 pulses of treatment. The remaining patient required 20 pulses of itraconazole as well as cryosurgery. Disease severity and duration did not appear to be predictive of treatment response. This study demonstrated that the monthly pulse regimen is well tolerated and as effective as the conventional continuous 200–400 mg daily regimen for the treatment of *F. pedrosoi*. The authors recommend that treatment is continued until absence of organisms is proven by histology and tissue culture. Given that the total drug dosage is reduced, there is a marked reduction in cost of therapy by 50% to 75%. They also claim that pulse therapy is associated with higher compliance, although therapy duration remains long.

The cost of long-term itraconazole therapy is expensive in endemic settings, making this an important and relevant study.

Treatment of chromoblastomycosis with itraconazole, cryosurgery and a combination of both. Bonifaz A, Martinez-Soto E, Carrasco-Gerard E, et al. Int J Dermatol 1997; 36: 542–7.

This study included 12 patients assigned to three different groups. Group 1, with small lesions, was treated with itraconazole 300 mg/day. Group 2, also with small lesions, was treated with one or more sessions of cryosurgery. Group 3, with large

lesions, started treatment with itraconazole 300 mg/day until reduction of lesions was achieved, followed by one or more sessions of cryosurgery. The results showed complete clinical and mycologic cure in two out of four patients in both groups 1 and 3. All four patients in group 2 achieved complete cure.

Although the case numbers were small, this study suggests that cryosurgery is a more suitable treatment option than antifungal therapy for small lesions.

Treatment of chromomycosis with terbinafine: preliminary reports of an open pilot study. Esterre P, Inzan CK, Ramarcel ER, et al. Br J Dermatol 1996; 134: 33–6.

A multicentre study from Madagascar. Of 43 patients treated, 36 (*F. pedrosoi*, *n*=29; *C. carrionii*, *n*=7) could be completely evaluated. Approximately one-third of the patients had been resistant to previous treatment with thiabendazole. Oral terbinafine 500 mg daily was given for 6–12 months. Within 2–4 months of commencement of treatment, there was a marked clinical improvement with resolution of secondary bacterial infection, edema, and elephantiasis. There was mycologic cure in 83% (24/29) of patients infected with *F. pedrosoi* at 12 months. Of those infected with *C. carrionii*, there was a cure in one and clinical improvement in a further three. Total cure was observed even in imidazole-refractory patients or those with chronic disease present for over 10 years. There was a mild transient rise in hepatic enzymes in some patients, but no serious adverse effects were reported.

Treatment of chromoblastomycosis with terbinafine: experience with four cases. Bonifaz A, Saul A, Paredes-Solis V, et al. J Dermatolog Treat 2005; 16: 47–51.

Four cases from Mexico (*F. pedrosoi*, *n*=3; *P. verrucosa*, *n*=1) were treated with oral terbinafine 500 mg daily. Three cases achieved clinical and mycologic cure after a mean treatment period of 7 months. Treatment was well tolerated with no abnormalities of liver enzymes.

Treatment of chromoblastomycosis with terbinafine: a report of four cases. Xibao Z, Changxing L, Yuqing H. J Dermatolog Treat 2005; 16: 121–4.

Four cases from China (*C. carrionii*, *n*=2; *F. pedrosoi*, *n*=2) treated with terbinafine 500 mg daily for the first month followed by 250 mg daily were cured after 4–8 months of therapy without evidence of relapse at follow-up 6 months later. The total dosage of terbinafine ranged from 37.5 g to 60 g.

Alternate week and combination itraconazole and terbinafine for chromoblastomycosis caused by *Fonsecaea pedrosoi* in Brazil. Gupta AK, Taborda PR, Sanzovo AD. Med Mycol 2002; 40: 529–34.

Four patients with longstanding disease refractory to standard therapies were treated with alternate week and combination therapy with itraconazole (200–400 mg daily) and terbinafine (250–1000 mg daily). Combination therapy proved to be more effective and was well tolerated.

The authors suggest that combination therapy with itraconazole and terbinafine may be synergistic, with in vitro studies having already demonstrated this against other fungi. Larger studies are required to evaluate combination therapy with itraconazole and terbinafine. However, it must be noted that both drugs are expensive in endemic settings.

Chromoblastomycosis: a neglected tropical disease. Queiroz-Telles F. Rev Inst Med Trop Sao Paulo 2015; 57 (Suppl 19): 46–50.

Itraconazole, either as monotherapy or associated with other drugs or with physical methods, is the mainstay of treatment. More recently, photodynamic therapy has been successfully used in combination with antifungals.

A case of chromoblastomycosis caused by *Fonsecaea pedrosoi* successfully treated with itraconazole together with terbinafine. Xu-Cheng S, Xiang-Nong D, Zhi-Min X, et al. *Dermatol Ther* 2020; 10(2): 321–7.

A case report of chromoblastomycosis diagnosed in a 56-year-old man by fungal culture and gene sequencing as caused by *Fonsecaea pedrosoi*. The treatment advocated is combination therapy with itraconazole and terbinafine.

Second-Line Therapies

• Amphotericin B	D
• Flucytosine	D
• Posaconazole	D
• Voriconazole	E

Extensive chromoblastomycosis caused by *Fonsecaea pedrosoi* successfully treated with a combination of amphotericin B and itraconazole. Paniz-Mondolfi AE, Colella MT, Negrin DC, et al. *Med Mycol* 2008; 46: 179–84.

This report describes a case of extensive disease affecting almost all of the right lower leg of 22 years' duration that had 15 years of previous failed therapy consisting of ketoconazole and fluconazole. The patient then achieved clinical and mycological cure with amphotericin B (cumulative dose of 2150 g) in combination with itraconazole 100 mg twice daily for approximately 3 months, followed by a further 1 year of itraconazole 100 mg daily.

Combination of amphotericin B and terbinafine against melanized fungi associated with chromoblastomycosis. Deng S, Lei W, de Hoog GS, et al. *Antimicrob Agents Chemother* 2018; 62(6): e00270–18.

This in vitro study showed that a combination of amphotericin B and terbinafine have a synergistic effect against several dematiaceous fungi responsible for chromoblastomycosis. This combination may be an alternative for treatment in refractory disease.

Posaconazole treatment of refractory eumycetoma and chromoblastomycosis. Negroni R, Tobón A, Bustamante B, et al. *Rev Inst Med Trop Sao Paulo* 2005; 47(6): 339–46.

Study of 12 patients with eumycetoma or chromoblastomycosis that had failed to respond to standard therapies. They were given posaconazole 800 mg/day in divided doses for a maximum of 34 months. Clinical good response was reported in five of six patients with eumycetoma and five of six patients with chromoblastomycosis. Two patients were reported as having stable disease. Posaconazole was well tolerated throughout the long-term administration of the drug. It should be considered in patients who fail to respond to standard therapies.

Extensive long-standing chromomycosis due to *Fonsecaea pedrosoi*: three cases with relevant improvement under voriconazole therapy. Criado PR, Careta ME, Valente MY, et al. *J Dermatol Treat* 2011; 22: 167–74.

Three patients with longstanding (10, 20, and 21 years) and extensive disease refractory to previous therapy with itraconazole and terbinafine were treated with voriconazole 200 mg twice daily for 12 months. Clinical response was evident after 30–50 days,

but at the end of treatment despite significant clinical improvement, none of the patients achieved cure. All patients showed elevation of serum gamma-glutamyl transpeptidase during the treatment without clinical relevance, and a single patient developed visual abnormalities and tremors requiring dose reduction.

This is the first report on the use of voriconazole for chromoblastomycosis. The partial response may be attributed to the severity of the disease. The report suggests that voriconazole represents an option for extensive disease refractory to conventional treatment.

Chromoblastomycosis. Quieroz-Telles F, de Hoog S, Santos DW, et al. *Clin Microbiol Rev* 2017; 30: 233–76.

The best review available on this condition to date. A group of experts, most of whom are contributors to the evidence and the publications available so far, review all literature available on the disease and ensure we understand all epidemiology, distribution, clinical presentations, diagnostic technologies, and controversies about management of this neglected skin disease. It is a delight to read.

Third-Line Therapies (May Also Be Used in Combination with First- and Second-Line Therapies; They May Also Be First-Line for Small Lesions or If Systemic Treatment Is Contraindicated)

• Cryotherapy	B
• Surgical excision	D
• Thermotherapy	D
• Laser therapy	D
• Photodynamic therapy	D
• Combined	D

Treatment of chromomycosis by cryosurgery with liquid nitrogen: 15 years' experience. Castro LG, Pimentel ER, Lacaz CS. *Int J Dermatol* 2003; 52: 408–12.

This retrospective study included 22 patients with *F. pedrosoi*. Small lesions were frozen in a single session, whereas larger lesions were frozen in small parts. The average number of cryosurgery treatments that each patient received was 6.7 (range 1–22 sessions). Nine patients (40.9%) were considered cured (clinically disease-free period of at least 3 years), and eight patients (36.4%) were under observation (clinically disease-free but fewer than 3 years of follow-up). The rest failed to clear with treatment.

This study suggests high efficacy for cryosurgery therapy, and also suggests, as do other studies, that cryosurgery is a useful and inexpensive therapeutic option for small lesions.

Successful treatment of chromoblastomycosis with topical heat therapy. Tagami H, Ginosa M, Imaizumi S, et al. *J Am Acad Dermatol* 1984; 10: 615–9.

Four cases (*F. pedrosoi* isolated from three) were treated with topical application of tolerable heat from hand warmers. Three patients responded after 2, 3, and 6 months of treatment. The fourth patient, who received treatment in an irregular manner, cleared only after a 12-month period.

Cutaneous chromoblastomycosis effectively treated with local heat monotherapy. Huang TH, Lan CE. *Clin Exp Dermatol* 2019; 44: 461–2.

A case report of a 61-year-old man with a 7-year history of a plaque on the right forearm. The diagnosis of chromoblastomycosis was made on culture of *Fonsecaea* spp. Difficulties for treatment arose when the patient showed abnormal levels of liver

enzymes. Therefore, the decision was made to treat the patient with a disposable chemical hand warmer. This was applied to the lesion and held in place with a bandage for 8 h/day. Clinically complete remission was achieved after 8 weeks.

Chromomycosis – successful CO₂ laser vaporization. Tsianakas A, Pappai D, Basoglu Y, et al. J Eur Acad Dermatol Venereol 2008; 22(11): 1385–6.

Case report of a 45-year-old man with a plaque on the left buttock for 12 years. This was diagnosed as chromomycosis after *F. pedrosoi* was identified in culture. Patient had 1-month treatment with itraconazole 100 mg/day, which he discontinued after 1 month. Patient was successfully treated with CO₂ laser vaporization (wavelength 10,600 nm) with no complications on wound healing and no recurrence after 2 years of follow-up.

This type of intervention may only be suitable for localized lesions.

5-aminolevulinic acid-based photodynamic therapy associated with itraconazole successfully treated a case of

chromoblastomycosis. Yan W, Zhang W, Luo J, et al. Photodiagnosis Photodyn Ther 2020; 29: 101589.

Refractory cases of chromoblastomycosis are not uncommon and there is no optimal treatment for them. This is the case of a 71-year-old male farmer, who responded to this combination treatment after 2 months.

Topical application of imiquimod as a treatment for chromoblastomycosis. Texeira de Sousa M, Belda W Jr, Spina R, et al. Clin Infect Dis 2014; 58(12): 1734–7.

First report of treatment of chromoblastomycosis with imiquimod, which shows benefits in four patients. All patients were treated with imiquimod in combination with oral itraconazole either together at the start of therapy, or after no improvement of the condition with oral antifungals, including terbinafine, or initiated as monotherapy followed by itraconazole.

This study only shows the benefit of accelerating response to conventional antifungal drugs.

Chronic actinic dermatitis

Sally H. Ibbotson, Robert S. Dawe

Chronic actinic dermatitis (CAD) is a chronic dermatitis mainly involving photoexposed sites, which is associated with objective evidence of abnormal photosensitivity. The photosensitivity is usually broadband although predominantly involving the ultraviolet B (UVB) waveband and often extending into the ultraviolet A (UVA) and even visible wavebands. The condition is considered to have an immunological basis, and no specific genetic susceptibility has been identified. Typically, CAD affects elderly males, although in younger patients it is reported particularly in association with atopic dermatitis. It is increasingly recognized in females and in patients of higher skin phototypes. Most cases arise on the background of a dermatitis, such as atopic, seborrheic, or contact allergic dermatitis. In more than 75% of cases of CAD, patch testing is positive, confirming the association with contact allergic dermatitis. Patient and clinician may not be aware of the link with sunlight because of perennial symptoms and covered site involvement, leading to delays in diagnosis.

MANAGEMENT STRATEGY

Thus the essential first step of management is accurate diagnosis and exclusion of other conditions, such as photoaggravated eczema or reversible causes, particularly drug-induced photosensitivity. Phototesting is essential and the gold standard investigation is monochromator phototesting, allowing accurate definition of wavelengths involved (action spectrum) and the degree of photosensitivity.

Photoprotection is essential, with emphasis on *environmental and behavioral measures* (including use of window film to prevent all ultraviolet (UV) transmission and double-envelope compact fluorescent lamps or light-emitting diodes (LEDs) for those with severe photosensitivity; seeking out the shade and avoiding sunlight in the middle of the day), *clothing choices* (tightly woven and dark colors if visible wavelengths are involved), and high SPF fragrance-free sunscreens. Patient education to reduce exposure to *contact allergens* is also essential, as contact allergy tends to persist indefinitely, whereas photosensitivity can resolve over time.

Active disease should be treated with *emollients* and *topical corticosteroids*. With severe flares or erythroderma, admission to hospital may be required to allow the patient to be nursed behind photoprotective screens. *Systemic corticosteroids* may be required for acute flares and then tapered over weeks. *Treatment with photo(chemo)therapy* may be possible, although patients are usually too UVB sensitive to be able to tolerate UVB phototherapy, and, thus, psoralen-UVA (PUVA) may be more effective and better tolerated. If these measures are inadequate for disease control, systemic immunosuppression may be needed.

Specific Investigations

- Phototesting (with UVB, UVA, and visible light from monochromator or broadband sources)
- Provocation testing (with solar simulator or other broadband source)
- Patch and, if not too severely photosensitive to allow this, photopatch tests
- Consider concomitant disease

Comparison of demographic and photobiological features of chronic actinic dermatitis in patients with lighter v darker skin types. Tan KW, Haylett AK, Ling TC, et al. *JAMA Dermatol* 2017; 153: 427–35.

Chronic actinic dermatitis: changing trends. Fityan A, Cho S-Y, Plant A, et al. *Br J Dermatol* 2019; 181(S1): 99.

These reports from UK centers indicate that CAD is now less frequently seen as a disease of elderly males, with Tan et al., reporting on 70 patients, with mean age of onset of 42.6 years and 41% (much higher than in their catchment area population) being of skin phototype V or VI. There was younger onset in the higher skin phototype patients and also a 2:1 male to female ratio in the lower skin phototypes and 1:2 in those of higher skin phototype. The authors also found that 23% had positive photopatch tests to sunscreens and/or non-steroidal antiinflammatories. Fityan et al. reported on 110 cases of CAD, with a mean age of onset of 42.3 years and males and females equally represented. Again, there was overrepresentation of skin phototypes V and VI and most were atopic, particularly in younger patients.

A preliminary investigation into the effect of exposure of photosensitive individuals to light from compact fluorescent lamps. Eadie E, Ferguson J, Moseley H. *Br J Dermatol* 2009; 160: 659–64.

Energy-saving lamps and their impact on photosensitive and normal individuals. Fenton L, Ferguson J, Ibbotson S, et al. *Br J Dermatol* 2013; 169: 910–5.

Tungsten lamp and chronic actinic dermatitis. Hu SC, Lan CE. *Australas J Dermatol* 2017; 58: e14–6.

Is photodynamic diagnostic flexible ureterorenoscopy suitable for a patient presenting with chronic actinic dermatitis? Valentine R, Kata S, Ibbotson S, et al. *Photodermatol Photoimmunol Photomed* 2015; 31: 279–81.

Patients with CAD may be at risk from exposure to UV radiation from compact fluorescent ('energy-saving') lamps. They also can have severe visible light sensitivity (such as through window glass and exposure to a bright 'ordinary' tungsten source used for ear cleaning), may be at risk from exposure to a wide range of artificial light sources, and this should be investigated and considered in management approaches.

Contact allergic sensitivity to plants and the photosensitivity dermatitis and actinic reticuloid syndrome. Frain-Bell W, Johnson BE. *Br J Dermatol* 1979; 101: 503–12.

Contact and photocontact sensitization in chronic actinic dermatitis: sesquiterpene lactone mix is an important allergen. Menagé H, Ross JS, Norris PG, et al. *Br J Dermatol* 1995; 132: 543–7.

Case report of chronic actinic dermatitis accompanied by UVA sensitivity in a chrysanthemum farmer. Fujii S, Washio K, Masaki T. *J Dermatol* 2019; 46: e229–30.

This case highlights the importance of considering CAD in any patient with Asteraceae (Compositae) contact allergy.

A European multicenter photopatch test study. European Multicenter Photopatch Test Study (EMCPPTS) Taskforce. *Br J Dermatol* 2012; 166: 1002–9.

Photopatch testing: recommendations for a European photopatch test baseline series. Goncalo M, Ferguson J, Boneville A, et al. *Contact Dermatitis* 2013; 68: 239–43.

Contact and/or photocontact allergy is common in CAD. Standard allergens, including fragrances, plants, and sunscreens, must be considered. Patch and photopatch testing, repeated at intervals as indicated by history, are essential investigations in order not to 'miss' new allergens or photoallergens. Because many CAD patients are abnormally sensitive to the UVA sources used for photopatch testing, this technique may be difficult to undertake and interpret. However, photopatch testing with suberythral UVA doses should be undertaken where possible.

Contact and photocontact sensitization in chronic actinic dermatitis: a changing picture. Chew AL, Bashir SJ, Hawk JLM, et al. *Contact Dermatitis* 2010; 62: 42–6.

Be aware of changing allergen patterns with alteration in exposure over time. Paraphenylenediamine reactions in CAD may have increased.

Chronic actinic dermatitis in Asian skin: a Singaporean experience. Tan AW, Lim KS, Chong WS. *Photodermatol Photoimmunol Photomed* 2011; 27: 172–5.

Three of 26 Singaporean patients with CAD were positive for HIV.

Other case series have found even greater proportions of CAD patients to have HIV. This does not prove a cause-and-effect relationship and may not be specific to HIV, but the possible association should be considered.

First-Line Therapies

• Photoprotective measures	C
• Avoidance of relevant contact allergens	C
• Topical corticosteroids	C
• Topical emollients	C

Photodermatoses: environmentally induced conditions with high psychological impact. Rizwan M, Reddick CL, Bundy C, et al. *Photochem Photobiol Sci* 2013; 12: 182–9.

Depression, anxiety, and dermatology life quality index scores were assessed in 185 of 260 adult patients with photosensitivity diseases who returned questionnaires. Twenty-three percent showed evidence of anxiety and 7.9% depression, and particular risk factors were facial involvement and duration of photosensitivity. This study showed high levels of psychological comorbidity in patients with photosensitivity diseases.

Chronic actinic dermatitis: a retrospective analysis of 44 cases referred to an Australian photobiology clinic. Yap LM, Foley P, Crouch R, et al. *Australas J Dermatol* 2003; 44: 256–62.

Restriction of sunshine and allergen exposure, along with sunscreens and topical corticosteroids, gave relief in 36% of CAD patients. The remainder also required oral immunosuppressants or phototherapy.

Photosensitivity dermatitis/actinic reticuloid syndrome in an Irish population: a review and some unusual features. Healy E, Rogers S. *Acta Derm Venereol* 1995; 75: 72–4.

Of nine CAD patients treated with sunscreens, emollients, topical corticosteroids, and antigen avoidance, six responded well, two achieved complete remission, and four were controlled on topical corticosteroids alone, although five also required oral corticosteroids initially.

Protection against ultraviolet radiation by commercial summer clothing: need for standardised testing and labelling. Gambichler T, Rotterdam S, Altmeyer P, et al. *BMC Dermatol* 2001; 1: 6.

Summer clothing textiles ($n=236$) were investigated spectrophotometrically for their ultraviolet protection factors (UPF). Over 70% of wool and polyester, but less than 30% of cotton, linen, and viscose fabrics, had UPFs over 30.

Second-Line Therapies

• Azathioprine	A
• Ciclosporin	E
• Mycophenolate	E
• Hydroxycarbamide	E
• PUVA	D
• UVB	D
• Topical calcineurin inhibitors	B

Chronic actinic dermatitis. Paek SY, Lim HW. *Dermatol Clin* 2014; 32: 355–61.

If conservative management of CAD with photoprotection and topical therapies is insufficient, systemic immunosuppressants,

such as glucocorticoids, azathioprine, ciclosporin, or mycophenolate mofetil, may be effective.

Azathioprine treatment in chronic actinic dermatitis: a double-blind controlled trial with monitoring of exposure to ultraviolet radiation. Murphy GM, Maurice PD, Norris PG, et al. *Br J Dermatol* 1989; 121: 639–46.

Five of eight patients with CAD treated in this randomized trial had complete clinical disease remission within 6 months of azathioprine (150 mg/day) commencement. No useful clinical response was seen in 10 patients treated with placebo. It is not known whether azathioprine causes objective improvement in photosensitivity.

Azathioprine in dermatology: a survey of current practice in the UK. Tan BB, Gawkrödger DJ, English JSC. *Br J Dermatol* 1997; 136: 351–5.

A questionnaire survey of 253 UK dermatologists demonstrated that 68% use azathioprine in CAD, 66% alone, and the others as a steroid-sparing agent. Most used 100 mg daily, with only 13% prescribing it by body weight. CAD had the highest proportion of perceived efficacy (62%) of all disorders treated with azathioprine.

Severe chronic actinic dermatitis treated with cyclosporine: 2 cases. Paquet P, Piérard GE. *Ann Dermatol Venereol* 2001; 128: 42–5.

Two patients with CAD unresponsive to high-dose oral steroids responded well to oral ciclosporin (at a maximum daily dose of 4 mg/kg for 3 months), without significant adverse effects. One relapsed in summer when ciclosporin was stopped but the other patient was in remission for 3 years after drug cessation.

Chronic actinic dermatitis treated with mycophenolate mofetil. Thomson MA, Stewart DG, Lewis HM. *Br J Dermatol* 2005; 152: 784–6.

Two patients with CAD who had failed to respond to topical steroids, prednisolone, PUVA, azathioprine, and ciclosporin were treated with mycophenolate mofetil, resulting in improvement within 6 weeks and subsequent clearance, without adverse effects. Remission was maintained with a continuous mycophenolate mofetil dose of 500 mg BD in one patient and 1 g BD in spring and summer only in the other patient.

Chronic actinic dermatitis (photosensitivity dermatitis/actinic reticuloid syndrome): beneficial effect from hydroxyurea. Gramvussakis S, George SA. *Br J Dermatol* 2000; 143: 1340.

Hydroxycarbamide (previously called hydroxyurea) at 500–1000 mg/day induced remission of CAD in one patient.

Chronic actinic dermatitis: successful treatment with psoralen-ultraviolet A photochemotherapy. Chee SN, Novakovic L, Fassihi H, et al. *Br J Dermatol* 2018; 178: e189–90.

A retrospective study of 16 patients with CAD treated with oral (one topical 8-methoxypsoralen) PUVA found 63% achieved patient-reported efficacy, with two confirmed to have reduced photosensitivity on phototesting. A low fixed dose (starting with a test UVA exposure at 0.05 J/cm² and UVA dose increments of 0.05 J/cm² at each treatment as tolerated for those receiving

oral PUVA [8-methoxypsoralen 25 mg/m² or 5-methoxypsoralen 50 mg/m²]) using a twice-weekly regimen over 10 weeks was used (one patient had a more intensive three times a week regimen at a starting UVA dose of 1 J/cm²). Typically, PUVA was commenced in February, with topical corticosteroids applied after each treatment and oral prednisolone taken on treatment days if there were flares. PUVA was most effective in younger male patients of higher skin phototype and in those only sensitive to UVB on phototesting. Two patients who failed previous immunosuppressants did not respond to PUVA and, likewise, positive patch tests to metals also seemed to be predictive of a poor response to PUVA.

Evaluation of narrow band ultraviolet B phototherapy in the treatment of chronic actinic dermatitis in Chinese patients. Ma L, Zhang Q, Hu Y, et al. *Dermatol Therapy* 2017; 30(6). doi: 10.1111/dth.12528.

A total of 19 patients were treated with NB-UVB (mean 27 treatments) along with a parenteral corticosteroid: there was clinical and phototest improvement and after the course only 1/19 rather than 12/19 still required systemic immunosuppressants.

Chronic actinic dermatitis with leonine facies and iatrogenic adrenal insufficiency successfully treated with topical tacrolimus. Busaracome P, Wattanakrai P, Rajaraman N. *Case Rep Dermatol* 2011; 3: 49–54.

A case report of one patient with CAD who had been treated with systemic corticosteroids for almost 20 years, which resulted in secondary adrenal insufficiency. The patient was subsequently well controlled with topical tacrolimus and photoprotection.

Successful treatment of chronic actinic dermatitis with topical pimecrolimus. Larangeira de Almeida H. *Int J Dermatol* 2005; 44: 343–4.

Pimecrolimus can be considered as an alternative therapy.

No comparative studies have been reported. Potent topical corticosteroids should generally be favored over topical calcineurin inhibitors, but these newer topical immunomodulators are appropriate to consider for those with inadequate responses to topical corticosteroids.

Third-Line Therapies

• Hydroxychloroquine	D
• Etretinate	E
• Danazol	E
• Thalidomide	E
• Interferon	E
• Infliximab	E
• Dupilumab	E
• Colostrum-macrophage-activating factor	E

Chronic actinic dermatitis. An analysis of 51 patients evaluated in the United States and Japan. Lim HW, Morison WL, Kamide R, et al. *Arch Dermatol* 1994; 130: 1284–9.

Photoprotection and topical corticosteroids were useful in 51 patients with CAD. Azathioprine (50–200 mg/day) was also commonly helpful. PUVA and oral corticosteroids were beneficial in

seven patients, ciclosporin in four, and etretinate in two. Hydroxychloroquine (200 mg once or twice daily) achieved partial/good responses in nine patients.

Chronic actinic dermatitis responding to danazol. Humbert P, Drobacheff C, Vigan M, et al. *Br J Dermatol* 1991; 124: 195–7.

A patient with CAD with low α_1 -antitrypsin levels responded dramatically to danazol (600 mg/day for 3 weeks), relapsed on stopping, improved on restarting, and remained controlled 18 months later while still on the drug. Danazol raises low serum α_1 -antitrypsin and protease inhibitor levels, and a protease–anti-protease imbalance has been said to cause abnormal inflammatory responses in several dermatoses.

Recalcitrant chronic actinic dermatitis treated with low-dose thalidomide. Safa G, Piéto-Le Corvaisier C, Hervagault B. *J Am Acad Dermatol* 2005; 52: E6.

A patient with CAD resistant to PUVA, azathioprine, ciclosporin, and hydroxychloroquine responded dramatically to thalidomide (100 mg/day reduced to 50 mg twice weekly) over 5 months without adverse effect.

Actinic reticuloid: treatment with recombinant interferon alpha-2b. Trevisi P, Farina P, Borda G, et al. *G Ital Dermatol Venereol* 1993; 128: 327–31.

Natural α -interferon in chronic actinic dermatitis. Report of a case. Parodi A, Gallo R, Guarrera M, et al. *Acta Derm Venereol* 1995; 75: 80.

In one patient with CAD in whom ciclosporin had to be discontinued because of hypertension, natural α -interferon (3 MU three times per week) was effective.

Successful therapy of chronic actinic dermatitis with infliximab. Schopf RE, Poblete-Gutiérrez P. *Exp Dermatol* 2009; 18:

302 (abstract at 36th Annual Meeting of Arbeitsgemeinschaft Dermatologische Forschung, Heidelberg, 2009).

Infliximab infusions were associated with marked improvement in one patient who had not shown useful response to previous therapies, including topical corticosteroids, PUVA, and ciclosporin.

A case report of therapeutically challenging chronic actinic dermatitis. Verma L, Pratt M. *JCMS Case Reports* 2019; 7: 1–3.

This was a report of a patient with CAD, who failed to respond to or tolerate methotrexate, hydroxychloroquine, apremilast, and ciclosporin, who went on to have only partial response to dupilumab. This mirrors our own unpublished experience in two patients, whose atopic eczema improved on dupilumab, but photosensitivity and phototesting did not notably improve. It appears the photosensitivity is perhaps mediated by different pathways to the underlying atopic dermatitis, but further experience of its use in CAD is warranted as these are very early observations in small numbers of patients.

Dupilumab for the treatment of chronic actinic dermatitis. Patel N, Konda S, Lim HW. *Photodermatol Photoimmunol Photomed* 2020; 36: 398–400.

Clinical improvement was found in five patients. Only two had repeat phototesting: greatest improvement was to longer wavelengths than to UVB.

A case of chronic actinic dermatitis that responded completely to treatment with oral colostrum-macrophage-activating factor (colostrum-MAF). Ichihashi M, Nakamura Y, Muto M, et al. *Photodermatol Photoimmunol Photomed* 2019; 35: 290–2.

In keeping with a possible therapeutic role of immunomodulation in CAD, this is a case report of a 41-year-old man with presumed CAD, based on clinical picture and UVA sensitivity.

Coccidioidomycosis

Mahreen Ameen, Wanda Sonia Robles

Courtesy Julio Salas-Alanís, Instituto Dermatológico de Jalisco, Mexico

Coccidioidomycosis is an endemic systemic mycosis caused by inhalation of dimorphic fungi of the genus *Coccidioides* (*C. immitis* and *C. posadasii*). It is endemic in desert regions of the Southwestern United States and Central and South America. Primary pulmonary disease is usually subacute and self-limiting. The immunocompromised are particularly susceptible to chronic pulmonary disease. One percent progress to disseminated disease, and again those with impaired cell-mediated immunity are at greater risk. Coccidioidomycosis is an opportunistic infection with advanced human immunodeficiency virus (HIV) infection and CD4 counts less than 250. Solid-organ transplant recipients, patients with hematologic malignancies, and those on long-term immunosuppressants, including corticosteroids and TNF- α antagonists, are also at risk. Extrapulmonary hematogenous dissemination can affect almost any organ but most frequently involves the skin, lymph nodes, skeletal system, and meninges. Dissemination to the skin can give rise to ulcerative and verrucous lesions with a predilection for the nasolabial area. Subcutaneous abscesses, sinus tracts, and fistulae can develop as a result of coccidioidal infection in neighboring lymph nodes, bones, or joints. Other dermatological manifestations include erythema nodosum and erythema multiforme associated with primary pulmonary infection. Primary infection of the skin is rare.

Dermatologists should consider this diagnosis in patients with atypical skin lesions, pulmonary infiltrates, and a history of travel to endemic areas.

MANAGEMENT STRATEGY

Treatment depends on disease extent and predisposing factors. Those with primary pulmonary infection and no risk factors require only periodic assessments up to 2 years to ensure that the infection is self-limiting. Some clinicians, however, prefer to treat with oral azoles to prevent any risk of progression, although there are no trial data supporting this. Antifungal therapy is indicated for severe or chronic pneumonia, progressive or disseminated infection. *Fluconazole* (400–800 mg daily) and *itraconazole* (200–600 mg daily) are the initial options for most chronic pulmonary and disseminated infections. *Ketoconazole* (400 mg daily) shows comparable efficacy to the other azoles, but is associated with a higher risk of adverse effects with long-term use. Parenteral *amphotericin B* (AmB deoxycholate 0.5–1.5 mg/kg/day or lipid formulations of AmB 2.0–5.0 mg/kg/day) is recommended for those with severely acute infection with respiratory failure, those with rapidly progressive and disseminated infection, women during pregnancy, and those who fail azole therapy. Published reports of its use, however, are still limited to small numbers of patients treated in open-label studies. There have been no clinical trials assessing the efficacy of lipid formulations of AmB. Newly available antifungals, which may be used for refractory infection, include the *triazoles*, *posaconazole* and *voriconazole*, in vitro studies having demonstrated their efficacy. However, there have been no comparative studies evaluating their efficacy against azoles used for treating coccidioidomycosis. There are early reports, too, of the successful use of *caspofungin*, an echinocandin, although results of in vitro susceptibility studies have varied widely.

In addition to drug therapy, *surgery* is sometimes indicated for the removal of focal infection such as pulmonary cavities, focal osseous infection, or the debridement of soft tissue. *Long-term prophylaxis with azoles* is indicated for the immunocompromised, and meningeal infection requires lifelong azole therapy to prevent recurrence. Recovery from infection confers lifelong immunity and provides the rationale for ongoing development of a vaccine.

Primary cutaneous coccidioidomycosis: an update. Reyna-Rodríguez IL, Ocampo-Candiani J, Chavez-Alvarez S. *Am J Clin Dermatol* 2020; 21: 681–96.

The authors state that although a rare entity, primary cutaneous coccidioidomycosis appears to be increasing. They describe 82 cases, the majority of which were treated with first-line azoles. They also note that it has an excellent prognosis even without treatment.

Treatment considerations in pulmonary coccidioidomycosis. Hartmann CA, Aye WT, Blair JE. *Expert Rev Respir Med* 2016; 10(10): 1079–91.

This review discusses current literature regarding medical treatment options, including the various triazoles and AmB products. In addition, it discusses uncomplicated and complicated pulmonary infections and their sequelae and the approach to managing coccidioidomycosis in certain patient populations, such as pregnant women, transplant recipients, HIV-infected individuals, and recipients of TNF- α inhibitors.

Coccidioidomycosis. Infectious Diseases Society of America Guidelines. Galgiani JN, Ampel NM, Blair JE, et al. *Clin Infect Dis* 2016.

Management of early coccidioidal infections, which are the commonest clinical presentation; coccidioidal meningitis;

management of coccidioidomycosis in specific at-risk groups such as those with HIV; solid-organ transplants; and pregnancy are specifically addressed.

Specific Investigations

- Direct microscopy
- Culture
- Serological tests
- Imaging studies (chest and bone radiography)
- Serology for HIV/acquired immunodeficiency syndrome infection (where relevant)

The characteristic globular spherules may be seen in potassium hydroxide mounts of infected material: sputum, cerebrospinal fluid, or pus. Culture is the definitive method of establishing the diagnosis. *Coccidioides* spp. grow rapidly on most media within 5 days. In the mycelial form, the fungus is highly infectious, so cultures should be handled with care. Serological tests are useful and can be used to assess response to therapy.

First-Line Therapies

• Fluconazole	A
• Itraconazole	A

Tolerability of long-term fluconazole therapy. Davis MR, Nguyen MH, Donnelly MA, et al. J Antimicrob Chemother 2019; 74(3): 768–71.

This was a single-center, retrospective study investigating the tolerability of long-term (> 28 days) fluconazole in 124 adult patients with coccidioidomycosis. They were treated with fluconazole 100–1600 mg daily (the most commonly prescribed dose was 400 mg daily). The median duration of treatment was 147 days (interquartile range [IQR] 59–399 days); 51.6% experienced adverse effects. The most common adverse effects were xerosis (16.9%), alopecia (16.1%), and fatigue (11.3%). Two-thirds experiencing adverse effects required a therapeutic intervention such as dose reduction, discontinuation, or switch to a new antifungal. Patients experiencing adverse effects were prescribed higher total daily fluconazole doses (6.7 vs. 5.7 mg/kg; $p < 0.01$).

The authors report a relatively high rate of adverse effects in a real-world setting as opposed to clinical trials.

Fluconazole therapy for coccidioid meningitis. The NIAID Mycoses Study Group. Galgiani JN, Catanzaro A, Cloud GA, et al. Ann Intern Med 1993; 119: 28–35.

Uncontrolled clinical trial, which included 50 patients with coccidioid meningitis. Of these, 47 were evaluated: 25 had received no previous treatment, and nine were HIV positive. Of the 47 patients, 37 (79%) responded to treatment. Response rates were similar in patients whether they had received previous therapy or not.

Fluconazole demonstrates efficacy in the treatment of coccidioid meningitis.

Comparison of oral fluconazole and itraconazole for progressive, nonmeningeal coccidioidomycosis. A randomized, double-blind trial. Galgiani JN, Catanzaro A, Cloud GA, et al. Ann Intern Med 2000; 133: 676–86.

In this randomized, double-blind, placebo-controlled trial, 198 patients with pulmonary and non-meningeal infection were treated with either fluconazole 400 mg daily or itraconazole 200 mg twice daily. Overall efficacy rates at 12 months were similar (itraconazole, 63%; fluconazole 50%; $p = 0.8$). However, the response rate was higher in patients with bone disease treated with itraconazole (52% vs. 26%; $p = 0.05$). The rates of relapse were comparable (itraconazole, 18%; fluconazole, 28%; $p > 0.2$). Both drugs were well tolerated.

This is the first prospective, randomized trial comparing two different azole drugs for the treatment of an endemic mycosis. The results demonstrate that both itraconazole and fluconazole are effective therapies for non-meningeal coccidioidomycosis.

Second-Line Therapies

• Amphotericin B	B
• Ketoconazole	B

Evaluation of amphotericin B lipid formulations for treatment of severe coccidioidomycosis. Sidhu R, Lash DB, Heidari A, et al. Antimicrob Agents Chemother 2018; 62(7): e02293–17.

69 patients with severe coccidioidomycosis. Infections were treated with a standard intravenous dose of 5 mg/kg daily of either amphotericin B lipid complex (ABLC) or liposomal amphotericin B (L-AmB). Treatment duration varied depending on clinical responses. The median treatment period was 16 weeks for ABLC (IQR 6–23) and 16.5 weeks for L-AmB (IQR 10–24.25). Both were equally efficacious. L-AmB may have less renal toxicity than ABLC and may be the preferred agent in baseline renal impairment.

The availability of effective azoles and triazoles mean that amphotericins are generally only used for severe and widely disseminated infection.

Ketoconazole therapy of progressive coccidioidomycosis. Comparison of 400- and 800-mg doses and observations at higher doses. Galgiani JN, Stevens DA, Graybill JR, et al. Am J Med 1988; 84: 603–10.

In this trial involving 112 patients with progressive pulmonary, skeletal, or soft tissue infections, patients were randomized to receive either 400 mg or 800 mg daily of oral ketoconazole. Success rate was similar for the two groups (23.2% vs. 32.1% for low- and high-dose therapy). Side effects were significantly higher with high-dose therapy (66% vs. 38%). Relapse rates were also higher with high-dose therapy (52% vs. 11%), although it depended also on the organs involved. Treatment duration depended on clinical responses. The study concluded little or no benefit with high-dose ketoconazole for non-meningeal infection.

Third-Line Therapies

• Posaconazole	B
• Voriconazole	C
• Caspofungin	D
• Isavuconazole	E
• Adjunctive corticosteroids	B
• Adjunctive interferon- γ immunotherapy	E

Safety, tolerance, and efficacy of posaconazole therapy in patients with nonmeningeal disseminated or chronic pulmonary coccidioidomycosis. Catanzaro A, Cloud GA, Stevens DA, et al. Clin Infect Dis 2007; 45(5): 562–8.

In this multicenter trial, 20 patients with chronic pulmonary or non-meningeal disseminated coccidioidomycosis were treated with posaconazole 400 mg daily for up to 6 months (median 173 days). Seventeen (85%) patients had a satisfactory response to treatment ($\geq 50\%$ reduction in the Mycoses Study Group score from baseline). No serious adverse effects were reported. Paired baseline and end-of-treatment culture results for *Coccidioides* species were available for four patients, all of whom converted from being positive to being negative for *Coccidioides* species. Relapse was experienced by three of nine patients who did not receive antifungal therapy during the follow-up period.

Posaconazole therapy for chronic refractory coccidioidomycosis. Stevens DA, Rendon A, Gaona-Flores V, et al. Chest 2007; 132(3): 952–8.

This was an open-label multinational study, which included 15 patients with pulmonary ($n=7$) and disseminated ($n=8$) disease that was refractory to previous therapy, which included AmB with and without an azole. They were treated with posaconazole 800 mg daily in divided doses for 34–365 days (median 306 days). Seventy-three percent of patients (11/15) responded to treatment with cure in four patients. Treatment was very well tolerated.

Treatment of refractory coccidioidomycosis with voriconazole or posaconazole. Kim MM, Vikram HR, Kusne S, et al. Clin Infect Dis 2011; 53(11): 1060–6.

This was a retrospective study of all cases treated with either voriconazole 200 mg twice daily ($n=21$) or posaconazole 400 mg twice daily ($n=16$) in a single center. There was a 67% and 75% improvement after a median duration of 6 and 17 months of treatment with voriconazole and posaconazole, respectively.

The authors concluded that voriconazole and posaconazole are reasonable but not infallible options for salvage treatment of refractory coccidioidomycosis.

Use of the echinocandins (caspofungin) in the treatment of disseminated coccidioidomycosis in a renal transplant recipient. Antony S. Clin Infect Dis 2004; 39: 879–80.

Oral caspofungin monotherapy at a dose of 50 mg daily for 4 weeks was successfully used to treat this case of disseminated infection without meningeal involvement.

Treatment of pediatric refractory coccidioidomycosis with combination voriconazole and caspofungin: a retrospective case series. Levy ER, McCarty JM, Shane AL, et al. Clin Infect Dis 2013; 56(11): 1573–8.

A retrospective review of nine pediatric patients treated with combination intravenous voriconazole (7.5 mg/kg daily) and caspofungin (0.7 mg/kg daily) salvage therapy for refractory coccidioidomycosis after failing conventional therapy consisting of a triazole, AmB, or a combination of both. Eight of the nine patients achieved remission. Caspofungin was only added when patients failed to respond to voriconazole monotherapy. The mean treatment period with voriconazole was 6 months (range 2–13 months).

The dramatic response of two cases of persistent and progressive respiratory coccidioidomycosis to adjunctive corticosteroid therapy is described. One case had been treated with combination fluconazole and liposomal amphotericin for over 6 weeks, with persistent fever and pneumonia. The other was treated with fluconazole and then amphotericin for 3 weeks, with progression to acute respiratory distress syndrome and shock. Both recovered after receiving short courses of intravenous methylprednisolone: one patient received a 12-day course starting at 40 mg daily and reducing by 10 mg every 3 days; the other received 60 mg 4 times daily for 4 days only.

The authors concluded that addition of systemic corticosteroids might hasten recovery in patients with severe coccidioidomycosis where it treated ongoing destructive inflammation as opposed to hypersensitivity.

Two cases illustrating successful adjunctive interferon- γ immunotherapy in refractory disseminated coccidioidomycosis. Duplessis CA, Tilley D, Bavaro M, et al. J Infect 2011; 63(3): 223–8.

The authors report two cases of refractory coccidioidomycosis, which demonstrated improved responses with adjunctive IFN- γ .

IFN- γ augments the antifungal activity of effector immune cells against a variety of fungi. Adjunctive immunotherapy given with chemotherapy has the potential to improve host immune responses and facilitate complete eradication of pathogens.

Isavuconazole in the treatment of coccidioidal meningitis. Heidari A, Quinlan M, Benjamin DJ, et al. Antimicrob Agents Chemother 2019; 63(3): e02232–318.

This was a retrospective review of nine patients with coccidioidal meningitis treated with isavuconazole 200 mg daily for a mean treatment period of 504 days (range 274–810 days). The authors report treatment success in three patients and stable disease in six patients.

Patients with coccidioidal meningitis require lifelong antifungal therapy. In the case of insufficient antifungal efficacy or if there is a risk of cumulative toxicity, salvage therapy may be required. Isavuconazole may represent a useful antifungal in these circumstances.

46

Condyloma acuminata

Ismael Maatouk

Arising from infection with human papillomavirus (HPV), predominantly types 6 and 11, anogenital warts (AGWs) are the most commonly diagnosed viral sexually transmitted infection. Annual AGW incidence is 1%–2%. Out of over 200 types of HPV, at least 40 infect the anogenital tract. Condyloma acuminata (CA), the classic form of AGWs, are associated with 'benign' HPV types 6 and 11 (up to 90%) but may also be caused by oncogenic types such as 16 and 18 (70% of all cervical cancer), 31, 33, and 35.

MANAGEMENT STRATEGY

AGWs are contagious, associated with slow spontaneous clearance, significant impact on the quality of life and healthcare costs, and, potentially, progression to in situ squamous cell carcinoma (erythroplasia of Queyrat in penile mucosa) or to transformation into squamous cell carcinomas and other invasive cancers (cervical, vaginal, vulvar cancer, etc.). It is essential to identify effective treatment strategies and appraise evidence from controlled studies.

In the absence of an 'anti-HPV' drug per se, current treatments focus on stimulation of the host's immune response to enhance virus recognition. Treatments are categorized as either patient-administered (i.e., *podophyllotoxin*, *imiquimod*, *sinecatechins*, and *5-fluorouracil cream*) or provider-administered (bi- or trichloroacetic acid [TCA] application, *podophyllin resin*, CO_2 laser, cryotherapy, surgery, electrosurgery, intramuscular prophylactic or intralesional therapeutic HPV vaccine). In the latter, reduction or clearance was achieved by a cross-protection (HPV L1 capsids) or a non-specific upregulation (aluminum-containing adjuvant's immunity) in prophylactic vaccines and by a cytotoxic response against papilloma-transformed cells in therapeutic vaccines.

Podophyllotoxin treatment consists of twice daily application for 3 days, followed by 4 days' rest, for 4–5 cycles. Supervision is recommended if total area is $>4\text{ cm}^2$. Repeat cycles may be used if lesions are responding. Imiquimod 5% activates dendritic cells (adaptive T-cell response). It is applied overnight and washed off 6–10 hours later, 3 times a week, for 16 weeks. Longer courses have been used without clear evidence. Other concentrations

(3.75%) have been approved by the US Food and Drug Administration (FDA) in 2010 and showed similar cure rates, similar patient compliance, and fewer side effects compared with 5%. Sinecatechin 15% extract of green tea (*Camellia sinensis*) contains epigallocatechin gallate, exhibiting antiviral, anti-tumor, and immunostimulatory properties. It is applied 3 times a day for 16 weeks. Other green tea-based ointments are available. 5-Fluorouracil cream is not recommended for routine management.

Provider-administered therapies are either topical or surgical. Topical modalities include podophyllin resin, bi- or TCA, intralesional bleomycin, and ingenol mebutate. TCA 80–90% is not recommended for large volumes and requires a weekly application in a specialist clinic setting only. Podophyllin resin is applied for 1–6 hours and is less effective on dry areas (penile shaft, scrotum, and labia majora). Intralesional interferon- α and bleomycin are also effective therapies. Surgical treatments include cryotherapy, surgical removal by tangential shave (cold knife or scissors), curettage with or without electrosurgery, and lasers (CO_2 and pulsed dye laser [PDL]). Cryotherapy causes thermolysis and necrosis of keratinocytes hosting HPV. Liquid nitrogen usually requires one or two freeze–thaw cycles per session for two or three sessions. Recurrence rates are up to 40%. As this is the most used therapeutic intervention, a meta-analysis to compare the efficacy and safety of cryotherapy concluded, with low-level quality of evidence, that no evidence supports cryotherapy superiority or inferiority when compared with TCA, imiquimod, or podophyllin (see later). Surgery and CO_2 lasers are useful for treating extensive giant (i.e., Buschke–Löwenstein tumor) intraurethral and recalcitrant warts. Excision and electrosurgery require local anesthetic and are useful for large volume warts and difficult anatomic sites. Several case reports mentioned imiquimod as a successful treatment of Buschke–Löwenstein. All electrosurgical and laser techniques may generate a plume of smoke, which contains HPV DNA, potentially infectious to the respiratory tract in the operating personnel. Therefore, masks should be worn during these procedures.

Estimates of clearance and recurrence rates with various therapies are difficult due to differences in method of analysis, patient population, and duration of follow-up. No available therapy can be guaranteed to clear AGWs without any recurrence. Combination therapy using an immunomodulator after physical ablative therapy reduces recurrence rates with risky adverse events.

The development of the three FDA-approved multivalent HPV vaccines have shown high efficacy for HPV prevention. Cervarix and Gardasil were the first vaccines for cervical cancer prevention. Cervarix targets types 16 and 18 (responsible for 70% of all cervical cancer), while Gardasil also adds activity against types 6 and 11 (cause 90% of AGWs). In addition to these four types, the 9vHPV vaccine contains type 31, 33, 45, 52, and 58 antigens. Vaccines are safe with minor adverse effects. They also protect against precancerous lesions caused (types 16 and 18) in a naïve population. They are available for both males and females, preferably before they become sexually active, and are being successfully implemented in many developed countries with different inclusion criteria.

During pregnancy, podophyllotoxin and 5-fluorouracil should be avoided (teratogenic). Imiquimod is not approved for use (no data). Treatment is not always warranted but aims at preventing vertical transmission. Caesarean section is not indicated as it has not been shown to prevent the neonatal exposure to the virus. Caesarean section is only indicated in case of gross cervical warts. For the newborn, the only serious (rare) complication is recurrent respiratory papillomatosis. Cryotherapy, excision, and ablative methods are safe in pregnancy.

Treatments in children and adolescents follow the same principles as in adults. Anoscopy and/or speculum examination are used to evaluate the anal canal, vagina, or cervix. Biopsy is indicated for atypical-looking and recalcitrant lesions or in immunocompromised patients. Sexual abuse should be suspected but is not systematic.

Immunocompromised people (organ transplant recipients or living with HIV) experience lower response and increased relapse rates. Treatment recommendations are not modified but longer courses may be required.

Specific Investigations

- Papanicolaou (Pap) smear
- HPV typing (not standard of care)
- Biopsy
- Acetic acid 3%–5%

Cytology versus HPV testing for cervical cancer screening in the general population. Koliopoulos G, Nyaga VN, Santesso N, et al. *Cochrane Database Syst Rev* 2017; 8: CD008587.

In primary cervical cancer screening, HPV tests are less likely to miss cases of cervical intraepithelial neoplasia (CIN) grade 2 or worse and lead to more unnecessary referrals. However, a negative HPV test is more reassuring than a negative cytological test, as the latter has a greater chance of false negative, which could delay appropriate treatment.

First-Line Therapies

• Imiquimod (5%, 3.75%)	A
• Podofilox (podophyllotoxin)	A
• Sinecatechin extract of green tea	A
• Cryotherapy	A
• Podophyllin	B

Imiquimod versus podophyllotoxin, with and without human papillomavirus vaccine, for anogenital warts: the HIPvac factorial RCT. Gilson R, Nugent D, Bennett K, et al. Southampton (UK): NIHR Journals Library; 2020 Sep (Health Technology Assessment, No. 24.47). <https://www.ncbi.nlm.nih.gov/books/NBK562414/>. <https://doi.org/10.3310/hta24470>.

A 2020 randomized, controlled trial (RCT) did not support earlier evidence of a lower recurrence with use of imiquimod than with use of podophyllotoxin. Podophyllotoxin without quadrivalent human papillomavirus vaccine is the most cost-effective strategy at the current vaccine list price.

Cryotherapy to treat anogenital warts in non-immunocompromised adults: systematic review and meta-analysis. Bertolotti A, Dupin N, Bouscarat F, et al. *J Am Acad Dermatol* 2017; 77: 518–26.

In this systematic review, cryotherapy efficacy did not appear to differ from that of TCA, podophyllin, or imiquimod. Electro-surgery was weakly associated with better AGW clearance than cryotherapy (risk ratio [RR] 0.80). Cryotherapy was associated with immediate low-level adverse events and immediate pain but fewer erosions.

Imiquimod for anogenital warts in non-immunocompromised adults. Grillo-Ardila CF, Angel-Müller E, Salazar-Díaz LC, et al. *Cochrane Database Syst Rev* 2014; 12: CD010389.

The benefits and harms of imiquimod compared with placebo should be regarded with caution due to the risk of bias. The evidence that shows imiquimod and patient-applied treatment (podophyllotoxin or podophyllin) have similar benefits but fewer systematic reactions with the imiquimod is of low, or very low, quality.

Imiquimod cream 2.5% and 3.75% applied once daily to treat external genital warts in men. Rosen T, Nelson A, Ault K. *Cutis* 2015; 96: 277–82.

Evaluation of imiquimod cream 3.75% or 2.5% or placebo once daily until complete clearance or maximum of 8 weeks was reported in a placebo-controlled study ($n=447$). Complete clearance was 18.6% in the 3.75% imiquimod group and 14.3% in the 2.5% imiquimod group (compared with 4% in placebo; $p<0.03$ for both dosages). Both groups were significantly superior to placebo. The FDA approved 3.75% imiquimod cream.

Self-administered interventions for anogenital warts in immunocompetent patients: a systematic review and meta-analysis. Werner RN, Westfechtel L, Dressler C, et al. *Sex Transm Infect* 2017; 93: 155–61.

Complete clearance (CC) of imiquimod 3.75% and 5% cream, and podophyllotoxin 0.5% solution and gel, were superior to placebo. CC of podophyllotoxin 0.15% cream was inferior to podophyllotoxin 0.5% solution (active-controlled trial). No significant differences existed between imiquimod 5% and podophyllotoxin 0.5%. Due to the limited comparisons, conclusions on the efficacy of the different treatments are restricted.

Second-Line Therapies

• Surgical excision (with cold knife or scissors)	B
• Lasers (CO ₂ and PDL)	B
• Loop electrosurgical excisional procedure	B
• Electrodesiccation (see also earlier)	B
• Trichloroacetic acid (see also earlier)	B
• HPV vaccination:	
• 0–2–6-month (intramuscular prophylactic)	A
• or once per week every 5 weeks for men and 6 weeks for women (intralesional therapeutic vaccine)	C

Complete resolution of chronic multiple verruca vulgaris treated with quadrivalent human papillomavirus vaccine. Daniel BS, Murrell DF. *JAMA Dermatology* 2013; 149(3): 370.

Six patients of different ages received intramuscular HPV vaccine for their recalcitrant multiple warts. Improvement was noticed within weeks without adverse reactions. The mechanism of action could include cross-protection (HPV L1 capsids) or, alternatively, the aluminum-containing adjuvant through non-specific immune upregulation. This alternative can be useful for resistant warts, including AGWs.

Regression of human papillomavirus intraepithelial lesions is induced by MVA E2 therapeutic vaccine. Rosales R, López-Contreras M, Rosales C, et al. *Hum Gene Ther* 2014; 25: 1035–49.

Intraepithelial lesions (uterus, urethra, vulva, or anus) of 1176 females and 180 males were directly injected with a recombinant vaccinia virus Ankara containing the bovine papilloma virus E2 protein (MVA E2). All males (one injection per week for 5 weeks) and 1051 (89.3%) females (one injection per week for 6 weeks)

showed complete histological elimination. A specific cytotoxic response against papilloma-transformed cells (antibodies against MVA E2) was observed. No side effects were reported.

Pulsed dye laser therapy in the treatment of warts: a review of the literature. Veitch D, Kravvas G, Al-Niaimi F. *Dermatol Surg* 2017; 43: 485–93.

A literature review showed that facial and AGWs demonstrated excellent outcomes with pulsed dye laser (PDL). Recalcitrant warts displayed significant variability in their response (50%–100%). Recurrence rates at 4 months of follow-up were documented as 0%–15%. Cost and availability of this treatment remain a limitation; however, this modality can be used when other treatments have failed.

Human papilloma virus type and recurrence rate after surgical clearance of anal condylomata acuminata. D'Ambrogio A, Yerly S, Sahli R, et al. *Sex Transm Dis* 2009; 36: 536–40.

Patients ($n=140$) with anal canal condylomas had surgery followed by cauterization. Recurrence rate was 25% after day 120 of follow-up. HPV type 11 was statistically associated with higher recurrence rates.

CO₂ laser therapy versus cryotherapy in treatment of genital warts; a randomized controlled trial (RCT). Azizjalali M, Ghaffarpour G, Mousavifard B. *Iran J Microbiol* 2012; 4: 187–90.

Patients ($n=160$) with genital warts were treated with CO₂ laser or cryotherapy. CC was achieved in 95% treated by CO₂ laser and 46.2% treated with cryotherapy ($p<0.001$). Laser therapy was associated with less recurrence compared with cryotherapy (0.05% vs. 0.18%).

Treating vaginal and external anogenital condylomas with electrosurgery vs. CO₂ laser ablation. Ferenczy A, Behelak Y, Haber G, et al. *J Gynecol Surg* 1995; 148: 9–12.

In 208 patients, the efficacy and adverse effects of loop electrosurgical excision procedure (LEEP) were similar to those associated with laser ablation. LEEP adverse events included bleeding and scarring. Scarring of the penis can result in dysfunction; therefore, most physicians prefer CO₂ laser ablation or cryotherapy for penile warts.

Third-Line Therapies

• Intralesional interferon- α	A
• Interferon- β gel	A
• Oral isotretinoin	B
• Intralesional fluorouracil/epinephrine gel	A
• Cidofovir	B
• Aminolevulinic acid (ALA)-photodynamic therapy	B
• Intralesional bleomycin	C
• Ingenol mebutate	C

Natural interferon alfa for treatment of condyloma acuminata. Friedman-Kien AE, Eron LJ, Conant M, et al. *JAMA* 1988; 259: 533–8.

In this double-blind, placebo-controlled trial, CC was 62% (with intralesional interferon- α injections twice weekly for up to 8 weeks) versus 21% (placebo). Combinations of interferon with cryosurgery, podophyllin, or laser ablation have been promising.

Treatment of condylomata acuminata with oral isotretinoin. Tsambaos D, Georgiou S, Monastirli A, et al. *J Urol* 1997; 158: 1810–2.

Oral isotretinoin 1 mg/kg daily for 3 months achieved complete response in 39.6% of 56 male patients with history of refractory AGWs. It may be considered in immature and small AGWs.

Topical cidofovir (HPMPC) is an effective adjuvant to surgical treatment of anogenital condylomata acuminata. Coremans G, Margaritis V, Snoeck R, et al. *Dis Colon Rectum* 2003; 46: 1103–8.

Patients were treated with repetitive electrocoagulations ($n=27$) (control) or cidofovir ($n=20$) 1% cream applied daily for 5 hours for 5 consecutive days per week, repeated weekly for up to 18 weeks or until CC. Lesions refractory to cidofovir were cleared up with additional coagulations. Complete and partial responses with cidofovir were 32% and 60%, respectively. The relapse rate was significantly lower in the cidofovir group (3.7% versus 55%).

Combined surgery and cidofovir is an effective treatment for genital warts in HIV-infected patients. Orlando G, Fasolo MM, Beretta R, et al. *AIDS* 2002; 16: 447–50.

An open, randomized prospective pilot study included 74 HIV-positive patients. They received for AGWs: surgery (S); surgical-cidofovir (SC) (5 days per week for 2 weeks within 1 month of cautery), or cidofovir (C) 1% gel (5 days per week for up to 6 weeks). Complete response was 93.1% in S, 76.2% in C, and 100% in SC (*significant*). After 6 months, recurrences were significantly lower in SC.

Evaluation of photodynamic therapy using topical aminolevulinic acid hydrochloride in the treatment of condylomata acuminata: a comparative, randomized clinical trial. Liang J, Lu XN, Tang H, et al. *Photodermatol Photoimmunol Photomed* 2009; 25: 293–7.

In a trial, 91 patients received ALA-PDT or CO₂ laser. Complete response was 95.93% and 100%, respectively ($p>0.05$). At week 12 of follow-up, 9.38% and 17.39% had recurrent lesions ($p<0.05$). Adverse reactions were 8.82% and 100%, respectively ($p<0.05$). Pain and cost of the treatment are still a great challenge for the therapy.

Preliminary study of intralesional bleomycin injection for the treatment of genital warts. Lee JY, Kim CW, Kim SS. *Ann Dermatol* 2015; 27: 239–41.

Fifteen patients with a total of 164 refractory genital warts were treated with intralesional bleomycin 1.5 mg/mL every 2 weeks until clearance. Clearance was achieved in 73.3%.

Ingenol mebutate gel is effective against anogenital warts – a case series in 17 patients. Schopf RE. *J Eur Acad Dermatol Venereol* 2016; 30: 1041–3.

Seventeen patients were treated with one to three applications of ingenol mebutate gel (500 or 150 mcg/g). Curative effect was achieved very rapidly in 76% of the cases after 3–35 days with complete response in 16/17 patients. Remission was maintained after up to 240 days. The main challenge for this therapy is irritation and lack of clinical trials.

COVID-19 dermatoses

Justine Fenner

COVID-19 RELATED RASHES IN ADULTS

Coronavirus disease 2019 (COVID-19) is an acute respiratory viral infection caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The disease first appeared in China in December 2019 and has since spread throughout the globe, officially being called a pandemic by the World Health Organization (WHO) in March 2020.

Much is still being learned about this disease as it continues to affect millions of people worldwide. Typical symptoms of COVID-19 are fever, chills, dry cough, sore throat, nausea, headache, and myalgias. The incubation period is believed to be on average between 2 and 14 days, with some studies reporting incubation periods as long as 19–27 days. The main mode of transmission is believed to be by droplets but fecal transmission and direct contact are other possible modes of transmission. Some patients experience anosmia and ageusia without any other symptoms. More severe cases can present with shortness of breath or severe respiratory distress. Older patients with comorbidities are at higher risk for complications including respiratory failure and multiorgan dysfunction.

Initial studies coming out of China reported low frequencies of skin manifestations. Since then further studies with greater involvement of dermatologists have demonstrated rash in as high as 20.4% of patients with COVID-19. The most frequently reported cutaneous manifestations are: (1) maculopapular/morbilliform; (2) chilblain-like; (3) vesicular; (4) urticarial; (5) livedoid; and (6) purpuric. The differential diagnosis of these rashes

depends on the morphology. For example, morbilliform, vesicular, and urticarial rashes could be due to other viral infections or a drug reaction. The main differential for chilblain-like rashes is pernio or chilblain lupus.

Cutaneous manifestations related to coronavirus disease 2019 (COVID-19): a prospective study from China and Italy. De Giorgi V, Recalcati S, Jia Z, et al. *JAAD* 2020 May 19 [Epub ahead of print].

In this multicenter, prospective study of 678 patients with COVID-19, 53 patients had new inflammatory skin findings, and 13 patients had new vascular skin manifestations. Diffuse petechiae, multiple/generalized purpura, and acroischemia were seen in more severe cases, whereas erythematous, vesicular, and urticarial rashes could not be correlated with disease severity.

Classification of the cutaneous manifestations of COVID-19: a rapid prospective nationwide consensus study in Spain with 375 cases. Galván Casas C, Català A, Carretero Hernández G, et al. *Br J Dermatol* 2020; 183(1): 71–7.

Patients with a pseudo-chilblain presentation of COVID-19 tended to be younger with less severe disease while patients with livedoid/necrotic lesions were older with more severe disease.

MANAGEMENT STRATEGY

The best way to mitigate the effects of SARS-CoV-2 is to prevent its spread. In the setting of a pandemic, this means maintaining excellent hand hygiene, keeping 6 feet (2 m) apart from others when in public, and wearing a mask when this is not possible, as well as self-isolating/quarantining when appropriate. With the introduction of safe and effective vaccines, individuals who can be vaccinated against COVID-19 should receive the vaccine.

Often fever and respiratory symptoms in the setting of an epidemic allow for the clinical diagnosis of COVID-19 infection. If there is any question, reverse-transcription polymerase chain reaction (RT-PCR) of samples, such as nasal swabs, often establishes the diagnosis. Unfortunately, more needs to be learned about the sensitivity of this test as several studies using chest computed tomography (CT) scans have found the sensitivity of RT-PCR to be as low as 71%. In diagnosing COVID-19, CT scan can identify viral pneumonia, but cannot distinguish what specific virus is implicated. The presence of SARS-CoV-2 antibodies suggests prior infection, however more studies are needed to determine the sensitivity and utility of this test.

For mild cases of COVID-19 the therapy is *supportive care*. Supportive care includes *anti-pyretics* for fever in addition to *hydration*. More severe disease requires hospitalization and *supplemental oxygen* as needed. Skin findings are generally mild and resolve without specific therapy.

The cutaneous manifestations of COVID-19 infection are typically self-limited and resolve without intervention. *Antihistamines* are helpful for urticarial presentations; *systemic corticosteroids* are seldom needed for the maculopapular rash; topical steroids may be tried, especially if the eruption is pruritic; and anticoagulation with agents like *enoxaparin* may help the ischemic manifestations. For the chilblain-like changes called “COVID toes”, *topical nitroglycerin* preparations may be helpful.

Treatments for systemic complications of COVID-19 are still evolving or controversial and will not be covered in detail.

Laboratory abnormalities seen in COVID-19 include leukopenia, leukocytosis, and elevated CRP. While leukopenia is seen more

commonly, leukocytosis has been associated with a worse prognosis. Other laboratory abnormalities reported include elevated aspartate aminotransferase (AST) and elevated ESR. More severe cases have been associated with elevated levels of alanine transaminase, creatinine, lactate dehydrogenase (LDH), and prothrombin time. Additionally, the cytokine storm seen in severely ill patients results in elevated proinflammatory cytokines including interleukin (IL)-2, IL-6, IL-8, IL-10, interferon- γ , IL-1 β , tumor necrosis factor-alpha (TNF- α), and granulocyte colony stimulating factor.

Specific Investigations

- Reverse-transcription polymerase chain reaction
- CT scan when diagnosis is unclear or patient is ill
- Immunoassay to detect SARS-CoV-2 antibodies
- Chest X-ray when patient requires hospitalization
- Skin biopsy may be needed to rule out other diagnostic possibilities
- CBC, comprehensive metabolic panel, C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), lactate dehydrogenase (LDH), prothrombin time, D-dimer when patients are ill

What do we need to know to improve diagnostic testing methods for the 2019 novel coronavirus? Mustafa Z, Ghaffari M. *Cureus* 2020; 12: e8263.

This review discusses the various modes of testing for COVID-19, highlighting their value and limitations.

Correlation of chest CT and RT-PCR testing in coronavirus disease 2019 (COVID-19) in China: a report of 1014 cases. Ai T, Yang Z, Hou H, et al. *Radiology* 2020; 296: E32–E4 [Epub ahead of print].

In this study using RT-PCR as a reference, sensitivity of CT of the chest for COVID-19 was 97%. In the subgroup of patients who initially tested negative but went on to test positive by RT-PCR for COVID-19, 67% had positive chest CT findings before initial negative RT-PCR testing. This study highlights the high sensitivity of CT imaging in diagnosing COVID-19, especially in the early stages of disease.

Value of leukocytosis and elevated C-reactive protein in predicting severe coronavirus 2019 (COVID-19): a systematic review and meta-analysis. Yamada T, Wakabayashi M, Yamaji T, et al. *Clinica Chimica Acta* 2020; 509: 235–43.

In this study compiling data from 3278 patients with COVID-19, elevated white blood cell count (WBC) and CRP were associated with poor outcomes, while leukopenia was associated with a better prognosis.

Dysregulation of immune response in patients with COVID-19 in Wuhan, China. Qin C, Zhou L, Hu Z, et al. *Clin Infect Dis* 2020 [Epub ahead of print].

This retrospective, single center study demonstrated that patients with severe COVID-19 had significantly elevated inflammatory cytokines including TNF- α , IL-2R, IL-6, IL-8, and IL-10 compared with non-severe cases.

First-Line Therapies

- Antipyretics (e.g. acetaminophen) **D**
- Supportive care/hydration **D**

Second-Line Therapies

- Enoxaparin and topical nitroglycerin 2% for COVID toes **E**
- Experimental therapies for COVID-19 infection continue to be developed and studied

Treatment of COVID-19 induced chilblains with topical nitroglycerin. Weingarten M, Abittan B, Rivera-Oyola R, et al. *Int J Dermatol* 2020; 59: 1522–4.

In this case series a patient with COVID-19 associated chilblains experienced rapid improvement of cutaneous symptoms after initiation of topical nitroglycerin 0.2% twice daily along with systemic enoxaparin therapy.

IDSA Guidelines on the treatment and management of patients with COVID-19. Bhimraj A, Morgan RL, Shumaker AH et al. *IDSA* 2021; Version 4.2.0.

This living guideline created by an expert panel of infectious diseases specialists, experts in public health and front-line physicians summarizes the therapeutic options for mild and severe COVID-19 infections.

PEDIATRIC MULTISYSTEM INFLAMMATORY SYNDROME

Preliminary evidence suggests that while children are as likely as adults to contract SARS-CoV-2, they are less likely to become symptomatic or develop severe disease. While there is less pediatric literature describing cutaneous findings in association with COVID-19 compared with the adult literature, there are case reports describing erythema multiforme, chilblain-like lesions, maculopapular, varioliform, and roseoliform eruptions in COVID-19 pediatric patients. More recently pediatric patients have been reported to present with an inflammatory syndrome similar to Kawasaki disease, macrophage activation syndrome, and toxic shock syndrome. While this multisystem inflammatory syndrome in children (MIS-C) is rare, its presentation is severe with end organ damage. Most patients present with fever, gastrointestinal symptoms, and mucocutaneous features including rash, conjunctivitis, and lip redness/swelling.

Mucocutaneous manifestations of multisystem inflammatory syndrome in children during the COVID-19 pandemic. Young TK, Shaw KS, Shah JK, et al. *JAMA Dermatol* 2021; 157: 207–12.

In this retrospective case series of 35 pediatric patients suspected of having MIS-C the most common cutaneous findings were conjunctival injection (n = 21), palmoplantar erythema (n = 18), lip hyperemia (n = 17), lip cracking (n = 13), periorbital erythema and edema (n = 7), strawberry tongue (n = 8), and malar erythema (n = 6). Less common findings were scarlatiniform eruptions (n = 5), morbilliform eruptions (n = 3), urticarial eruptions (n = 3), and reticulated eruptions (n = 3). Mucocutaneous findings were not associated with disease severity.

Multisystem inflammatory syndrome in children in New York State. Dufort EM, Koumans EH, Chow EJ, et al. *N Engl J Med* 2020; 383: 347–58.

Through descriptive analysis this group summarized the clinical findings of 99 suspected or confirmed MIS-C cases in New

York between March 1 and May 10, 2020. They found that 100% of patients presented with subjective fever or chills, 80% had gastrointestinal symptoms, 60% had rash, 56% had conjunctival injection, and 27% had mucosal changes.

MANAGEMENT STRATEGY

The WHO and Centers for Disease Control and Prevention (CDC) have each created their own recommended diagnostic criteria requiring fever, laboratory evidence of inflammation, and evidence of COVID-19. The main difference between the two criteria is that the WHO is more specific in the features required for diagnosis, requiring two of the following: (1) rash or bilateral non-purulent conjunctivitis or mucocutaneous inflammation; (2) hypotension or shock; (3) features of cardiac dysfunction; (4) evidence of coagulopathy; or (5) acute gastrointestinal problems, while the CDC requires evidence of dysfunction of any two organ systems.

A range of immunomodulatory medications have been used to treat pediatric multisystem inflammatory syndrome associated with COVID-19 including intravenous immunoglobulin (IVIG), aspirin, steroids, anakinra, infliximab, and tocilizumab. Remdesivir has also been used. Additionally, some patients have recovered with supportive care alone. The American College of Rheumatology recommends first line treatment of hospitalized patients with MIS-C with IVIG. Methylprednisolone should be added in patients with shock or organ threatening disease.

Specific Investigations

- CBC, ESR, CRP, ferritin, comprehensive metabolic profile, lipid profile
- Procalcitonin levels, urinalysis
- Fibrinogen, D-dimer, IL-1, IL-6, IL-8, TNF- α levels
- Troponin 1, creatinine kinase-MB, N-terminal pro-B-type natriuretic peptide
- Echocardiogram at 0, 2, and 6 weeks

Pediatric COVID-19: systematic review of the literature. Patel N. Am J Otolaryngol 2020; 41: 102573.

In this systematic review of pediatric patients with COVID-19, without multisystem inflammatory syndrome, median lab values for WBC, lymphocyte count, and CRP were within reference range. Procalcitonin levels were slightly elevated. These findings are notably different from adults with COVID-19.

Multisystem inflammatory syndrome in children (MIS-C) related to COVID-19: a New York City experience. Riollano-Cruz M, Akkoyun E, Briceno-Brito E, et al. J Med Virol 2020 June 25 [Epub ahead of print].

Retrospective chart review in which all patients had elevation of CRP, D-dimer, IL-6, and IL-8. Lymphopenia was found in 87%

of patients and thrombocytopenia was found in 40% of patients. Interestingly, TNF- α was only minimally elevated in 73% of patients and no patients had elevated IL-1.

Clinical characteristics of 58 children with a pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2. Whittaker E, Bamford A, Kenny J, et al. JAMA 2020 June 8 [Epub ahead of print].

This case series of 58 children from eight hospitals in England divided the patients into three groups in order to make comparisons: (1) patients with persistent fever and elevated inflammatory markers without features of Kawasaki disease, shock, or organ failure; (2) patients who fulfilled diagnostic criteria for Kawasaki disease; and (3) patients with shock or evidence of myocardial injury. Patients who developed shock had higher CRP, neutrophil count, troponin, and N-terminal pro-B-type natriuretic peptide as well as lower albumin and lymphocyte count. Laboratory findings between children who developed coronary artery dilatation or aneurysms were not significantly different from those without coronary artery abnormalities.

First-Line Therapies

- IVIG and low-dose aspirin
- Methylprednisone in patients with shock or organ threatening disease

Second-Line Therapy

- Anakinra or methylprednisolone

Kawasaki-like multisystem inflammatory syndrome in children during the COVID-19 pandemic in Paris, France: prospective observational study. Toubiana J, Poirault C, Corsia A, et al. BMJ 2020; 369: 2094.

In this case series all 21 children met criteria for either Kawasaki disease or incomplete Kawasaki disease. All 21 patients received IVIG and low-dose aspirin. Seven patients also received steroids. Five patients were resistant to the first IVIG dose, with four of those patients also receiving a second dose of steroids. All patients were discharged home with no deaths.

American College of Rheumatology clinical guidance for multisystem inflammatory syndrome in children associated with SARS-CoV-2 and hyperinflammation in pediatric COVID-19: Version 2. Henderson LA, Canna SW, Friedman KG, et al. Arthritis Rheumatol 2021; 73: e13-e29.

These guidelines, designed by experts in rheumatology, infectious diseases, cardiology and cytokine storm-related syndromes, offer a diagnostic pathway for MIS-C as well as an algorithm for immunomodulatory treatment of MIS-C.

Cryopyrin-associated periodic syndrome (CAPS)

Margaret A. MacGibeny, Edward W. Cowen

Cryopyrin-associated periodic syndrome (CAPS) is a rare autosomal dominantly-inherited autoinflammatory disease characterized by urticarial rashes, conjunctivitis, fever, fatigue, articular involvement, and inflammation, which may be triggered by cold exposure in some patients. It encompasses a spectrum of mild-to-severe conditions including familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID). Left untreated, patients with severe involvement may develop sensorineural hearing loss, visual loss, chronic meningitis, and amyloidosis. CAPS is caused by gain-of-function mutations in the *NLRP3* gene, which lead to inappropriate *NLRP3* inflammasome activation and overproduction of interleukin-1 β (IL-1 β). New nomenclature for CAPS was recently proposed to incorporate FCAS, MWS, and NOMID under one name, *NLRP3*-associated autoinflammatory disease (*NLRP3*-AID), with mild, moderate, and severe phenotypic subtypes.

MANAGEMENT STRATEGY

Early diagnosis and aggressive treatment of CAPS are essential to prevent organ damage, and early symptoms may be reversible if treatment is commenced expediently. Symptoms may be present from birth or may not become apparent until childhood or early adulthood. Diagnosis is complicated by the fact that, even if molecular genetic analysis of *NLRP3* is performed, mutations cannot always be demonstrated. However, high-throughput sequencing has identified somatic mosaic *NLRP3* mutations in some 'mutation-negative' patients, including adults with late-onset CAPS symptoms. Evidence-based criteria were proposed in 2019 for the classification of CAPS based on clinical symptoms with or without genetic analysis (Table 48.1).

Table 48.1 Criteria for CAPS classification

With genetic analysis

Confirmatory *NLRP3* mutation plus at least one symptom:^{*}
or Non-confirmatory *NLRP3* mutation plus at least two symptoms:^{*}

- Urticarial rash
- Red eye (conjunctivitis, episcleritis, uveitis)
- Sensorineural hearing loss

With unknown genetics

At least two of five symptoms:^{*}

- Urticarial rash
- Cold/stress-triggered episodes
- Sensorineural hearing loss
- Chronic aseptic meningitis
- Skeletal abnormalities (epiphyseal overgrowth/frontal bossing)

^{*}Must have recurrent disease symptoms (≥ 6 months), elevated acute phase reactants (C-reactive protein [CRP]/serum amyloid A [SAA]) during at least one flare, and exclusion of confounding disease (i.e., infection, neoplasm, autoimmune condition, inborn errors of immunity).

CAPS is ideally managed by a multidisciplinary team with expertise in autoinflammatory disease. Patients should have access to genetic counseling, psychosocial support, hearing aids, orthotic aids, and physiotherapy. The mainstay of medical management is pharmacologic blockade of IL-1.

Three IL-1 blockers are currently used to treat CAPS: *anakinra*, *canakinumab*, and *rilonacept*. All are administered as subcutaneous injections. Anakinra is a recombinant IL-1 receptor antagonist; canakinumab is a human monoclonal antibody targeting IL-1 β and has a much longer half-life than anakinra; and rilonacept is a fusion protein consisting of the binding domains of the IL-1 receptor and its accessory protein linked to the Fc portion of human IgG1. All three drugs currently have US Food and Drug Administration (FDA) approval for use in CAPS, whereas only anakinra and canakinumab are approved by the European Medicines Agency (EMA).

Side effects associated with IL-1 blockers include injection-site reactions and increased risk of infection. Most injection-site reactions occur within the first 6 months of treatment and are generally mild and resolve over a period of weeks without requiring discontinuation of treatment. Headaches and arthralgia may also occur. Live vaccines are not recommended during IL-1 blockade.

The primary treatment target is complete remission, and the dosing of IL-1 blockers should be individually adjusted using a treat-to-target strategy. Anakinra is given at a starting dose of 1–2 mg/kg/day in adults and children but can be escalated based on phenotypic severity and clinical response. Doses as high as 5–8 mg/kg/day have been required in some children. Anakinra is currently FDA approved for patients of all ages with NOMID.

Canakinumab dosing is also weight-based but given every 8 weeks, starting at 150 mg (> 40 kg) or 2 mg/kg (15–40 kg); some patients require dose escalation up to 8 mg/kg every 8 weeks. Canakinumab is currently FDA approved for patients 4 years and older with MWS and FCAS.

Rilonacept is initiated with a loading dose of 320 mg (adults) or 4.4 mg/kg (children), followed by weekly injections of 160 mg (adults) or 2.2 mg/kg (children). It is FDA approved for patients 12 years and older with MWS and FCAS.

During symptomatic flares, short courses of non-steroidal anti-inflammatory drugs (NSAIDs) or oral corticosteroids may be used as adjunct therapy in association with IL-1 blockers. However, monotherapy with NSAIDs or oral corticosteroids is not recommended due to the potential disease-modifying effect of IL-1 blockers. Treatment with tocilizumab, a monoclonal antibody targeting the IL-6 receptor, has led to symptomatic improvement in isolated CAPS patients as monotherapy (initiated prior to CAPS diagnosis) or when used as adjunct therapy with IL-1 blockers. Evidence supporting the efficacy of tocilizumab for CAPS is currently lacking.

Specific Investigations

- Skin biopsy of urticarial rash will show characteristic scattered dermal neutrophilic infiltrate without vasculitis
- C-reactive protein (CRP) and serum amyloid A (SAA) to determine systemic inflammatory activity
- Genetic testing for *NLRP3* mutation to confirm diagnosis (mutation may not be apparent by Sanger sequencing in some patients due to mosaicism)
Autoinflammatory disease panels are available from multiple genetic testing labs

Monitoring

- Full physical examination, urine testing for proteinuria, audiogram, and ophthalmologic examination

In severe disease consider:

- Cognitive testing
- Radiologic imaging (brain, inner ear, skeletal)
- Lumbar puncture

Consensus proposal for taxonomy and definition of the autoinflammatory diseases (AIDs): a Delphi study. Ben-Chetrit, E, Gattorno M, Gul A, et al. *Ann Rheum Dis* 2018; 77: 1558–65.

Revision of autoinflammatory diseases nomenclature by an international expert committee after systematic literature review. The proposed name for CAPS is *NLRP3*-associated autoinflammatory disease.

Classification criteria for autoinflammatory recurrent fevers. Gattorno M, Hofer M, Federici S, et al. *Ann Rheum Dis* 2019; 78: 1025–32.

Consensus report of evidence-based criteria for classifying hereditary recurrent fever syndromes, including CAPS. Criteria were developed by an international consensus committee after systematic literature review, statistical analyses, and cross-sectional validation on 1018 patients randomly selected from the Eurofever Registry.

Consensus protocols for the diagnosis and management of the hereditary autoinflammatory syndromes CAPS, TRAPS, and MKD/HIDS: a German PRO-KIND initiative. Hansmann S, Lainka E, Horneff G, et al. *Pediatr Rheumatol* 2020; 18: 17.

Consensus evidence-based treat-to-target therapeutic guidelines for autoinflammatory diseases, including CAPS, developed by an expert committee.

Late-onset cryopyrin-associated periodic syndromes caused by somatic *NLRP3* mosaicism – UK single center experience. Rowczenio DM, Gomes SM, Aróstegui JI, et al. *Front Immunol* 2017; 8: 1410.

Retrospective cohort study of eight patients with CAPS onset at median age of 50 years, who were *NLRP3* mutation-negative by Sanger sequencing but found to have somatic *NLRP3* mutations by amplicon-based deep sequencing. All patients responded to anakinra therapy with improvement of end organ function in four patients.

First-Line Therapies

• Anakinra	B
• Canakinumab	A
• Rilonacept	A

Sustained response and prevention of damage progression in patients with neonatal-onset multisystem inflammatory disease treated with anakinra: a cohort study to determine 3- and 5-year outcomes. Sibley CH, Plass N, Snow J, et al. *Arthritis Rheum* 2012; 64: 2375–86.

Observational open-label study of 26 patients (22 children and 4 adults) with NOMID receiving anakinra over 3–5 years. Dose escalation was described in some patients. Damage progression in the eye, ear, and CNS was prevented, but bony lesions progressed.

Long-term safety profile of anakinra in patients with severe cryopyrin-associated periodic syndromes. Kullenberg T, Löfqvist M, Leinonen M, et al. *Rheumatology* 2016; 55: 1499–506.

Prospective open-label study of 43 patients (36 children, 7 adults) with severe CAPS treated for up to 5 years, in which 14 patients experienced 24 serious adverse events, such as pneumonia and gastroenteritis, all of which resolved during the study period and did not result in discontinuation of the drug. Continued anakinra treatment during infective episodes did not appear to complicate their course and prevented complications of CAPS.

Use of canakinumab in the cryopyrin-associated periodic syndrome. Lachmann HJ, Kone-Paut I, Kuemmerle-Deschner JB, et al. *N Engl J Med* 2009; 360: 2416–25.

Randomized, double-blind, placebo-controlled withdrawal study after an open run-in period demonstrated 34 of 35 patients aged 4–75 years with CAPS associated with an *NLRP3* mutation had complete response to treatment. Disease flares occurred in 13 of 16 patients receiving placebo, whereas all 15 patients who received canakinumab remained in remission during the withdrawal phase of the study.

Rapid and sustained long-term efficacy and safety of canakinumab in patients with cryopyrin-associated periodic syndrome ages five years and younger. Brogan PA, Hofer M, Kuemmerle-Deschner JB, et al. *Arthritis Rheumatol* 2019; 71: 1955–63.

Prospective open-label, extension study of 17 patients ages 5 years and younger (6 patients under 2 years) with all types of CAPS who received canakinumab for up to 152 weeks. A complete response was achieved in 94% of patients within 56 weeks and in 100% of the patients within 72 weeks. Dose titration was required in patients with more severe phenotypes. Severe adverse events, such as pneumonia and bronchitis, were experienced by 47% of patients during the extension study, none of which resulted in discontinuation of treatment.

Efficacy and safety of rilonacept (interleukin-1 trap) in patients with cryopyrin-associated periodic syndromes: results from two sequential placebo-controlled studies. Hoffman HM, Throne ML, Amar NJ, et al. *Arthritis Rheum* 2008; 58: 2443–52.

In the first study, 47 patients with *NLRP3* mutations and symptoms of CAPS underwent a 6-week trial of weekly 160-mg rilonacept injections versus placebo in a randomized, double-blinded trial. A second study followed, which consisted of 9 weeks of single-blind treatment plus a 9-week double-blind, randomized withdrawal. Of the patients who received rilonacept, 87% achieved at least 50% reduction in key symptom score versus 8% who received placebo.

Long-term efficacy and safety profile of rilonacept in the treatment of cryopyrin-associated periodic syndromes: results of a 72-week open-label extension study. Hoffman HM, Throne ML, Amar NJ, et al. Clin Ther 2012; 34: 2091–103.

A total of 101 patients were studied, including 44 of the 47 patients who were involved in the phase III studies described earlier. All had *NLRP3* gene mutations. The improvements seen after 6 weeks of treatment with rilonacept were sustained for up to 96 weeks after treatment, with persistence of biomarker normalization for up to 48 weeks after treatment.

Second-Line Therapies	
• NSAIDs	D
• Oral corticosteroids	D

Treatment of autoinflammatory diseases: results from the Eurofever Registry and a literature review. Ter Haar N, Lachmann H, Özen S, et al. Ann Rheum Dis 2013; 72: 678–85.

Analysis of 94 patients with CAPS on the Eurofever Registry found that NSAIDs and corticosteroids were beneficial in 19/24 and 25/36 patients already receiving IL-1 blockers. Four patients receiving NSAIDs alone showed partial response, and one was reported to have complete response. One patient had partial response to corticosteroids alone. Two patients had partial response to NSAIDs and corticosteroids.

Third-Line Therapy	
• Tocilizumab	E

The first case series of cryopyrin-associated periodic syndrome in Korea. Han JH, Je YJ, Yoon HJ, et al. Allergy Asthma Immunol Res 2019; 11: 583–8.

Case series of three Korean patients with CAPS. Tocilizumab monotherapy, initiated prior to genetic testing, led to symptomatic improvement and CRP normalization in a 4-year-old male.

Cryptococcosis

Wanda S. Robles, Mahreen Ameen

Cryptococcosis is a systemic mycosis acquired most commonly by the respiratory route with the primary focus of infection in the lungs. It is caused by yeasts associated with avian excreta of which there are two species: *Cryptococcus neoformans* and *Cryptococcus gattii*. These two species can further be classified into three varieties and five serotypes. *C. neoformans* is classified into serotype A and D and the hybrid strain AD. *C. gattii* is classified into serotype B and C. It was considered that *C. neoformans* was distributed worldwide, whereas *C. gattii* was restricted to tropical and subtropical areas. More recently it has been recognized that the latter has been responsible for outbreaks in new geographical environments including temperate climates. In the past it was a relatively uncommon disease. However, it has become more common over the past decades with the increase of the immunocompromised population, though it may also affect the immunocompetent host. Susceptible individuals include HIV/AIDS patients, organ transplant recipients, cancer patients, and other immunosuppressed patients for other conditions, including those on biologic interventions. Pulmonary and central nervous system infections are by far the most common. Pulmonary disease can be asymptomatic and self-limiting. Hematogenous dissemination is responsible for involvement of other organs including the central nervous system, causing meningitis. Skin lesions are seen in 10%–15% of cases and produce a variety of them, including flesh-colored or erythematous papules and nodules as well as subcutaneous abscesses. In the immunocompromised, molluscum contagiosum-like and acneiform lesions occur, particularly on the face. Cryptococcal cellulitis with necrotizing vasculitis can mimic bacterial cellulitis and is more common in the immunocompromised patient.

With the global emergence of AIDS the incidence of cryptococcosis increased and it is considered the most common invasive mycosis in advanced HIV infection. In this cohort of patients, the infection is characteristically widespread, affecting the lungs, meninges, skin, bone marrow, and genitourinary tract, including the prostate. Certainly, the use of highly active antiretroviral therapy (HAART) has dramatically improved the outcome of cryptococcosis in HIV-infected patients. Immune restoration and low serum cryptococcal antigen titers are associated with lower cryptococcosis relapse rates. However, a subset of HIV-infected

individuals started on HAART is at risk of immune reconstitution inflammatory syndrome (IRIS)-associated cryptococcosis that can be severe. In developing countries with limited access to HAART, the morbidity and mortality associated with cryptococcosis remains very high. Both *C. neoformans* and *C. gattii* can cause cryptococcosis in the immunocompetent host. However, the percentage of *C. gattii* infections is significantly higher in this population than *C. neoformans*. Other predisposing factors in addition to HIV/AIDS infection include malignancies, autoimmune diseases, biologic therapies, use of systemic steroids and/or immunosuppressive therapies, solid organ transplantation recipients, chronic pulmonary or liver disease, diabetes mellitus, renal failure, and/or peritoneal dialysis.

MANAGEMENT STRATEGY

Cryptococcal infection left untreated is fatal. Treatment depends on disease extent and predisposing factors, particularly AIDS or any other immunosuppressive state. The recommended treatment in the immunocompetent individual with symptomatic non-meningeal infection is fluconazole 200–400 mg daily for 3–6 months. An alternative is itraconazole 200–400 mg daily for 6–12 months. More severe non-meningeal infection is treated with amphotericin B (AmB), either lipid formulation or deoxycholate, for 6–10 weeks. Meningeal infection in the immunocompetent or non-HIV immunocompromised is treated with AmB 0.7–1.0 mg/kg daily plus 5-flucytosine (5-FC) 100 mg/kg daily for 2 weeks followed by fluconazole 400 mg daily for a minimum of 10 weeks (up to 6–12 months depending on the clinical status of the patient).

Cryptococcal disease with HIV always requires treatment. For non-disseminated infection, fluconazole 400 mg daily is given. Itraconazole 20–400 mg daily, voriconazole 200–400 or posaconazole 400–800 mg daily are good alternatives in the immunocompetent. More severe infection is treated with a combination of fluconazole 400 mg daily and 5-FC 100–150 mg/kg daily for 10 weeks followed by fluconazole maintenance therapy 200 mg daily. Cryptococcal meningitis with HIV is treated with AmB 0.7–1.0 mg/kg daily and 5-FC 100 mg/kg daily for a 2- to 10-week induction period followed by itraconazole maintenance therapy or alternatively with fluconazole 400–800 mg daily and 5-FC 100–150 mg/kg daily for 6 weeks. The lipid formulation of AmB can be used instead in those with impaired renal function.

Dexamethasone as adjunctive therapy did not reduce mortality in HIV-associated cryptococcal meningitis.

Specific Investigations

- Direct microscopy
- Culture
- Cytology and histopathology
- Serology
- Pulmonary and brain imaging studies
- Serology for HIV

India ink examination of cerebrospinal fluid (CSF), pus, skin scrapings, and other fluids may demonstrate the yeast. Culture of skin, CSF, blood, sputum, urine, or bone marrow enables confirmation. *C. neoformans* is difficult to visualize with routine hematoxylin and eosin stains, requiring the use of special stains. Histopathological staining of centrifuged CSF sediment allows a sensitive and rapid diagnosis of cryptococcal meningitis. The gold standard diagnostic test for serological diagnosis of cryptococcosis is the detection of cryptococcal capsular polysaccharide

antigen in serum or body fluids by a latex agglutination technique. It is considered both sensitive and specific. The detection of cryptococcal antibodies has not been adopted for the diagnosis of cryptococcosis.

Clinical practice guidelines for the management of cryptococcal disease: 2010 update by the Infectious Diseases Society of America. Perfect JR, Dismukes WE, Dromer F, et al. Clin Infect Dis 2010; 50: 291–322.

These are the latest updated guidelines available. They emphasize that control of host immunity, the site of infection, antifungal drug toxicity, and underlying disease are still the most critical factors for the successful treatment of cryptococcosis. The management strategy for cryptococcal disease is organized under four major headings with additional subdivisions: treatment of meningoencephalitis (in HIV-infected individuals, transplant recipients, and others); treatment of non-meningeal cryptococcosis (pulmonary and extrapulmonary sites); complications during treatment (including IRIS and relapse); and cryptococcosis in special clinical situations (pregnancy, children, resource-limited regions, and *C. gattii* infections).

The recommended treatment for immunosuppressed and immunocompetent patients with mild-to-moderate non-meningeal cryptococcosis is fluconazole 400 mg daily for 6–12 months. The treatment of choice for patients with HIV infection and cryptococcal meningitis is induction therapy with parenteral AmB 0.7–1.0 mg/kg daily plus oral flucytosine 100 mg/kg daily for 2 weeks followed by fluconazole 400 mg daily for a minimum period of 8 weeks. Amphotericin B in lipid formulation can be used for patients with renal impairment. It is recommended that all HIV-infected individuals receive prophylaxis against cryptococcosis and that this is continued for life. Fluconazole 200 mg daily is given or itraconazole 200 mg twice daily in those unable to tolerate fluconazole.

First-Line Therapies

• Amphotericin B (AmB)	B
• AmB plus 5-flucytosine	B
• Fluconazole	B

Combination antifungal therapies for HIV-associated cryptococcal meningitis: a randomized trial. Brouwer AE, Rajanuwong A, Chierakul W, et al. Lancet 2004; 363: 1764–7.

This controlled trial assessed the fungicidal activity of the combination of AmB, 5-FC, and fluconazole for the treatment of cryptococcal meningitis. Sixty-four patients with a first episode of HIV-associated cryptococcal meningitis were randomized to initial treatment with AmB (0.7 mg/kg daily); AmB plus 5-FC (100 mg/kg daily); AmB plus fluconazole (400 mg daily); or triple therapy with AmB, flucytosine, and fluconazole. Results demonstrated that clearance of cryptococci from the CSF was exponential and significantly faster with AmB and flucytosine dual therapy than with any other drug combination.

Successful use of amphotericin B lipid complex in the treatment of cryptococcosis. Baddour LM, Perfect JR, Ostrosky-Zeichner L. Clin Infect Dis 2005; 40: S409–13.

The efficacy and renal safety of AmB lipid complex (ABLC) were assessed in 106 patients, 83 (78%) of whom had CNS infection. Twenty-seven received concomitant azole therapy. Sixty-six percent of evaluable patients (67/101) achieved clinical response (cured or improved). Response rates with and without

CNS infection were 65% (51/78) and 70% (16/23), respectively, and for patients with HIV infection it was 58% (30/52). A mean serum creatinine level decrease of 0.02 mg/dL occurred. ABLC was an effective treatment for cryptococcal infection in immunocompromised patients.

Treatment of cryptococcosis in the setting of HIV coinfection. Khawcharoenporn T, Apisarnthanarak A, Mundy LM. Expert Rev Anti Infect Ther 2007; 5: 1019–30.

This review discusses evidence-based treatment algorithms that exist for the use of antifungal drugs, as well as the importance of maintaining normal intracranial pressure in HIV-infected hosts with cryptococcal meningitis. It suggests that further studies are required for the management of refractory infection, cryptococcosis-related immune reconstitution syndrome, and the role of adjuvant therapies. Primary and secondary prevention strategies remain at the crux of global control strategies for cryptococcal disease.

High-dose amphotericin B with flucytosine for the treatment of cryptococcal meningitis in HIV-infected patients: a randomized trial. Bicanic T, Wood R, Meintjes G, et al. Clin Infect Dis 2008; 47: 123–30.

In this study from South Africa, 64 HIV-seropositive, antiretroviral therapy-naïve patients with a first episode of cryptococcal meningitis were randomized to receive either AmB 0.7 mg/kg/day plus flucytosine 25 mg/kg four times daily ($n=30$) or AmB 1 mg/kg daily plus flucytosine 25 mg/kg four times daily ($n=34$). Both regimens were given for 2 weeks followed by oral fluconazole. The primary outcome measure was early fungicidal activity determined by CSF cryptococcal cultures. Early fungicidal activity was significantly greater for the first regimen. The 10-week mortality rate was 24% with no difference between groups.

Cutaneous cryptococcosis in solid organ transplant recipients. Sun HY, Alexander BD, Lortholary O, et al. Med Mycology 2010; 48: 785–91.

Fluconazole and lipid formulation AmB were used to treat localized and disseminated disease, respectively. The outcomes in both groups were comparable.

This study described cutaneous cryptococcosis representing disseminated infection in transplant recipients with preferential involvement of the extremities.

Cryptococcosis. Marziarz EK, Perfect JR. Diag Treat Fungal Inf 2015:175–93.

A highly comprehensive review of cryptococcosis that highlights the fact that infection may occur in the immunocompetent host as well the immunocompromised, a population that is expanding and will continue to expand with availability of new therapies with direct impact on the immune system. Therefore, they argue that cryptococcosis will remain a very important opportunistic fungal infection, particularly of the immunocompromised population.

Cryptococcal infections in non-HIV-infected patients. Pappas PG. Trans Am Clin Climatol Assoc 2013; 124: 61–79.

This is a very good review that stresses the differences in the epidemiology, clinical features, treatment, and outcome between HIV-infected patients (knowledge acquired over the last 3 decades) and non-HIV-infected hosts with cryptococcosis. It includes a review of an outbreak of *C. gattii* reported in the Pacific Northwest of the USA and Canada affecting mainly immunocompetent individuals.

Cryptococcosis. Zavala S, Baddley JW. *Semin Respir Crit Care Med* 2020; 41: 69–79.

This comprehensive review article highlights the importance of early diagnosis as it is now well recognized that cryptococcal infection occurs not only in the immunocompromised, but also in the immunocompetent host. It also reviews the mainstay of treatment, which continues to be amphotericin B preparations plus 5-flucytosine for cryptococcal meningitis, moderate-to-severe lung disease, and disseminated infection, followed by fluconazole as consolidation therapy.

Integrated therapy for HIV and cryptococcosis. Srichatrapimuk S, Sungkanuparph S. *AIDS Res Ther* 2016; 13: 42.

This study highlights the three aspects of treatment of cryptococcosis aiming to decrease mortality caused by the disease in HIV-infected patients. These include antifungal therapy, management of intracranial pressure in cryptococcal meningitis, and antiretroviral therapy to restore immune function. In terms of antifungal treatment, it advocates the use of a combination of two drugs, either amphotericin B plus flucytosine or fluconazole for the induction phase, and fluconazole monotherapy for consolidation and maintenance phases. It also stresses the importance of delaying the start of antiretroviral therapy until 5 weeks after starting antifungal drugs in HIV patients with cryptococcal meningitis and the safety of the combination of the two treatments, as drug interactions between antiretroviral drugs and AmB, flucytosine, and fluconazole are minimal.

Second-Line Therapies

- Itraconazole **C**
- Voriconazole **C**

The efficacy of fluconazole 600mg/day versus itraconazole 600mg/day as consolidation. Mootsikapun P, Chetchotisakd P, Anunnatsiri S, et al. *J Med Assoc Thai* 2003; 86: 293–8.

In this trial, HIV-infected patients with primary cryptococcal meningitis who had been treated with AmB preparations for 2 weeks were randomized to receive either fluconazole 600mg daily or itraconazole 600mg daily for 10 weeks. The results demonstrated equal efficacy of both regimens. In addition, the results suggested that the higher dose regimen may be superior to treatment regimens using lower doses of these medications.

Voriconazole treatment for less-common, emerging, or refractory fungal infections. Perfect JR, Marr KA, Walsh TJ, et al. *Clin Infect Dis* 2003; 36: 1122–31.

A multicenter, controlled clinical trial to assess the efficacy, tolerability, and safety of voriconazole as salvage treatment for patients with refractory and intolerant-to-treatment fungal infections, as well as primary treatment for patients with infections for which there is no approved treatment. The efficacy rate for voriconazole in the treatment of cryptococcosis was 38.9%. Voriconazole was reported to be well tolerated, and discontinuation of treatment was observed in less than 10% of patients.

Third-Line Therapies

- Dexamethasone **A**
- Recombinant interferon-gamma 1b **A**

Adjunctive dexamethasone in HIV-associated cryptococcal meningitis. Beardsley J, Wolbers M, Kibengo FM, et al. *N Engl J Med* 2016; 374: 542–54.

A double-blind, randomized, placebo-controlled trial. This trial was stopped for safety reasons and after enrollment of 451 patients. Mortality was reported as 47% in the dexamethasone group and 41% in the placebo group by 10 weeks. The study concluded that dexamethasone did not reduce mortality among patients with HIV-associated cryptococcal meningitis. It was indeed associated with more adverse events and disability than placebo.

Recombinant interferon-gamma 1b as adjunctive therapy for AIDS-related acute cryptococcal meningitis. Pappas PG, Bustamante B, Ticona E, et al. *J Infect Dis* 2004; 189: 2185–91.

This was a phase II, double-blind, placebo-controlled study to evaluate the safety and antifungal activity of adjuvant recombinant interferon (rIFN)-gamma (γ) 1b in patients with AIDS and acute cryptococcal meningitis. Patients received 100 or 200 mcg of rIFN-γ 1b or placebo thrice daily for 10 weeks, plus standard therapy with AmB, with or without flucytosine, followed by fluconazole. Among 75 patients, 2-week culture conversion occurred in 13% of placebo recipients, 36% of rIFN-γ 1b (100 mcg) recipients, and 32% of rIFN-γ (200 mcg) recipients. There was evidence of improved combined mycologic and clinical success in rIFN-γ 1b recipients (26% vs. 8%; $p = 0.078$), and therapy was well tolerated.

Cutaneous candidiasis and chronic mucocutaneous candidiasis

Caroline Halverstam, Steven R. Cohen

CUTANEOUS CANDIDIASIS

Cutaneous candidiasis is typically caused by *Candida albicans*, which exists as normal flora of human skin as well as in the gastrointestinal and genitourinary systems. Overgrowth of *Candida* species is suppressed by normal bacterial flora. Other *Candida* species occasionally cause mucocutaneous infections, the second most common being *Candida tropicalis*. Under certain conditions, these *Candida* species overgrow and become pathogens. Warmth and moisture of the intertriginous skin (axilla, inguinal folds, abdominal creases, inframammary creases, finger or toe webs), an increased skin pH, and the administration of antibiotics can disrupt the normal bacterial flora, allowing *Candida* to proliferate. Clinically, candidiasis presents as scaly, erythematous patches with satellite papules and pustules. The diagnosis is made either microscopically, with a potassium hydroxide (KOH) preparation revealing spores and pseudohyphae, or by culture.

MANAGEMENT STRATEGY

Topical antifungal agents include, but are not limited to, polyenes, azoles, allylamines, and ciclopirox olamines. Most studies

required therapy twice daily for 4 weeks to ensure complete clearance in all patients. Notably, microscopic cure was often present before complete clinical clearance.

Topical corticosteroids are a source of controversy. Although the addition of corticosteroids to local antifungal therapy may reduce local inflammation in acute candidiasis, their use should be limited because of their immunosuppressant properties.

Systemic therapy may be appropriate for cutaneous infections in immunosuppressed patients, in the setting of extensive disease not responding to topical therapy, or in patients who are non-adherent to topical therapy. Fluconazole 150mg weekly appears to be as efficacious as fluconazole 50mg daily. As in topical therapy, microscopic cure often precedes complete clinical clearance. Since 2013, the Food and Drug Administration (FDA) has removed the indication for oral ketoconazole to be used in *Candida* and dermatophyte infections due to the risk of severe hepatotoxicity and adrenal insufficiency.

Specific Investigations

- KOH
- Culture

First-Line Therapies

• Topical antifungal	A
• Topical antifungal combined with topical corticosteroids	A

The efficacy and safety of sertaconazole cream in diaper dermatitis. Bonifaz A, Tiredo-Sánchez A, Graniel MJ, et al. Mycopathologia 2013; 175: 249–54.

Twenty-seven patients with a clinical and mycologic diagnosis of *Candida* diaper dermatitis were treated twice daily for 2 weeks with sertaconazole. Eighty-nine percent of patients showed a clinical and mycologic cure by the end of 4 weeks (2 weeks after treatment ended).

A multicenter, open-label study to assess the safety and efficacy of ciclopirox topical suspension 0.77% in the treatment of diaper dermatitis due to *Candida albicans*. Gallup E, Plott T. J Drugs Dermatol 2005; 4: 29–34.

A multicenter, open-label study that included 44 male and female subjects aged 6–29 months with diaper dermatitis due to *C. albicans*. The study medication was applied topically to the affected area twice daily for 1 week. The results showed a statistically significant improvement in both the rate of mycologic cure and the reduction of severity score.

Naftifine cream in the treatment of cutaneous candidiasis. Zaia N, Astorga E, Cordero CN, et al. Cutis 1988; 42: 238–40.

In a double-blind, parallel-group clinical trial, 60 patients with cutaneous candidiasis were randomly assigned to receive naftifine cream 1% or its vehicle twice a day for 3 weeks. Two weeks after the end of therapy, 77% of the naftifine-treated patients were mycologically cured (negative results on KOH preparations and culture) and had no clinically apparent disease, compared with only 3% of patients treated with vehicle alone.

A comparison of nystatin cream with nystatin/triamcinolone acetone combination cream in the treatment of candidal inflammation of the flexures. Beveridge GW, Fairburn E, Finn OA, et al. Curr Med Res Opin 1977; 4: 584–7.

In a multicenter, double-blind trial, 31 patients with bilateral candidal lesions of the flexures were treated for 14 days with nystatin cream on one side and with a combination of nystatin and triamcinolone acetonide cream on the other side. Both treatments proved equally effective in terms of mycologic cure rate and clinical improvement. There was a weak trend by both patients and physicians to favor the combination preparation because symptoms resolved more rapidly.

Second-Line Therapy

- Systemic azoles

B

Prospective aetiological study of diaper dermatitis in the elderly. Foureur N, Vanzo B, Meaume S, et al. *Br J Dermatol* 2006; 155: 941–6.

Of 46 patients, all over 85 years of age with dermatitis of the diaper area, 24 were identified as candidiasis. Of these, eight (33%) were cured after 1 month of topical bifonazole therapy, three (12.5%) improved, and 13 (54%) were cured after the addition of oral fluconazole 100 mg once daily for 1 month. Although topical antifungal drugs represent the first line of treatment for diaper dermatitis in the elderly, more than half the patients in this study required an oral antifungal to achieve a complete cure.

A comparison of the efficacy of oral fluconazole, 150 mg/week versus 50 mg/day, in the treatment of tinea corporis, tinea cruris, tinea pedis, and cutaneous candidosis. Nozickova M, Koudelkova V, Kulikova Z, et al. *Int J Dermatol* 1998; 37: 703–5.

Patients received either fluconazole 150 mg/week or 50 mg/day until clinically cured or for a maximum of 4 weeks. Of the patients in this study with candidiasis, 10 of 11 patients receiving fluconazole 150 mg weekly had a positive response (microscopic cure with marked clinical improvement) and 12 of 13 taking fluconazole 50 mg daily had a positive response. Thus weekly treatment was determined to be equivalent to daily dosing.

Clinical trials and double-blind studies of oral antifungals for cutaneous candidiasis are sparse.

Third-Line Therapies

- Lavender oil
- Topical mupirocin

E

C

Antifungal activity of *Lavandula angustifolia* essential oil against *Candida albicans* yeast and mycelial form. D'Auria FD, Tecca M, Strippoli V, et al. *Med Mycol* 2005; 43: 391–6.

The antifungal activity of the essential oil of *Lavandula angustifolia* (lavender oil) and its main components, linalool and linalyl acetate, was studied. Lavender oil showed both fungistatic and fungicidal activity against *C. albicans* strains.

Perianal candidosis: a comparative study with mupirocin and nystatin. De Wet PM, Rode H, Van Dyk A, et al. *Int J Dermatol* 1999; 38: 618–22.

This clinical trial compared the efficacy and clinical outcome of 2% mupirocin in a polyethylene glycol base and nystatin cream for the treatment of diaper candidiasis. Eradication of all *Candida* organisms was achieved within 2–6 days (mean 2.6 days) in 10 patients receiving topical mupirocin therapy (three to four times

daily or with each diaper change). The 10 patients who received topical nystatin cream successfully cleared within 5 days (mean 2.8 days). Although both agents eradicated *Candida*, a major difference was the marked response of the diaper dermatitis to mupirocin, presumably due to its well-documented bactericidal effects. The authors conclude that mupirocin is an excellent antifungal agent and a superior therapy for diaper dermatitis because of its polymicrobial toxicity.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis (CMC) is a heterogeneous group of disorders with progressive and recurrent infections of the skin, nails, and mucosal surfaces caused by *C. albicans*. The clinical presentation in patients with CMC can range from recurrent or recalcitrant thrush with a mild rash and dystrophic nails to severe, generalized, crusted plaques. It usually presents in childhood unless it is caused by an underlying disorder such as human immunodeficiency virus (HIV) or diabetes mellitus.

About half of those affected are identified as having autoimmune polyendocrinopathy, candidiasis, and ectodermal dysplasia (APECED), an autosomal recessive disorder. APECED is caused by mutations in the *AIRE* gene, which plays a key role in immunotolerance. It is characterized by multiorgan autoimmunity, including hypoparathyroidism, hypothyroidism, and adrenal or gonadal failure. Malabsorption, gastric cell atrophy, or autoimmune hepatitis occurs in about a third of patients. Alopecia, vitiligo, dental enamel dysplasia, and keratitis are frequent associations. *Candida* susceptibility in APECED is most likely due to autoantibodies directed against IL-17 and IL-22.

Autosomal dominant CMC has been associated with mutations in the *STAT1* gene that lead to defective Th1 and Th17 responses. Thymoma has been also associated with rare cases of IL-17 and IL-22 autoantibody-positive CMC.

MANAGEMENT STRATEGY

Once the symptom complex etiology is confirmed with a positive culture for *C. albicans*, a workup should test for immunodeficiency. Patients should also be tested for endocrine dysfunction characteristic of APECED. If clinical suspicion for APECED is high, genetic analysis for the *AIRE* gene can be performed. An association of CMC with abnormalities in iron metabolism or thymoma has also been reported in adult patients, so iron and radiologic studies may be warranted in HIV-negative patients with adult-onset CMC.

Treatment usually begins with an oral azole, most commonly fluconazole 100–200 mg/day. Intermittent use is sometimes advocated to prevent resistance. However, resistance in CMC patients to first-line drugs is frequent, and alternative options include second-generation azoles such as voriconazole and posaconazole, as well as echinocandins such as caspofungin and micafungin. Oral ketoconazole should be avoided because of the risk of hepatotoxicity and adrenal insufficiency. Amphotericin B can be administered orally with variable response but minimal side effects. Due to toxicity, intravenous amphotericin B should generally be limited to short treatment courses with a transition to alternative therapies. Relapse after withdrawal of these agents is the rule because the inherent immune defect remains.

There have been anecdotal reports of patients improving with Janus kinase (JAK) inhibitors (both reports have been in patients with *STAT1* mutations) and cimetidine in combination with zinc.

Specific Investigations

- Complete blood count with differential
- HIV-antibody test
- Thyroid-stimulating hormone
- Fasting blood glucose
- Plasma cortisol level
- Parathyroid hormone
- Serum calcium
- Serum iron and ferritin
- Chest X-ray or computed tomography (CT) scan if thymoma suspected
- Genetic testing for *AIRE* gene if suspicion of APECED

Chronic mucocutaneous candidiasis in APECED or thymoma patients correlates with autoimmunity to Th17-associated cytokines. Kisand K, Boe Wolff AS, et al. *J Exp Med* 2010; 207: 299–308.

Patients with APECED were found to have severely reduced IL-17F and IL-22 responses to *C. albicans* antigens.

STAT1 mutations in autosomal dominant chronic mucocutaneous candidiasis. van der Veerdonk FL, Plantinga TS, Hoischen A, et al. *N Engl J Med* 2011; 365: 54–61.

DNA sequencing identified missense mutations in *STAT1*.

First-Line Therapy

- Systemic azole antimycotics **D**

Fluconazole in the management of patients with chronic mucocutaneous candidiasis. Hay RJ, Clayton YM. *Br J Dermatol* 1988; 119: 683–4.

Eight patients with CMC (five idiopathic cases, three APECED cases) and oral candidiasis were treated with 50 mg of fluconazole daily for up to 4 weeks. Clinical and mycologic remissions were achieved in all patients after a mean of 10 days. Three patients relapsed within 4 months (mean 56 days), but all responded to fluconazole 50 mg daily for 3 days. The authors suggest intermittent oral antifungal therapy as the most appropriate method to manage patients with oral candidiasis in CMC after induction of remission.

Itraconazole in the treatment of two young brothers with chronic mucocutaneous candidiasis. Tosti A, Piraccini BM, Vincenzi C. *Pediatr Dermatol* 1997; 14: 146–8.

Two children with CMC involving the mouth and nails were successfully treated with itraconazole 200 mg/day for 2 months. A rapid cure rate of both infections was observed. No relapses of oral or nail candidiasis were identified at a follow-up examination more than a year later. The drug was very well tolerated.

Voriconazole: a broad spectrum triazole for the treatment of serious and invasive fungal infections. Maschmeyer G, Haas A. *Future Microbiol* 2006; 1: 365–85.

This is an excellent review of voriconazole (a second-generation triazole) for treating life-threatening fungal infections. Voriconazole can be given intravenously (6 mg/kg every 12 hours for two doses and then 4 mg/kg every 12 hours for maintenance dosing) or orally (200 mg every 12 hours for individuals over 40 kg and 100 mg every 12 hours for individuals less than 40 kg). It is

effective for fluconazole-susceptible and fluconazole-resistant candidiasis.

Although transient visual disturbances, liver enzyme abnormalities, skin cancers, and skin rashes are reported, these rarely lead to discontinuation of treatment.

Successful treatment of chronic mucocutaneous candidiasis caused by azole-resistant *Candida albicans* with posaconazole. Firinu D, Massidda O, Lorrain MM, et al. *Clin Dev Immunol* 2011; 4: Article ID 283239.

A 39-year-old female patient with familial CMC who developed candidiasis that was resistant to multiple antifungal drugs was successfully treated with amphotericin B 50 mg/day intravenously for 2 weeks followed by posaconazole 400 mg twice daily. After 2 months, the dose was reduced to 200 mg/day without a relapse. When posaconazole was discontinued, oral candidiasis recurred after 2 weeks. Thereafter, the patient was maintained successfully on cycles of posaconazole 200 mg, three times per day, for a month alternating with 15 days off-drug.

Second-Line Therapies

• Echinocandins	E
• Oral amphotericin B	D
• Intravenous amphotericin B	E

Activity of amphotericin B, anidulafungin, caspofungin, micafungin, posaconazole, and voriconazole against *Candida albicans* with decreased susceptibility to fluconazole from APECED patients on long-term azole treatment of chronic mucocutaneous candidiasis. Rautemaa R, Richardson M, Pfaller MA, et al. *Diagn Microbiol Infect Dis* 2008; 62: 182–5.

A total of 43 isolates of *C. albicans* were taken from 23 patients with APECED and tested for resistance to various antifungals. Isolates were divided into two groups: fluconazole-susceptible dose-dependent and fluconazole-susceptible groups. All isolates were highly susceptible to amphotericin B and echinocandins. Posaconazole and voriconazole were active against all isolates, but more active in the fluconazole-susceptible group, suggesting a possibility that patients may develop some cross-resistance to these drugs when they take fluconazole.

Successful treatment of azole-resistant chronic mucocutaneous candidiasis with caspofungin. Jayasinghe M, Schmidt S, Walker B, et al. *Acta Derm Venereol* 2006; 86: 563–4.

An 18-year-old woman with CMC developed severe symptoms from an azole-resistant strain of *C. albicans* after 3 years of treatment with fluconazole. After a 70-mg loading dose of intravenous caspofungin on the first day, the regimen was adjusted to 50-mg infusions four to seven times per week for almost 12 months. Clinical improvement of oral and cutaneous candidiasis was sustained during a follow-up period of 12 months. The treatment was well tolerated; the only side effect was a temporary elevation of hepatic enzyme levels that did not necessitate discontinuation of therapy.

Prolonged oral treatment of chronic mucocutaneous candidiasis with amphotericin B. Montes LF, Cooper MD, Bradford LG, et al. *Arch Dermatol* 1971; 104: 45–56.

Amphotericin B was given orally to four patients with CMC in doses of 1000–1800 mg/day. One patient had complete clearance of extensive candidal granulomas after 6 months of treatment; one patient had a slower but excellent response. Two other

patients had minimal or no response; of these, one was hypothyroid and the other had a thymoma. Of note, the serum levels were significantly higher in the first two patients than in the latter two. In all four patients the oral amphotericin B was free of side effects both clinically and in laboratory studies.

Chronic mucocutaneous candidiasis treated with amphotericin B. Case report. Waweru HW, Owili DM. *East Afr Med J* 1983; 60: 588–91.

A 5-year-old girl with CMC was treated with intravenous amphotericin B at a dose of 1 mg/kg every other day for a cumulative dose of 200 mg. The crusts and plaques completely cleared, but with residual atrophy, hypopigmentation, and scarring alopecia. She remained free of recurrence for 2 years.

Third-Line Therapies	
• JAK 1/2 inhibitors	C
• Cimetidine and zinc sulfate	E

Use of ruxolitinib to successfully treat chronic mucocutaneous candidiasis caused by gain-of-function signal transducer and activator of transcription 1 (STAT1) mutation. Higgins E, Al Shehri T, McAleer MA, et al. *J Allergy Clin Immunol* 2015; 135: 551–3.

A 28-year-old woman with CMC associated with a *STAT1* mutation had a 2-year history of severe alopecia areata and was treated with ruxolitinib. In addition to hair regrowth, the patient experienced resolution of oral candidiasis. It recurred within 2 weeks of discontinuing ruxolitinib, despite concomitant oral fluconazole.

Case report: successful treatment with cimetidine and zinc sulphate in chronic mucocutaneous candidiasis. Polizzi B, Origgi L, Zuccaro G, et al. *Am J Med Sci* 1996; 311: 189–90.

The clinical efficacy of high-dose cimetidine, 400 mg three times daily, and zinc sulfate, 200 mg daily (subsequently adjusted to maintain blood zinc levels at the upper normal range), was evaluated in a patient with CMC for 16 months. An impressive reduction in infectious events was correlated with an increased CD4 (helper/inducer) cell count.

Cutaneous larva migrans

Huda Al-Kutubi, Anthony Abdullah

Hookworm-related cutaneous larva migrans (Hr-CLM) is a disease caused by percutaneous penetration and migration of animal hookworm larvae in the human skin, most commonly *Ancylostoma braziliense*, *Ancylostoma caninum*, *Uncinaria stenocephala*, and *Bunostomum phlebotomum*. People at risk are the inhabitants and returning travelers from tropical/subtropical countries and children playing in sandpits. The incubation period can vary between a few days and 7 months after exposure to contaminated soil or sand. The clinical picture is that of a characteristic 'creeping eruption' with serpiginous, papular, vesicobullous, and erythematous lesions due to the presence of moving parasites. The common sites involved are the feet, buttocks, and thighs. Rare complications include pulmonary eosinophilic infiltrates, hookworm folliculitis, and oral mucosal lesions.

MANAGEMENT STRATEGY

Hr-CLM is self-limiting: most lesions resolve within 2–8 weeks because the human is a 'dead-end host.' However, the lesions can be extremely pruritic and extensive, significantly reducing quality of life, thus necessitating treatment.

The systemic treatment normally used by the authors for patients over the age of 2 years is oral *albendazole* 400 mg daily for 3 days. An alternative is *ivermectin* given as a single dose of 12 mg orally (or 200 mcg/kg) for adults and children older than 5 years or more than 15 kg in weight. Topical treatment usually takes the form of *thiabendazole* in a suitable lipophilic vehicle.

Specific Investigations

Clinical appearance is characteristic. Peripheral eosinophilia and raised serum IgE may be seen.

First-Line Therapies

• Systemic albendazole	B
• Systemic ivermectin	B

One-week therapy with oral albendazole in hookworm-related cutaneous larva migrans: a retrospective study on 78 patients. Veraldi S, Bottini S, Rizzitelli G, et al. *J Dermatolog Treat* 2012; 23: 189–91.

Seventy-eight patients with multiple and/or extensive lesions of Hr-CLM were treated with albendazole 400 mg/day for 1 week. Cure rate was 100% at 3-months' follow-up. The disappearance of pruritus was reported after 2–3 days and skin lesions after 5–7 days of therapy. The authors concluded the regime was very effective with no severe side effects reported.

Management of imported cutaneous larva migrans: a case series and mini review. Kincaid L, Klowak M, Klowak S, et al. *Travel Med Infect Dis* 2015; 13(5): 382–7.

Twenty-five patients were identified, 16 of whom had localized lesions to the feet. Twenty-three responded appropriately to a 3-day course of 400 mg albendazole. Two patients required a repeat course of treatment.

A randomized trial of ivermectin versus albendazole for the treatment of cutaneous larva migrans. Caumes E, Carriere J, Datry A, et al. *Am J Trop Med Hyg* 1993; 49: 641–4.

A comparison of efficacy between oral ivermectin (12 mg) and oral albendazole (400 mg). Twenty-one patients were randomly assigned to receive ivermectin ($n=10$) or albendazole ($n=11$). All patients who received ivermectin responded and none relapsed (cure rate 100%). All except one patient in the group receiving albendazole responded, but five relapsed after a mean of 11 days (cure rate 46%; p ts} = ts}0.017). No major adverse effects were observed. The authors suggest that a single dose of ivermectin is more effective than a single dose of albendazole.

Hookworm-related cutaneous larva migrans in Northern Brazil: resolution of clinical pathology after a single dose of ivermectin. Schuster A, Lesshaft H, Reichert F, et al. *Clin Infect Dis* 2013; 57: 1155–7.

Ninety-two patients, median age 9.5 years, were treated with a single dose of 200 mcg/kg ivermectin. Two weeks after treatment there was a significant reduction in complex tracts, and at 4 weeks all complex tracts had disappeared with marked symptomatic improvement.

The efficacy of single dose ivermectin in the treatment of hookworm related cutaneous larva migrans varies depending on the clinical presentation. Vanhaecke C, Perignon A, Monsel G, et al. *J Eur Acad Dermatol Venereol* 2014; 28: 655–7.

Sixty-two travelers with Hr-CLM and creeping dermatitis were treated with a single dose of ivermectin (200 mcg/kg). Six patients (10%) also had associated hookworm folliculitis. The authors concluded that efficacy of a single dose of oral ivermectin is higher in patients with only creeping dermatitis than in those with associated hookworm folliculitis ($p=0.02$).

Treatment of 18 children with scabies or cutaneous larva migrans using ivermectin. Del Mar Saéz-De-Ocariz M, McKinster CD, Orozco-Covarrubias L, et al. Clin Exp Dermatol 2002; 27: 264–7.

A report of 18 children aged 14 months to 17 years, of whom seven had Hr-CLM. All seven were cured with a single dose of 150–200 mcg/kg ivermectin, with no significant adverse effects. In the authors' experience, ivermectin is a safe and effective alternative treatment for cutaneous parasitosis in children.

Second-Line Therapies

• Topical thiabendazole in a lipophilic vehicle	D
• Carbon dioxide laser	D

Efficacy and tolerability of thiabendazole in a lipophilic vehicle for cutaneous larva migrans. Chatel G, Scolari C, Gulletta M, et al. Arch Dermatol 2000; 136: 1174–5.

Six patients were treated twice daily for 5 days with topical applications of 15% thiabendazole ointment in a lipophilic vehicle of base fat cream (24 g) and dimethyl sulfoxide gel (35 g). The ointment was prepared by crushing the tablets of thiabendazole in the lipophilic base. All patients experienced a clinical resolution within a median of 48 hours. No adverse effects and no recurrence had occurred in any patient at 3-months' follow-up.

Treatment with topical thiabendazole ointment at 10%–15% concentration in a hydrophilic vehicle has shown 98% efficacy within a median of 10 days of treatment.

Treatment of cutaneous larva migrans with a single session of carbon dioxide laser: a study of ten cases in the Philippines. Soriano LE, Piansay-Soriano ME. J Cosmet Dermatol 2017; 16(1): 91–4.

Ten cases (8 patients) were treated with a single session of carbon dioxide laser. The first three cases underwent 1–2 passes and experienced further larval migration. The subsequent cases

received 3–4 passes, with no further progression noted. There was no recurrence at 1-month follow-up. The authors concluded that this represented an effective physical modality for treatment.

Third-Line Therapies

• Topical albendazole	E
• Topical ivermectin	E
• Cryotherapy	E

Efficacy of albendazole ointment on cutaneous larva migrans in 2 young children. Caumes E. Clin Infect Dis 2004; 38: 1647–8.

Two patients, both 2 years old, were treated with a 10% albendazole ointment, prepared by crushing three 400-mg tablets of albendazole in 12 g of petroleum jelly. Treatment was applied three times daily for 10 days. The cutaneous lesions disappeared within a week. One patient had recurrence at 3 months, lesions disappearing within a week of re-treating. The author suggests that albendazole ointment is a safe and effective treatment for Hr-CLM in children.

Hookworm-related cutaneous larva migrans of the penis successfully treated with topical ivermectin. Gelmetti C, Brena M, Veraldi S. Pediatric Dermatology 2019; 36: 391–2.

A 4-year-old boy with Hr-CLM of the penis treated with topical ivermectin 1% cream BD for 2 weeks, with almost complete remission observed on day 2 and no recurrence at 6-weeks' follow-up. The authors concluded that this is an effective treatment in select patients.

A case of cutaneous larva migrans presenting in a pregnant patient. Kudrewicz K, Crittenden KN, Himes A. Dermatol Online J 2014; 20(10): 25526012.

Cryotherapy with liquid nitrogen resulted in complete resolution of the patient's lesion and symptoms. Oral anthelmintic agents are contraindicated in pregnancy.

Cutaneous polyarteritis nodosa

Cindy E. Owen, Jeffrey P. Callen

Polyarteritis nodosa (PAN) is a necrotizing vasculitis that predominantly involves medium-sized arteries. Small arteries may also be targeted, but small vessels (arterioles, capillaries, and venules) are not. Classic PAN is characterized by fever, weight loss, cutaneous ulcers, livedo reticularis, myalgias and weakness, arthralgias or arthritis, neuropathy, abdominal pain, ischemic bowel, testicular pain, hypertension, and renal failure. By contrast, cutaneous PAN (cPAN), sometimes termed *benign cutaneous polyarteritis*, is a localized necrotizing arteritis that does not affect internal organs and runs a chronic but benign course. It is characterized by livedo reticularis, retiform purpura, tender nodules, digital infarction, and ulceration. cPAN most often affects the legs but can appear on the arms and trunk. Extracutaneous manifestations can include fever, malaise, myalgias, arthralgias, and neuropathy. Many reports have linked cPAN to infections including group A streptococcus (most common), hepatitis B and C, parvovirus B19, *Mycobacterium tuberculosis*, and urinary tract pathogens. Inflammatory bowel disease, hairy cell leukemia, and minocycline exposure are also associated with cPAN. Occasional reports have linked cPAN to antiphospholipid antibodies, cryoglobulins, or antineutrophil cytoplasmic antibodies (pANCA or atypical ANCA more commonly than cANCA), but these are typically negative/normal in cPAN. One recent report has demonstrated that interleukin-6 is elevated in roughly 40% of patients. A mutation in the *CERC1* gene leading to deficiency in the ADA2 protein has been identified in some patients with early cPAN and early-onset vasculopathy. cPAN is seen more commonly in women than men (ratio of 1.7:1 in one study) in contrast to PAN, which is more common in men. Age of onset is typically between ages 30 and 50 but children can also be affected.

MANAGEMENT STRATEGY

cPAN causes pain and discomfort and may ulcerate, thereby causing disability. Therapy may include local measures, for example,

gradient pressure stockings, or systemic therapies, including colchicine, dapsone, pentoxifylline, hydroxychloroquine, systemic corticosteroids, methotrexate, azathioprine, cyclophosphamide, infliximab, etanercept, rituximab, and intravenous immunoglobulin (IVIG). Most of the reports are anecdotes or small case series.

Treatment is often indicated for underlying and associated conditions.

Specific Investigations

- Skin biopsy
- Serology for hepatitis B and C, assessment for tuberculosis, streptozyme titers, antineutrophil cytoplasmic antibodies, antinuclear antibodies, antiphospholipid antibodies, complement components (C3 and C4), rheumatoid factor, and cryoglobulins
- Assessment for systemic involvement (CBC, CMP, urinalysis with microscopic evaluation, blood pressure evaluation)
- Assessment for inflammatory bowel disease (history and possibly anti-*Saccharomyces cerevisiae* antibodies [ASCA])
- Assessment for drugs that have been linked to cPAN
- In cases with early onset, measurement of ADA2 levels

Cutaneous periarteritis nodosa: a clinicopathological study of 79 cases. Daoud MS, Hutton KP, Gibson LE. *Br J Dermatol* 1997; 136: 706–13.

In this analysis, ulceration was associated with neuropathy and a prolonged course. Most patients (60%) had no associated medical condition. Systemic PAN did not develop in any patient. Corticosteroids, azathioprine, pentoxifylline, and hydroxychloroquine appeared effective in individual patients, and patients with non-ulcerative disease responded better than those with ulcers.

Mutant adenosine deaminase 2 in a polyarteritis nodosa vasculopathy. Navon Elkan P, Pierce SB, Segel R, et al. *N Engl J Med* 2014; 370(10): 92.

This study identified recessive loss of function mutations in *CECR1*, the gene encoding adenosine deaminase 2 (ADA2), in six families with multiple cases of systemic or cutaneous PAN.

Clinical and laboratory markers associated with relapse in cutaneous polyarteritis nodosa. Kato A, Hamada T, Miyake T, et al. *JAMA Dermatol* 2018; 154(8): 922.

In this retrospective case series of cPAN, pretreatment cutaneous ulcer, and high C-reactive protein levels, absolute neutrophil count, neutrophil-to-lymphocyte ratio, and systemic immune-inflammation indices were associated with relapse; arthropathy and neuropathy were not.

High titer of phosphatidylserine–prothrombin complex antibodies in patients with cutaneous polyarteritis nodosa. Kawakami T, Yamazaki M, Mizoguchi M, et al. *Arthritis Rheum* 2007; 57: 1507–13.

Antiphosphatidylserine–prothrombin complex and/or anticardiolipin antibodies were positive in all 16 cPAN patients tested compared with none in the control group.

Epidemiological, clinical and laboratory profiles of cutaneous polyarteritis nodosa patients: report of 22 cases and literature review. Criado PR, Marques GF, Morita TC, et al. *Autoimmun Rev* 2016; 15: 558–63.

cPAN was more prevalent in women (77%) with a mean age at time of diagnosis of 39.4 years (9–61 years). Clinical manifestations in decreasing order of frequency were ulcers, livedo racemosa, subcutaneous nodules, atrophie blanche, and purpura. Lower limbs were affected in all cases, but trunk and upper limbs were affected at equal frequency of 27%. No cases of cPAN progressed to systemic PAN. Symptoms reported were pain (64%) and paresthesias (30%). Twenty-three percent were diagnosed with mononeuritis multiplex. The most common infectious agent in this study was *Mycobacterium tuberculosis*.

Polyarteritis-like vasculitis in association with minocycline use: a single center case series. Kermani T, Ham E, Camilleri M, et al. *Semin Arthritis Rheum* 2012; 42: 213–21.

Nine cases occurring in the context of minocycline use – four with cutaneous-only disease. All had positive pANCA. Minocycline was discontinued, and six patients required immunosuppressive therapy.

Vasculitic conditions mimicking cPAN have also been reported with isotretinoin and amphetamines.

Manifestations, clinical course and prognostic markers in cutaneous polyarteritis nodosa. Munera-Campos M, Bielsa I, Martínez-Morillo M, et al. *J Dtsch Dermatol Ges* 2020; 18(11):1250-1259.

In a series of 31 patients, cPAN manifestations were nodules (90.3%), livedo reticularis (45.2%), ulceration (35.5 %), livedo racemosa (12.9%) and purpura (3.2%). At least one extracutaneous manifestation was reported in 67.7% of patients—myalgia (58.1%), paresthesia (45.2%) and arthralgia without arthritis (19.4%). Mononeuritis multiplex was noted in 9 of 21 patients (29%) who had electroneuromyography. The most common comorbid conditions were hypertension (22.6%), Type 2 diabetes mellitus (16.1%) and autoimmune hypothyroidism (9.68%). Relapse was seen in 17 (54.8%) of patients. Ulceration at presentation was the strongest predictor of relapse.

First-Line Therapies

• Local measures (i.e., support stockings, rest, leg elevation, local wound care)	E
• Non-steroidal antiinflammatory drugs, penicillin (if antecedent streptococcal infection), systemic corticosteroids	E
• Immunosuppressants: azathioprine, methotrexate, mycophenolate mofetil, cyclophosphamide	E

Low-dose weekly methotrexate for unusual neutrophilic vascular reactions: cutaneous polyarteritis nodosa and Behçet's disease. Jorizzo JL, White WL, Wise CM, et al. *J Am Acad Dermatol* 1991; 24: 973–8.

Three patients responded dramatically.

Ulcerative cutaneous polyarteritis nodosa treated with mycophenolate mofetil and pentoxifylline. Kluger N, Guillot B, Bessis D. *J Dermatolog Treat* 2011; 22: 175–7.

This single case report combines a second-line and a third-line therapy.

Complete resolution of refractory cutaneous arteritis by intravenous cyclophosphamide pulse therapy. Kawakami T, Okano T, Takeuchi S, et al. *Int J Dermatol* 2015 Aug; 54(8): e323–5.

In two patients with steroid-dependent cPAN, the addition of pulsed IV cyclophosphamide resulted in remission, allowing discontinuation of systemic steroids.

Gangrenous digital infarcts in a severe case of cutaneous polyarteritis nodosa. Mahmood-Rao H, Gandhi N, Ding T. *BMJ Case Rep* 2017; 2017: bcr-2017-220300.

A patient with severe cPAN and gangrenous infarcts failed initial immunosuppressive treatment with high-dose steroids and azathioprine. Escalation of therapy to intravenous cyclophosphamide resulted in disease remission.

Second-Line Therapies

• Intravenous immunoglobulin	E
• Pentoxifylline	E
• Hydroxychloroquine	E

Intravenous immunoglobulins as treatment of severe cutaneous polyarteritis nodosa. Marie I, Miranda S, Girszyn N, et al. *Intern Med J* 2012; 42: 459–62.

Three patients with refractory cPAN resulting in painful leg ulcers and toe necrosis were treated with IVIG 1 g/kg/day for 2 days monthly. Skin signs dramatically improved after two infusions and completely healed after the third.

Intravenous immunoglobulins for cutaneous polyarteritis nodosa resistant to conventional treatment. Breda L, Franchini S, Marzetti V, et al. *Scand J Rheumatol* 2016; 45(2): 169–70.

cPAN in an 8-year-old associated with streptococcal pharyngitis responded to IVIG after failing systemic steroids, ibuprofen, azathioprine, and indomethacin. Review of the literature revealed two cases of pediatric streptococcal-associated cPAN responding to IVIG.

Successful treatment of cutaneous PAN with pentoxifylline. Calderon MJ, Landa N, Aguirre A, et al. *Br J Dermatol* 1993; 12: 706–8.

A patient who failed to respond to aspirin and penicillin was treated with pentoxifylline. Withdrawal of the pentoxifylline resulted in a relapse that again responded to therapy.

New use for an old treatment: hydroxychloroquine as a potential treatment for systemic vasculitis. Casian A, Sangle SR, D'Cruz DP, et al. *Autoimmun Rev* 2018; 17(7): 660–4.

The authors report two cases of cPAN responding to hydroxychloroquine.

Third-Line Therapies

• Tamoxifen	E
• Infliximab	E
• Etanercept	D
• Rituximab	E
• Tonsillectomy	D
• Warfarin	E
• Tocilizumab	E

Estrogen-sensitive cutaneous polyarteritis nodosa: response to tamoxifen. Cvancara JL, Meffert JJ, Elston DM. *J Am Acad Dermatol* 1998; 39: 643–6.

Tamoxifen at a dose of 10–20 mg daily led to control of disease in a patient who seemed to worsen with conjugated estrogen therapy. Relapse occurred within 5 days of interruption of the therapy and rapidly responded with reinitiation of the tamoxifen.

Successful response to infliximab in a patient with undifferentiated spondyloarthropathy coexisting with polyarteritis nodosa-like cutaneous vasculitis. Garcia-Porrúa C, Gonzalez-Gay MA. Clin Exp Rheumatol 2003; 21: S138.

Remission induced by infliximab in a childhood polyarteritis nodosa refractory to convention immunosuppression and rituximab. Campanilho-Marques R, Ramos F. Joint Bone Spine 2014; 81: 267.

A 13-year-old boy responded to infliximab after failing prednisolone, methotrexate, cyclophosphamide, and rituximab.

Cutaneous polyarteritis nodosa in pediatric patients successfully treated with TNF- α inhibitor and methotrexate: case series and literature review. Do N, Ringold S, Brandling-Bennett H. Pediatr Dermatol 2019; 36(6): 932–5.

The authors report successful treatment of pediatric cPAN with infliximab in combination with methotrexate. They also review four cases from the literature treated successfully with either etanercept or infliximab without concomitant methotrexate.

A case of refractory cutaneous polyarteritis nodosa in a patient with hepatitis B carrier status successfully treated with tumor necrosis alpha blockade. Zoshima T, Matsumura M, Suzuki Y, et al. Mod Rheumatol. 2013; 23: 1029–33.

Report of a case, and literature review of five similar cases, successfully treated with etanercept.

Rituximab in refractory cutaneous polyarteritis. Krishnan S, Bhakuni DS, Kartik S. Int J Rheum Dis 2012; 15: e127.

A 34-year-old woman with cPAN refractory to prednisolone and cyclophosphamide developed digital gangrene of two fingers. Rituximab (two courses) resulted in complete healing of ulcers within 4 weeks. Six-month follow-up showed no recurrence on prednisolone and azathioprine.

Cutaneous polyarteritis nodosa: therapy and clinical course in four cases. Misago N, Mochizuki Y, Sekiyama-Kodera H, et al. J Dermatol 2001; 28: 719–27.

Two cases resolved after tonsillectomy. The authors proposed that chronic streptococcal disease might be responsible for cPAN.

Use of warfarin therapy at a target international normalized ratio of 3.0 for cutaneous polyarteritis nodosa. Kawakami T, Soma Y. J Am Acad Dermatol 2010; 63: 602–6.

Three patients with antiphosphatidylserine–prothrombin complex antibodies resolved on sustained warfarin therapy.

Successful treatment of tumor necrosis factor inhibitor-resistant cutaneous polyarteritis nodosa with tocilizumab. Inoue N, Shimizu M, Mizuta M, Yachie A. Pediatr Int 2020; 62: 753–755.

An 8-year old girl with TNF inhibitor-resistant cPAN responded to tocilizumab, a humanized monoclonal anti-IL-6 receptor antibody, given intravenously every 2 weeks at a dose of 8 mg/kg.

Darier disease

Benjamin S. Daniel, Genevieve A. Casey, Dedee F. Murrell

Darier disease (DD) is inherited in an autosomal dominant manner with an incidence of 1:25,000–1:100,000. Patients begin to develop malodorous, greasy, and crusted hyperkeratotic papules in seborrheic and flexural areas around puberty. DD is caused by mutations in the *ATP2A2* gene, which encodes sarcoplasmic/endoplasmic reticulum calcium-ATPase type 2 (SERCA2). There is no validated scoring system for DD to enable proper RCTs. An increased risk of cardiac failure has been demonstrated by a case-control study related to the role of this enzyme in the cardiac muscle.

MANAGEMENT STRATEGY

General measures include antiseptic washes, liquid soap-free washes, and loose, cotton clothing. Some patients flare with ultraviolet (UV) exposure and need photoprotection.

In mild disease or linear disease reflecting genetic mosaicism, *topical retinoids* may be sufficient. These include topical isotretinoin (0.05%), tretinoin cream (0.05%), adapalene gel (0.1%), and tazarotene gel (0.1% short contact for 15 minutes). Treatment is applied on alternate days to begin with, increasing to once daily if possible, as irritation is common. The addition of a topical corticosteroid (alternating with the retinoid) may alleviate some of the side effects. Superinfection with viruses and bacteria is frequent, so combined corticosteroid/antibiotic preparations are logical. Sweating may be reduced by a trial of oral naltrexone.

In more extensive disease, an *oral retinoid* is required. Isotretinoin (0.5–1.0 mg/kg daily) and alitretinoin (30 mg daily) are preferred over acitretin because teratogenicity is a problem, and

pregnancy is contraindicated for 2 years after stopping treatment with acitretin and 1 month after isotretinoin or alitretinoin. In males acitretin is an alternative but, bearing in mind that 50% of genetic relatives may have the same condition, such drugs could be dangerous if shared among females in the family. Compliance with contraceptive measures in females is very important as the treatment is usually long term.

The rare vesiculobullous form of the disease may respond to *prednisolone*. Hypertrophic flexural disease unresponsive to retinoids may require a surgical approach with *laser*, *electrosurgery*, *debridement*, or *excision*. Recurrence is a problem.

Oral lithium exacerbates the disease and should be avoided if possible.

Specific Investigations

- Skin biopsy. The characteristic finding is focal, suprabasal, acantholytic dyskeratosis
- Skin swab/scraping for bacterial, viral, and fungal culture
- Genetic testing for the mutation (counseling for prenatal diagnosis if desired)

Darier-White disease: a review of the clinical features in 163 patients. Burge SM, Wilkinson JD. *J Am Acad Dermatol* 1992; 27: 40–50.

Fourteen percent of patients in this series had herpes simplex complicating their disease.

Painful blisters arising in a patient with DD are usually due to secondary infection with *Staphylococcus aureus* or herpes simplex.

First-Line Therapies

• Cool cotton clothing	E
• Emollients	D
• Topical corticosteroids	D
• Topical retinoids	D

Darier's disease. Cooper SM, Burge SM. *Am J Clin Dermatol* 2003; 4: 97–105.

A detailed review of the management of DD.

Genetic counseling can be helpful, and written information is often appreciated.

Topical isotretinoin in Darier's disease. Burge SM, Buxton PK. *Br J Dermatol* 1995; 133: 924–8.

Six of 11 patients improved with 0.05% isotretinoin gel applied to a test patch. Patients were treated up to twice/day for 3 months if tolerated. Erythema, burning, and irritation were common. All patients relapsed after 1 month of stopping the treatment.

Successful treatment of Darier's disease with adapalene gel. Abe M, Inoue C, Yokoyama Y, et al. *Pediatr Dermatol* 2011; 28: 197–8.

Adapalene gel 0.1% applied daily for 2 months to the right side of the abdomen of a 12-year-old boy resulted in dramatic improvement in the area that was treated.

Tazarotene gel for Darier's disease. C G Burkhart CG, Burkhart CN. *J Am Acad Dermatol* 1998; 38: 1001–2.

Short-contact therapy with topical tazarotene in Darier disease. Sanz-Sánchez T, Díaz-Díaz RM, López-Barrantes O, et al. *Actas Dermosifiliogr* 2012; 103: 255–6.

Tazarotene has been used effectively as short contact or with topical steroids with improvement within 3 months.

Second-Line Therapies

• Oral isotretinoin	B
• Oral alitretinoin	C
• Oral acitretin	B
• Topical 5-fluorouracil 5%	E
• Topical tacrolimus 0.03%, 0.1%	E
• Topical pimecrolimus 0.05%	E
• Topical diclofenac sodium 3%	E

Clinical and ultrastructural effects of acitretin in Darier's disease. Lauharanta J, Kanerva L, Turjanmaa K, et al. *Acta Dermatol Venereol* 1988; 68: 492–8.

Thirteen patients treated with acitretin starting at 30 mg daily for 16 weeks showed some improvement, but side effects included itching (5 patients) and hair loss (2 patients).

Acitretin monotherapy in Darier's disease. Van Dooren-Greebe RJ, van de Kerkhof PC, Happle R. *Br J Dermatol* 1989; 121: 375–9.

Acitretin monotherapy at initial dose of 35 mg/day in five patients showed marked improvement with up to total clearance in four out of the five.

Isotretinoin treatment of Darier's disease. Dicken CH, Bauer EA, Hazen PG, et al. *J Am Acad Dermatol* 1982; 6: 721–6.

This multicenter open study assessed the effect of short and longer courses of treatment. The starting dose was 0.5 mg/kg, but longer courses were adjusted according to symptoms. Isotretinoin was effective but did not give long-term remission. Some patients were maintained on alternate-day or alternate-week regimens.

Successful treatment with oral alitretinoin in women of childbearing potential with Darier's disease. Zamiri M, Munro CS. *Br J Dermatol* 2013; 169: 709–10.

Two women were treated with 30 mg daily, with improvement after 4–6 weeks. Relapse occurred upon stopping, and treatment was continued in one patient for 18 months.

A case of Darier's disease successfully treated with topical tacrolimus. Rubegni P, Poggiali S, Sbrano P, et al. *J Eur Acad Dermatol Venereol* 2006; 20: 84–7.

Topical tacrolimus 0.1% ointment to the face and neck resulted in complete remission after 6 weeks, with no relapse 1 year later using maintenance therapy of 0.03%.

Improvement of Darier disease with diclofenac sodium 3% gel. Millan-Parrilla F, Rodrigo-Nicolas B, Moles-Poveda P, et al. *J Am Acad Dermatol* 2014; 70: e89–90.

Third-Line Therapies

• Ciclosporin	E
• Oral prednisolone (vesiculobullous)	E
• Laser (CO ₂ , erbium:YAG, pulse-dye)	E
• Photodynamic therapy	D
• Botulinum toxin	E
• Electron beam radiation	E
• Dermabrasion	E
• Debridement	E
• Excision	E

Darier's disease: severe eczematization successfully treated with cyclosporine. Shahidullah H, Humphreys F, Beveridge GW. *Br J Dermatol* 1994; 131: 713–6.

Ciclosporin may be helpful in widespread eczematized DD but had no effect on the underlying disease.

Vulvar Darier's disease treated successfully with cyclosporine. Stewart LC, Yell J. *J Obstet Gynaecol* 2008; 28: 108–9.

A previously therapy-resistant case was treated with ciclosporin (initial dose 5 mg/kg) for 6 months with good response and was subsequently maintained on acitretin.

Vesiculobullous Darier's disease responsive to oral prednisolone. Speight EL. *Br J Dermatol* 1998; 139: 934–5.

A patient with the vesiculobullous form of the disease responded to a short course of oral prednisolone.

Prednisolone may also be useful in the eczematized form.

Extensive recalcitrant Darier disease successfully treated with laser ablation. Brown VL, Kelly SE, Burge SM, et al. *Br J Dermatol* 2010; 162: 227–8.

Trunk, limbs, and scalp were treated under general anesthetic every 2 months with CO₂ laser. Wounds healed within 33 weeks, and the patient remained disease free in some areas for 9 years.

Darier-White disease treated with fractional CO₂ laser in two cases. Raszewska-Famielec M, Dudra-Jastrzebska M, Borzecki A, et al. *Dermatol Ther* 2015; 24: 254–7.

Three sessions of fractional CO₂ laser resurfacing with 0.8- to 1-mm density every 6 weeks resulted in removal of papular lesions. Topical anesthetic (5% EMLA) cream was used. Some recurrence was observed after 6 months.

Efficacy of erbium:YAG laser ablation in Darier disease and Hailey-Hailey disease. Beier C, Kaufmann R. *Arch Dermatol* 1999; 135: 423–7.

Disease cleared in two patients, but follow-up was less than 2 years.

Successful treatment of Darier disease with the flashlamp-pumped pulse-dye laser. Roos S, Karsai S, Ockenfel HM, et al. *Arch Dermatol* 2008; 144: 1073–5.

Submammary disease improved at 8 weeks post treatment, with no progression at 15 months.

Treatment of Darier's disease with photodynamic therapy. Exadaktylou D, Kurwa HA, Calonje E, et al. *Br J Dermatol* 2003; 149: 606–10.

Six patients received photodynamic therapy with topical 5-aminolevulinic acid as a photosensitizer. One patient could not tolerate the treatment, but five experienced sustained improvement, with initial inflammatory response lasting 2–3 weeks.

Botulinum toxin type A: an alternative symptomatic management of Darier's disease. Kontochristopoulos G, Katsavou AN, Kalogirou O, et al. *Dermatol Surg* 2007; 33: 882–3.

Submammary disease was treated with botulinum toxin as adjuvant therapy: 100 U were injected, with improvement sustained for 4 months. Reduced sweating may alleviate maceration and reduce bacterial colonization.

Treatment of recalcitrant Darier's disease with electron beam therapy. Kittridge A, Wahlgren C, Fuhrer R, et al. *Dermatol Ther* 2010; 23: 302–4.

Electron beam radiation therapy to the inframammary folds resulted in initial severe local dermatitis, followed by complete resolution sustained for 18 months.

Recalcitrant hypertrophic lesions were debrided under local anesthesia. Symptomatic and cosmetic improvement was maintained for 2 years.

The surgical treatment of hypertrophic Darier's disease. Wheeland RG, Gilmore WA. J Dermatol Surg Oncol 1985; 11: 420-3.

Decubitus (pressure) ulcers

Lawrence Charles Parish, Ayse Serap Karadag,
Jennifer L. Parish

From Istanbul Medeniyet University Department of Dermatology archive.

Pressure ulcers (decubitus ulcers, bed sores, pressure sores, to torsion stress) represent damage within the skin and soft tissue that can extend through the subcutaneous tissue and muscle layer onto the underlying bone. They generally occur over bony prominences, the most common being the sacrum, ischial tuberosities, greater trochanters, calcaneus, and lateral malleoli.

MANAGEMENT STRATEGY

Prevention

Repositioning is a significant part of prevention. A patient in an ordinary bed who is at risk for developing a pressure ulcer should be repositioned at frequent intervals; however, the correct timing for turning has never been established. The National Pressure Ulcer Advisory Panel (NPUAP) has admitted that evidence on repositioning every 2 hours is arbitrary and varies from country to country, even from facility to facility, and that repositioning at 2–4-hour intervals may be more appropriate.

Pillows and foam wedges are used to maintain an appropriate position and to keep bony prominences apart. Completely immobile patients should have their heels raised from the bed by a pillow or boot and not be placed on their trochanters, unless a specialized bed is used. To avoid the latter, use a 30-degree position from the horizontal lying on the side. The head of the bed should not be raised more than 30 degrees from the horizontal for an extended period. Knees should be flexed at 5–10 degrees to minimize the risk of deep-vein thrombosis.

Where possible, use lifting devices or draw sheets to reposition or to transfer patients. Minimize pressure from medical devices, such as catheters, oxygen tubing, and restraints. Finally, when appropriate, the patient should be placed on a *pressure-reducing*

device such as *alternating air, gel, or water mattress*. Foam rings, foam cut-outs, or donut-style devices should not be used, as these devices distribute pressure inappropriately.

A patient sitting in a wheelchair should be repositioned frequently, perhaps every hour, and be taught to shift weight every 15 minutes. A pressure-reducing device made of foam, gel, air, or a combination of each is indicated. Unfortunately, even in paraplegics, the exact time interval for repositioning has never been accurately determined.

Barrier creams are useful for conserving the intact skin of incontinent patients and of those at risk for skin breakdown.

Theoretically, pressure ulcers should be preventable, but despite these measures, many simply are not. If they are associated with immobility, sustained pressure, and the loss of pain sensibility, these problems can and should be addressed. In practice, successful prevention is often foiled by our limited understanding of the pathogenesis, as well as by complicating comorbidities. There is also some evidence that many deep ulcers are initiated by multiple microthromboses of deep tissues. This indicates that dehydration, along with any factor that might increase blood coagulability, should be addressed.

Management

The management of skin lesions caused by pressure is based on these principles:

- Elimination of relative/sustained pressure
- Reposition of the patient regularly and frequently
- Removal of necrotic debris
- Maintenance of a moist wound environment
- Correction of the underlying contributing factors
- Nutritional supplements and screening for nutritional deficiencies
- Wound care with topical products and/or dressing

The patient should not lie on the ulcer. A patient who is at risk for developing additional ulcers and can assume a variety of positions without lying on the ulcer should be placed on a *static support surface* (i.e., *air, foam, or water*). If the patient cannot assume various positions without lying on the ulcer or bottoms out while on a static surface, or if the ulcer does not heal after 2–4 weeks of optimal care, place the patient on a *dynamic support surface* when possible. These supporting surfaces can be categorized as constant low-pressure (CLP) devices conforming to body shaper or replacing pressure devices that alter pressure mechanically. CLP devices, such as high-specification foam mattresses with overlays, and bead-filled and water-filled mattresses, may lessen the development of pressure ulcers and tend to be more successful than standard foam hospital mattresses. Alternating-pressure (AP) mattresses and overlays include a variety of compartments filled with air inflating and deflating in a coordinated way to alter pressure continually across the body. Unfortunately, there is no proof to show exactly which type is better for protection and treatment; however, both CLP and AP devices are more successful than standard hospital mattresses for prevention and treatment.

Removal of Necrotic Debris

Debridement is required to expose granulation tissue, decrease infection risk, and improve healing, especially when there is an extensive eschar or necrotic tissue. Debridement can be conducted through surgical (sharp) and nonsurgical (enzymatic, autolytic, mechanical, and biologic). The debridement method is dependent on several factors, including the characteristics of the patient, the wound, the risk of infection risk, and even the cost.

Surgical debridement is indicated for infected ulcers with necrotic debris, if the patient has advancing cellulitis and systemic infection, devitalized tissue, and eschars other than those on the heel; however, the extent of tissue needing to be removed is highly variable. An eschar on the heel should be excised only if it is fluctuant, draining, or surrounded by cellulitis, and if the patient is septic. If there is a high index of suspicion that a biofilm is present (i.e., wound failing to heal despite proper wound care and antimicrobial therapy), then surgical debridement is required.

Major debridement is performed in the operating room, but serial sharp debridement can be performed at the bedside. The use of *systemic antimicrobials* should be considered to prevent bacteremia during significant debridement. A *bone biopsy* is recommended while debriding ulcers, when bone is exposed, and for non-healing deep ulcers (stage 3 or 4) after 2–4 weeks of optimal therapy.

Mechanical debridement methods, such as hydrotherapy, whirlpool baths, and wound irrigation are among other measures that have benefits, such as improving local circulation, reducing pain and fever, relieving debris and bacteria, helping with wound removal, and accelerating wound healing. Saline wet-to-dry gauze is an additional alternative.

Autolytic debridement provides a moist wound area that allows the body enzymes to digest necrotic tissue. Similarly, enzymatic debridement uses enzymes for the liquefaction of dead tissue in the wound and clears them with dressings like collagenase to remove necrotic tissue, and moist wounds are the best place for them to work. Autolytic and enzymatic debridement is indicated for non-infected ulcers that are unlikely to get infected.

Biologic debridement utilizes non-infectious larvae and maggots, which has been observed to have increased complete debridement over conventional therapy (80% versus 48%, respectively).

Maintenance of a Moist Wound Environment

The choice of a synthetic dressing depends on the presence of infection, amount of exudate, status of the periwound skin, and amount of pain experienced by the patient. *Saline dressings* and *alginates* are indicated for infected ulcers. *Synthetic dressings* (i.e., *films*) are used on ulcers with minimal exudate, *hydrocolloid wafers* for moderate exudate, and *foam wafers* and *alginates* for ulcers with a large amount of exudate. Ulcers with fragile or dermatitic periwound skin should be covered with *hydrogel wafers* or *non-adherent foam wafers*. All occlusive dressings relieve pain, when present, but the hydrogel wafers are best for this purpose.

Correction of the Underlying Contributing Factors

Attention to the medical status is important; diabetes mellitus, nutritional conditions (malnutrition, hypoproteinemia, anemia), peripheral vascular disease, deep venous thrombosis, congestive heart failure, lower extremity edema, cardiac disease, malignancy, mental health problems, and even Alzheimer disease may prevent any ulcer healing. Unfortunately, even the best medical care may not permit healing.

General Measures

Treatment of the pressure ulcer can be simplified and made more effective if the following recommendations are considered:

- It is essential that the heels are inspected at least daily and any changes are recorded
- Saline should be used to clean most pressure lesions; soap and disinfectants are too irritating for more than occasional use. Scrubbing may prove too irritating, so gentle washing is indicated

- When ulcers are not infected, synthetic dressings should be changed only if they become dislodged or wound fluid escapes from under the dressing
- Periwound skin must be kept dry not only to avoid maceration but also to permit the dressing to adhere to the skin
- To obliterate dead space, *fill deep ulcers loosely with a hydrocolloid, a hydrogel wound filler, or an alginate rope* before applying a synthetic dressing. This same material should be placed under the edge of the ulcer when undermining is present. Bleeding after serial surgical debridement can often be controlled with an alginate dressing. Moistening with saline can loosen an alginate dressing that adheres to granulation tissue
- A clean ulcer failing to show signs of healing and revealing inflammatory signs of erythema, edema, and warmth, purulent discharge and persistent excessive exudate, discoloring or darkening of granulation tissue, giving off a foul odor, and presenting with heightened local pain should be treated with antibacterial agents, such as *1% silver sulfadiazine, cadexomer iodine, triple antibiotic, or retapamulin*, for 2 weeks to reduce the bacterial burden; however, topical antimicrobials may create the risk of resistant bacterial strains emerging. *Metronidazole gel* would be the exception, as the odor of an infected ulcer can often be eliminated by applying it to the ulcer bed. Increased bacterial burden may impede healing before clinical signs of infection become apparent. Cytotoxic agents, such as hydrogen peroxide and povidone-iodine, should be avoided
- Clinical observation is the key to making the diagnosis. Cutaneous biopsies will not be helpful, although biopsies for aerobic and anaerobic bacteriology cultures could be useful if infection is suspected
- *Systemic antibiotics* are recommended only in the presence of bacteremia, sepsis, advancing cellulitis, or osteomyelitis. Bacterial testing and analysis with comprehensive swabbing cannot provide all the information required. Infection that is described as a variety of bacteria bigger than 10^5 CFU/g of tissue is partially relevant. It is recommended the wound is controlled for signs of infections: pain, warmth, erythema, drainage, bad odor, and/or systemic manifestations. Osteomyelitis usually accompanies stage 4 pressure ulcers and deep ulcers. X-rays, MRI, and bone biopsy should be used to check for osteomyelitis
- Although most synthetic dressings relieve pain, treatment for moderate-to-severe pain can include topical anesthetics (lidocaine), non-steroidal antiinflammatory drugs, opiates, antidepressants, and sedatives

Dermatologic Observation

Observe for:

- Blanchable erythema
- Non-blanchable erythema
- Superficial ulcer
- Deep ulcer
- Eschar
- Necrosis
- Gangrene
- Decubitus dermatitis

Blanchable Erythema and Non-blanchable Erythema

Blanchable and non-blanchable erythema represent the initial development of the pressure ulcer. The early lesions of non-blanchable erythema are bright red; later, they become dark red to purple. Both can be treated with *adherent synthetic dressings* to protect the lesion from friction and shear, *topical corticosteroids*, or *zinc oxide paste*. The bright red lesion can also be treated with 2%

nitroglycerin ointment; 0.5–1 cm of the ointment is applied over the lesion and covered with an impermeable plastic wrap (such as Saran Wrap) for 12 hours daily.

Superficial and Deep Ulcers

Superficial and deep ulcers without necrotic debris are treated with *saline wet-to-dry gauze* or an *adherent synthetic dressing*. Deep ulcers should be loosely filled with a *synthetic wound filler* before applying a synthetic dressing.

Eschar and Necrosis

The deep ulcer with necrotic debris requires debridement and is then treated as a clean ulcer. Covering the lesion with an adhesive occlusive dressing for several days after scarification will often soften the eschar before excision is undertaken. The firmly adherent dry eschar that is not attached to underlying bone can often be separated from the surrounding skin with 5% 5-fluorouracil cream. After scarification and application of zinc oxide paste to protect the surrounding skin, 5-fluorouracil is applied to the eschar, including its margin, and then covered with an impermeable plastic wrap. Application is repeated every 8 hours. When separation occurs, it can be excised.

Decubitus Dermatitis

Decubitus dermatitis is treated with topical corticosteroids, vaseline gauze, or a hydrogel wafer. Large bullae may be debrided before applying the dressing.

Specific Investigations

- Categorize patient
- Stage the degree of ulceration
- Total protein, serum albumin, liver, and kidney function
- Daily calorie intake
- Complete blood count
- Physical examination for dehydration and malnutrition
- Care for comorbid disorders

Categories of Patients

Patients at risk need to be considered in terms of the underlying disease process:

- Spinal cord injury in an otherwise healthy person
- Neurologic disease with no medical disease but a devastating condition, such as multiple sclerosis or a cerebral vascular accident compromising the body integrity
- Debilitation with a multitude of medical diseases affecting the patient (e.g., arteriosclerosis, diabetes mellitus, Parkinson disease, Alzheimer disease, malignancy, malnutrition, and peripheral vascular disease)
- Surgical procedures requiring lengthy positioning on the operating table for cardiovascular or orthopedic procedures

Grading or Evaluation

Grading or evaluation can be accomplished by dermatologic observation and staging. Bear in mind that ulcer staging is arbitrary and does not reflect the dynamics of ulcer formation.

Staging

Stages are as follows:

- Stage 1: Non-blanchable erythema of intact skin

- Stage 2: Partial-thickness skin loss with exposed dermis. Adipose or deeper tissues are not exposed
- Stage 3: Full-thickness skin loss. Adipose tissue is visible in the ulcer bed, which may have undermining and tunneling (see figure)
- Stage 4: Full-thickness skin and tissue loss. Fascia, muscle, tendon, ligament, cartilage, or bone is exposed; undermining, tunneling, and epibole may be present
- Unstageable: Obscured full-thickness skin and tissue loss. Extent of tissue damage within the ulcer is obscured by slough or eschar and cannot be determined; removal of slough or eschar reveals a stage 3 or 4 pressure injury
- Deep tissue pressure injury: Persistent non-blanchable deep red, maroon, or purple discoloration (may be seen with intact or non-intact skin)

NPUAP recently have added two further pressure injury types to their definitions, both of which are caused by medical devices. Medical devices can lead to pressure injury and injury to mucosal membranes; staging is not possible for these types of pressure injury.

Most superficial ulcers do not progress to stage 2 or even 3 or 4 ulcers. The concept of staging need not be thought of as a progression.

Accumulating evidence suggests that a number of ulcers (most stages 3 and 4) may initially originate in the deep tissue compartment and progress outward to the dermis and epidermis (inside-out theory).

Pathophysiology

The relationship between common risk factors and the pathophysiology of pressure ulcer development: a systematic review. Blackburn J, Ousey K, Taylor L, et al. *J Wound Care* 2020; 29: 4–12.

The most important risk factors in pressure ulcer etiology are ischemia, recovery of blood flow, and the pathologic effect of pressure and shear. Among other risk factors are force and pressure (shear force, type of force, the relative position of external forces compared to bony prominences), agedness, spinal cord injury, and type 1 diabetes with cardiac autonomic neuropathy.

Dilemmas about the pressure ulcer: skin-fold ulcerations and apposition lesions. Parish LC, Lowthian PT. *Exp Rev Dermatol* 2008; 3: 287–91.

Pressure ulcers continue to have an uncertain etiology.

Risk Assessment Tools

Predictive validity of pressure ulcer risk assessment tools for elderly: a meta-analysis. Park SH, Lee YS, Kwon YM. *West J Nurs Res* 2016; 38: 459–83.

Typical screening tools (Braden, Norton, and Waterloo scales) utilized for pressure ulcer risk are limited as to their validity and accuracy among older adults due to heterogeneity throughout studies.

Risk assessment tools for the prevention of pressure ulcers. Moore ZE, Patton D. *Cochrane Database Syst Rev* 2019; 1: CD006471.

No proof suggesting the reduction of the incidence or the severity of pressure ulcers is available on the use of structured and systematic pressure ulcer risk assessment tools.

Predictive validity of Braden for pressure ulcers in critical care: a meta-analysis. Wei M, Wu L, Chen Y, et al. *Nurs Crit Care*. 2020; 25: 165–70.

Braden scale provided a moderately predictive validity and had a fair sensitivity and low specificity in critically ill adult patients.

Predictive efficacy of the Braden Q Scale for pediatric pressure ulcer risk assessment in the PICU: a meta-analysis. Chun X, Lin Y, Ma J, et al. *Pediatr Res* 2019; 86: 436–43.

The Braden Q scale anticipated the risk in the pediatric intensive care unit moderately accurate.

25 years of pressure ulcers. Parish LC, Sibbald RG. *Adv Skin Wound Care* 2012; 25: 57–8.

Role of staging may provide more confusion than merit.

Staging system: revised Pressure Injury Staging System. Edsberg LE, Black JM, Goldberg M, et al. Revised National Pressure Ulcer Advisory Panel. *J Wound Ostomy Continence Nurs* 2016; 43: 585–97.

The European Pressure Ulcer Advisory Panel developed a staging system in 1998 that is composed of four stages: Grade 1 to Grade 4. The classification system most popularly adopted and used is the one presented in 1989 by the NPUAP. This classification system has been updated and revised. A new stage, suspected deep tissue injury, was incorporated in 2016. The extent of the tissue loss present and the presence and absence of anatomical features in the stage of the injury is described in each definition. The revised description of a stage 2 pressure injury aims to demonstrate the difference between moisture-associated skin damage and injury led by pressure and/or shear. The suspected definition has been eliminated from the Deep Tissue Pressure Injury diagnostic label.

Noninvasive staging of pressure ulcers using photoacoustic imaging. Hariri A, Chen F, Moore C, et al. *Wound Repair Regen* 2019; 27: 488–96.

Q-switched Nd:YAG laser and light-emitting diode (LED)-based photoacoustic imaging systems analyze photoacoustic intensity and photoacoustic depth. The average and standard deviation of ulcer depths from 10 different A-lines are measured with this new technology.

Developing a mobile app for prevention and treatment of pressure injuries. Salomé GM, Ferreira LM. *Adv Skin Wound Care* 2018; 31: 1–6.

The current study defines the planning and development of a mobile application to prevent and treat pressure injuries for use by providers. The application outlines the risk factors for pressure injury development, supplies an assessment of the wound, suggests wound clearing procedures, maintains pressure injury staging, and suggests treatment interventions.

Factors Predicting Pressure Ulcers

Risk factors for pressure ulcer development in Intensive Care Units: a systematic review. Lima Serrano M, González Méndez MI, Carrasco Cebollero FM, et al. *Med Intensiva* 2017; 41: 339–46.

The occurrence of pressure ulcers cannot be explained by a single factor. Risk factors predictive of pressure ulcer development are usually age, length of ICU stay, diabetes, time of MAP <60–70 mmHg, length of mechanical ventilation, intermittent hemodialysis or continuous veno-venous hemofiltration therapy, vasopressor support, sedation, and turning.

A prediction tool for hospital-acquired pressure ulcers among surgical patients: surgical pressure ulcer risk score. Aloweni F, Ang SY, Fook-Chong S, et al. *Int Wound J* 2019; 16: 164–75.

Important risk factors for the likelihood of developing hospital-acquired pressure ulcers are age (≥ 75 years), female gender, low body mass index (< 23), preoperative Braden score ≤ 14 , anemia, respiratory disease, and hypertension.

Nutritional parameters predicting pressure ulcers and short-term mortality. Montalcini T, Moraca M, Ferro Y, et al. *J Transl Med* 2015; 13: 305.

Lower hemoglobin and albumin were inversely related to pressure ulcers, where patients with lower albumin showed notably higher short-term mortality than patients with higher serum albumin.

Factors predicting the development of pressure ulcers in an at-risk population who receive standardized preventive care. Demarre L, Verhaeghe S, Van Hecke A, et al. *J Adv Nurs* 2015; 71: 391–403.

Pressure ulcers in categories 2–4 were significantly related to non-blanchable erythema, urogenital disorders, and higher body temperature. Predictive factors relating to superficial pressure ulcers were: admittance to an internal medicine ward; incontinence-associated dermatitis; non-blanchable erythema; and a lower Braden score. Incontinence-associated dermatitis was greatly related to superficial sacral pressure ulcers.

Risk factors associated with pressure ulcer development in critically ill traumatic spinal cord injury patients. Wilczweski P, Grimm D, Gianakis A, et al. *J Trauma Nurs* 2012; 19: 5–10.

Clinical variables associated with pressure ulcers were fecal management systems, incontinence, acidosis, support surfaces, steroids, and additional equipment, with hypotension as the strongest predictor of pressure ulcers in 94 spinal cord injury patients.

Treatment

Wound, pressure ulcer and burn guidelines – 2: guidelines for the diagnosis and treatment of pressure ulcers, second edition. Fujiwara H, Isogai Z, Irisawa R, et al. *J Dermatol* 2020; 47: 929–78.

A comprehensive guide that is used to stage the wound according to color, acuteness, and chronicity in a pressure ulcer, with recommendations of care and treatment.

WOCN 2016 Guideline for Prevention and Management of Pressure Injuries (Ulcers): An Executive Summary. Wound, Ostomy and Continence Nurses Society–Wound Guidelines Task Force. *J Wound Ostomy Continence Nurs* 2017; 44: 241–6.

It offers an outline of the process that is exploited to update and improve the guideline, and lists the specific suggestions for evaluation, prevention, and treatment of pressure injuries.

Pressure ulcers: prevention and management. Mervis JS, Phillips TJ. *J Am Acad Dermatol* 2019; 81: 893–902.

This review article focuses on pressure ulcer prevention and management, with an emphasis on the evidence for commonly accepted practices.

First-Line Therapies

• Elimination of pressure	B
• Repositioning	B
• Pressure-reducing and -relieving devices	A
• Palliative care	B
• Removal of necrotic debris	B
• Maintenance of a moist environment	C
• Moisturizing	C
• Fatty acid cream	A
• Silicone foam	A
• Topical	B
• Cleansing	C
• Nutrition	C
• Dietary	C
• Maggot therapy	A

Eliminating Pressure and Relieving Devices

Support surfaces for pressure ulcer prevention: a network meta-analysis. Shi C, Dumville JC, Cullum N. *PLoS One* 2018; 13: e0192707.

The evidence that powered active air surfaces and powered hybrid air surfaces are likely to decrease pressure ulcer incidence was moderately certain; yet, standard hospital surfaces are possibly more comfortable than powered active air surfaces.

Support surfaces for the treatment and prevention of pressure ulcers: a systematic literature review. Rae KE, Isbel S, Upton D. *J Wound Care* 2018; 27: 467–74.

A useful tool to aid pressure ulcer prevention and wound healing is pressure mattresses and are accepted to be more suitable than standard foam mattresses. Medical grade sheepskins are agreed to be useful for those who have low-medium risk of developing pressure ulcers compared with standard foams. Higher specification mattresses are similar to each other (i.e., active and reactive surfaces) and it is hard to make a descriptive conclusion in terms of mattress superiority since the outcomes of the research are controversial.

Support surfaces for pressure ulcer prevention. McInnes E, Jammali-Blasi A, Bell-Syer SE, et al. *Cochrane Database Syst Rev* 2015; (9): CD001735.

Foam mattresses that are alternative to standard hospital foam mattresses decrease the occurrence of pressure ulcers for risk groups. Higher specification foam mattresses are recommended for people with a high risk of pressure ulcer development. The benefits of higher-specification CLP and AP support surfaces to prevent pressure ulcers are not clear but AP mattresses might be more affordable.

Support surfaces for treating pressure ulcers. McInnes E, Jammali-Blasi A, Bell-Syer SE, et al. *Cochrane Database Syst Rev* 2018; 10: CD009490.

The contribution of high-tech pressure support surfaces (such as low-air-loss beds, air suspension beds, and AP surfaces) or low-tech support surfaces to the improvement of the healing process of pressure ulcers.

Prevention of pressure ulcers with a static air support surface: a systematic review. Serraes B, van Leen M, Schols J, et al. *Int Wound J* 2018; 15: 333–43.

Static air mattress overlays are more efficient for the prevention of pressure ulcers when compared with standard mattresses in nursing homes and intensive care environments.

Comparing the effects of 3 different pressure ulcer prevention support surfaces on the structure and function of heel and sacral skin: an exploratory cross-over trial. Tomova-Simitchieva T, Lichterfeld-Kottner A, Blume-Peytavi U, et al. *Int Wound J* 2018; 15: 429–37.

Skin structure and function are affected by the type of support surface during loading. When gel and air mattresses are compared with foam mattresses, they were found to be more protective; however, the difference was insignificant.

An investigation of geriatric nursing problems in hospital. Norton D, McClaren R, Exton-Smith AN. London: Churchill Livingstone, 1975; 238.

Patients who developed fewer pressure sores were those who were turned every 2–3 hours.

This is based on a book published in 1916!

Shearing force as a factor in decubitus ulcers in paraplegics. Reichel SM. *JAMA* 1958; 166: 762–3.

As a result of shear, blood vessels in the sacral area become twisted and distorted, and the tissue may become ischemic and necrotic.

Drawsheets for prevention of decubitus ulcer. Witkowski JA, Parish LC. *N Engl J Med* 1981; 305: 1594.

Use of draw sheets reduces the incidence of friction burns.

Repositioning for pressure ulcer prevention in adults. Gillespie BM, Chaboyer WP, McInnes E, et al. *Cochrane Database Syst Rev* 2014; (4): CD009958.

Present evidence is not adequate and might be biased; and the evidence whether there is a decrease in pressure ulcers with the 30-degree tilt is not strong compared with the standard 90-degree position, nor is the evidence on the effect of repositioning.

The data collected from an economic assessment are not clear about the cost efficiency of nursing time of repositioning every 3 hours using the 30-degree tilt and whether or not it is more efficient than standard care including repositioning every 6 hours using a 90-degree tilt.

Palliative Care

Pressure ulcers in patients receiving palliative care: a systematic review. Ferris A, Price A, Harding K. *Palliat Med* 2019; 33: 770–82.

Patients who receive palliative care have 12.4% prevalence of pressure ulcers, and this is higher than the average population. Decreased mobility, older age, increased Waterlow score, and long duration of stay are among the most commonly identified risk factors.

Effectiveness of pressure ulcer prevention strategies for adult patients in intensive care units: a systematic review. Tayyib N, Coyer F. *Worldviews Evid Based Nurs* 2016; 13: 432–44.

The silicon foam dressing positively influences the reduction of sacrum and heel pressure ulcers' occurrence in patients who are critically ill. There is limited evidence on the efficiency of nutrition, skin-care regimen, positioning and repositioning program, support surfaces, and the role of education in preventing hospital-acquired pressure ulcers development in the ICU.

Moisturizing

Wound, pressure ulcer and burn guidelines – 2: guidelines for the diagnosis and treatment of pressure ulcers, second edition. Fujiwara H, Isogai Z, Irisawa R, et al. *J Dermatol* 2020; 47: 929–78.

Moisture creams should be applied to protect the skin and to avoid pressure ulcers. Should topical agents be necessary, oil-based ointments like white petrolatum, zinc oxide, and dimethyl isopropyl azulene should be used to protect the wound surface, and silver sulfadiazine to prevent infection.

Debridement

Debridement of cutaneous ulcer: medical and surgical aspects. Witkowski JA, Parish LC. *Clin Dermatol* 1991; 9: 585–93.

Debridement can be accomplished by cold steel cutting, by chemical application, or by autohemolytic destruction under an occlusive dressing.

Changing attitudes toward maggot debridement therapy in wound treatment: a review and discussion. King C. *J Wound Care* 2020; 29: 28–34.

Maggot debridement therapy induces healing and disinfects wounds. It may also be used for full debridement of a necrotic wound and clearing a methicillin-resistant *Staphylococcus aureus* infection. Irrigation of the wound by exudates formed by the host responding to the maggots, killing and ingestion of bacteria by the maggots, secretion of proteolytic enzymes by the maggots leading to breakdown and ingestion of necrotic tissue into liquid, and quick formation of granulation tissue by constant larval movement in the wound are included in the maggot-aided wound healing. The discussion about the engagement of health-care employees and the reduction of anxiety on the use of maggots as a treatment on hard-to-heal wounds is ongoing.

The role of surgical debridement in healing of diabetic foot ulcers. Gordon KA, Lebrun EA, Tomic-Canic M, et al. *Skinmed* 2012; 10: 24–6.

Evidence to support debridement in enhancing healing is scarce, and there are insufficient data to support debridement for venous ulcers and pressure ulcers.

Cleansing

Cleansing the traumatic wound by high pressure syringe irrigation. Stevenson TR, Thacker JG, Rodeheaver GT, et al. *J Am Coll Emerg Phys* 1976; 5: 17–21.

Cleansing provides enough force to remove bacteria and other debris and loosen eschar.

Wound cleansing for pressure ulcers. Moore ZE, Cowman S. *Cochrane Database Syst Rev* 2013; 3: CD004983.

Studies that used saline spray containing aloe vera, silver chloride, and decyl glucoside; isotonic saline solution; and pulsatile lavage, water, and sham (the lavage flow was directed into a wash basin positioned adjacent to the wound and not visible to the participants).

There currently is no promising trial evidence to advocate for the use of a specific wound cleansing solution or technique for pressure ulcers.

Wound cleansing, topical antiseptics and wound healing. Atiyeh BS, Dibo SA, Hayek SN. *Int Wound J* 2009; 6: 420–30.

Wound cleansers, povidone-iodine, chlorhexidine, alcohol, acetate, hydrogen peroxide, boric acid, silver nitrate, silver sulfadiazine, and sodium hypochlorite may affect normal human cells and may be antimetabolic, adversely affecting normal tissue repair. Negative outcomes may occur with repeated and excessive wound treatment with antiseptics without proper indications; however, when applied at the appropriate times and concentrations, some classes of antiseptics may function as a tool for the clinician to steer the wound bed in specific directions.

Beyond skin deep: managing pressure injuries. Podd D. *JAAPA* 2018; 31: 10–17.

Clearing the wounds should be done first, preferably with 0.9% sodium chloride solution at each dressing change. The use of cytotoxic antiseptic agents such as 5% mafenide acetate, 0.25% sodium hypochlorite solution, povidone-iodine, 3% hydrogen peroxide, and 0.25% acetic acid, killing granulation tissue and impairing wound healing, should be avoided on clean wounds. Sodium hypochlorite, which is antiseptic, is suitable on infected and malodorous wounds that have large slough, and debrides necrotic tissue.

Antimicrobial Agents

Topical metronidazole for odor control in pressure ulcers. Lyvers E, Elliott DP. *Consult Pharm* 2015; 30: 523–6.

When metronidazole was applied to the wound two or three times daily (0.75% and 1% creams, gels, lotions, and intravenous solutions of metronidazole) it was effective with nearly complete odor resolution in 2 to 7 days. Although there was the risk for systemic absorption, almost no systemic adverse events were reported in the literature. Monitoring is still required, as nausea, gastrointestinal distress, and neural toxicities from long-term use are still possible but unlikely.

Dressings and topical agents for preventing pressure ulcers. Moore ZEH, Webster J. *Cochrane Database Syst Rev* 2018; 12: CD009362.

No harm or benefit was displayed on many trials that explore the effect of topical applications on pressure ulcer occurrence. Dimethyl sulfoxide (DMSO) cream might raise the pressure ulcer risk. The incidence of pressure ulcers can be decreased by the use of fatty acid versus a control compound (a cream not including fatty acid). Pressure ulcer incidence at any stage may be reduced with silicone dressings.

Bacteriology of pressure ulcers in individuals with spinal cord injury: what we know and what we should know. Dana AN, Bauman WA. *J Spinal Cord Med* 2015; 38: 147–60.

Staphylococcus aureus, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Enterococcus faecalis* were the organisms most frequently identified in pressure ulcers.

Nutrition

Efficacy of a disease-specific nutritional support for pressure ulcer healing: a systematic review and meta-analysis. Cereda E, Neyens JCL, Caccialanza R, et al. *JMGA. J Nutr Health Aging* 2017; 21: 655–61.

The improvement of PU healing in comparison to standard formulas is linked with the use of high-calorie, high-protein, disease-specific formulas enhanced with arginine, zinc, and antioxidants as oral supplements and tube feeds for at least 8 weeks.

Pressure ulcer and nutrition. Saghaleini SH, Dehghan K, Shadvar K, et al. *Indian J Crit Care Med* 2018; 22: 283–9.

The main risk factors for the development of pressure ulcers and impaired wound healing are dietary deprivation and deficient nutritional intake. How much nutrient intake is ideal for wound healing is not clear, but increased need for energy, protein, zinc, vitamins A, C, E, and amino acids have been reported. Sufficient fluid intake is required for the support of the blood flow toward wound tissue and the prevention of additional breakdown of the skin.

The role of nutrition for pressure injury prevention and healing: The 2019 International Clinical Practice Guideline Recommendations. Munoz N, Posthauer ME, Cereda E, et al. *Adv Skin Wound Care* 2020; 33: 123–36.

Adults experiencing noticeable weight loss and those underweight might need extra energy intake. If dietary needs are insufficient, fortified foods and/or high-calorie, high-protein oral nutritional supplements between meals should be provided.

The EPUAP/NPIAP/PPPIACPG recommends 30–35 kcal/kg of body weight per day for malnourished adults with a pressure injury (PI) or those at risk of malnutrition. The recommended protein intake is 1.25–1.5 g/kg of body weight per day. The EPUAP/NPIAP/PPPIA CPG suggests providers encourage adequate fluids, which is an intake of 1 mL fluid/kcal.

Synthetic Dressing

Second-Line Therapies

• Hydrocolloid wafer dressing	C
• Hydrogel	C
• Synthetic dressing	C

Wound, pressure ulcer and burn guidelines – 2: guidelines for the diagnosis and treatment of pressure ulcers, second edition. Fujiwara H, Isogai Z, Irisawa R, et al. *J Dermatol* 2020; 47: 929–78.

When dressing materials are used in the acute phase, those allowing observation of the wound surface (such as polyurethane film and hydrocolloids) are preferable. To prevent pressure ulcers, polyurethane film application, polyurethane foam, polyurethane foam/soft silicone, bone protrusions should be used.

Successful treatment of unstageable pressure ulcers by using advanced wound dressing. Sunarti S. *Med Indones* 2015; 47: 251–2.

The stages of healing are cleaning, granulation, and epithelialization. Alginate dressing, dextranomer dressing, hydrofiber dressing, flax dressing, silver-supplemented dressing, or enzyme-supplemented dressing are the proposed dressings for the cleaning phase, whereas for the granulation phase, alginate dressing, hydrocolloid dressing, flax dressing, polyurethane foam dressing, or tender wet dressing should be utilized. For the epithelialization phase, hydrofiber dressing, hydrocolloid dressing, hydrogel dressing, flax dressing, and semipermeable dressing may be used.

Using transparent polyurethane film and hydrocolloid dressings to prevent pressure ulcers. Dutra RA, Salomé GM, Alves JR, et al. *Wound Care* 2015; 24: 268, 270–1, 273–5.

The transparent polyurethane film (8.7%) performed better and was more effective than the hydrocolloid dressing (15%) in preventing pressure ulcer development, as evidenced in 160 patients.

Hydrogel dressing for treating pressure ulcers. Dumville JC, Stubbs N, Keogh SJ, et al. *Cochrane Database Syst Rev* 2015; 2: CD011226.

It is not explicit if hydrogel dressings are more or less effective than other treatments in healing pressure ulcers or if different hydrogels have contrasting effects. Most trials that have been performed in this area are very small and poorly reported, so the risk of bias is uncertain.

Dressings and topical agents for preventing pressure ulcers. Moore ZE, Webster J. *Cochrane Database Syst Rev* 2018; 12(12): CD009362.

Although the occurrence of pressure ulcers was reduced when dressings were employed to protect the skin, results were compromised by the low quality of the included trials.

No harm or benefit was displayed on many trials that explore the effect of topical applications on pressure ulcer occurrence. The incidence of pressure ulcers can be decreased by the use of fatty acid versus a control compound (a cream not including fatty acid). Pressure ulcer incidence at any stage may be reduced with silicone dressings.

A cost and clinical effectiveness analysis among moist wound healing dressings versus traditional methods in home care patients with pressure ulcers. Souliotis K, Kalemikerakis I, Saridi M, et al. *Wound Repair Regen* 2016; 24: 596–601.

In this study, 85.56 ± 52.09 days was reported as the average healing time for moist-wound healing dressings group, while it was 121.4 ± 52.21 days for the 'gauze group'. The dressing change frequency per patient was lower in the moist wound healing dressings group, and total treatment cost was lower than the gauze group.

Third-Line Therapies

• Becaplermin gel	A
• Hyperbaric oxygen	E
• Honey	B
• Platelet-rich plasma	B
• Platelet-derived growth factor	C
• Electrical stimulation	A
• Negative pressure wound therapy	C
• Surgical management	D

Cost effectiveness of becaplermin gel on wound closure for the treatment of pressure injuries. Gilligan AM, Waycaster CR, Milne CT. *Wounds* 2018; 30: 197–204.

Becaplermin gel once daily plus good wound care (debridement, infection management, and moisture balance) showed substantially higher-pressure weeks free of ulcers when compared with control patients and had insignificantly increased cost.

Hyperbaric oxygen therapy for chronic wounds. Kranke P, Bennett MH, Martyn-St James M, et al. *Cochrane Database Syst Rev* 2012; 4: CD004123.

There are no satisfactory studies available to prove that hyperbaric oxygen is useful in pressure or arterial ulcers.

Atypical wounds; hyperbaric oxygen therapy (HBO). Benedict Mitnick CD, Johnson-Arbor K. *Clin Podiatr Med Surg* 2019; 36: 525–33.

HBO is the main treatment for decompression sickness, air embolism, and carbon monoxide poisoning, as well as an adjunctive treatment of extra medical conditions, with compromised grafts and flaps, chronic refractory osteomyelitis, and diabetic

foot ulcerations. Pressure ulcers are not one of the HBO indications suggested by the Undersea and Hyperbaric Medical Society.

Nonpharmacologic interventions to heal pressure ulcers in older patients: an overview of systematic reviews (the SENA-TOR-ONTOP series). Vézé-Díaz-Pallarés M, Lozano-Montoya I, Abraha I, et al. *J Am Med Dir Assoc* 2015; 16: 448–69.

The evidence grade is too low or insufficient to support the utilization of any support surface, nutrition intervention, multicomponent interventions, repositioning, or other adjunctive therapy (ultrasound, negative pressure, laser, electromagnetic, light, shock wave, hydrotherapy, radiofrequency, or vibration therapy) to increase the rates of pressure ulcer healing in older patients. Electrotherapy may demonstrate some beneficial effect in the treatment of pressure ulcers, although the quality of evidence is low.

Honey as a topical treatment for wounds. Jull AB, Cullum N, Dumville JC, et al. *Cochrane Database Syst Rev* 2015; 3: CD005083.

Honey has become in vogue for healing partial-thickness burns more quickly than conventional treatment (which included polyurethane film, paraffin gauze, Soframycin-impregnated gauze, sterile linen, and leaving the burns exposed) and healing infected postoperative wounds more quickly than antiseptics and gauze, but the evidence remains unconvincing.

Platelet-rich plasma improves healing of pressure ulcers as objectively assessed by digital planimetry. Volakakis E, Papadakis M, Manios A, et al. *Wounds* 2019; 31: 252–6.

Local applications of platelet-rich plasma (PRP) speed the healing of pressure ulcers when objectively assessed by digital planimetry. A magnificent reduction in the surface area, diameter, and circumference of PUs was seen after the application of PRP compared with conventional treatment.

Optimal use of negative pressure wound therapy (NPWT) in treating pressure ulcers. Gupta S, Ichioka S. *Int Wound J* 2012; 9: 8–16.

Retrospective research or case series were published for NPWT in patients with pressure ulcers. These show the effective use of NPWT on stage 3 and 4 pressure ulcers. The outcomes displayed an increase in granulation tissue formation reduction of fibrin tissue, diminishing necrosis. It is concluded by the writers that NPWT is reliable, effective, and user-friendly.

Negative pressure wound therapy for treating pressure ulcers. Dumville JC, Webster J, Evans D, et al. *Cochrane Database Syst Rev* 2015; 5: CD011334.

There is currently no rigorous randomized, controlled trial evidence available regarding the effects of NPWT compared with alternatives for the treatment of pressure ulcers.

Phototherapy for treating pressure ulcers. Chen C, Hou WH, Chan ES, et al. *Cochrane Database Syst Rev* 2014; 7: CD009224.

Trials compared the use of phototherapy with standard care only (six trials) or sham phototherapy (one trial). Among five studies reporting the rate of change in the ulcer area, three studies found no statistically remarkable difference between the two groups. These are very uncertain as to the effects of phototherapy in treating pressure ulcers. The quality of evidence is very low due to the unclear risk of bias and small number of trials available for analysis.

Electromagnetic therapy for treating pressure ulcers. Aziz Z, Bell-Syer SE. *Cochrane Database Syst Rev* 2015; 9: CD002930.

There is no strong evidence indicating benefits of using electromagnetic therapy to treat pressure ulcers; however, the possibility of a beneficial or harmful effect cannot be eliminated, because there were only two trials included, both with methodologic limitations and small numbers of participants.

Electrical stimulation for pressure injuries: a health technology assessment. Health Quality Ontario. *Ont Health Technol Assess Ser* 2017. PMID: 29201261.

There was a significant difference in wound surface area reduction favoring electrical stimulation compared with standard wound care; however, there was no significant difference in complete pressure injury healing between adjunct electrical stimulation and standard wound care.

Low-level laser therapy (LLT) in the treatment of pressure ulcers: systematic review. Machado RS, Viana S, Sbruzzi G. *Lasers Med Sci* 2017; 32: 937–44.

The use of LLT with a wavelength of 658 nm and a dose of 4 J/cm² showed significant results in the assessed outcomes, and evidence was not found with single wavelengths above it.

A review of the surgical management of heel pressure ulcers in the 21st century. Bosanquet DC, Wright AM, White RD, et al. *Int Wound J* 2016; 13: 9–16.

Surgical interventions, such as simple debridement, partial or total calcanectomy, arterial revascularization in the context of coexisting peripheral vascular disease, or using free tissue flaps may be the only means of encountering successful healing in stage 3 pressure ulcers. Amputation may be necessary for failed surgical intervention or as a definitive first-line procedure in certain high-risk or poor-prognosis patient groups.

A systematic review of complication and recurrence rates of musculocutaneous, fasciocutaneous, and perforator-based flaps for treatment of pressure sores. Sameem M, Au M, Wood T, et al. *Plast Reconstr Surg* 2012; 130: 67e–77e.

Surgery is usually necessary for the descriptive treatment of stage 3 and 4 pressure ulcers. Various reconstructive alternatives are available for skin coverage and filling dead space after debridement of pressure ulcers, containing regional musculocutaneous, fasciocutaneous, and, currently, perforator-based flaps. The writers' view showed no statistically significant difference in terms of recurrence or complication rates among musculocutaneous, fasciocutaneous, or perforator-based flaps.

Surgical treatment and strategy in patients with multiple pressure sores. Chiang IH, Wang CH, Tzeng YS. *Int Wound J* 2018; 15: 900–8.

Conservative management is insufficient for stage 3 or 4 pressure sores and surgery is unavoidable for creating flap coverage. Complete excision of all devitalized tissue in the wound and filling of the defect with a long-lasting and well-perfused flap are included in basic surgical principles to treat pressure sores. A treatment protocol of a multistaged surgery is recommended for old patients who have multiple pressure sores. This may provide a lessened surgery duration, less bleeding, and low complication rate, as well as an increased quality of life for the patient after sepsis control, and reduction of caregiver burden.

Delusions of parasitosis

Nicholas D. Brownstone, Quinn Thibodeaux, John Y.M. Koo

Delusions of parasitosis (DOP) is a form of delusional disorder, somatic type. It is a type of monosymptomatic hypochondriacal psychosis and is also known as Morgellons disease, delusions of infestation, and Ekbom disease. Patients with this disorder have cutaneous dysesthesias that cause them to pick at their skin continuously in order to 'extract' a perceived organism or 'foreign body'. The cutaneous findings that result from these attempts to dig out the suspected parasites range from normal skin to excoriations to frank ulcerations. Patients develop elaborate delusional ideations associated with their condition. Frequently, these patients often collect 'samples' in bottles, Ziploc bags, jars, or slides of what is often lint, hair, debris, dead skin, and even common insects found in the home, using these specimens to provide 'evidence'. Many of these patients can also have tactile hallucinatory experiences that are compatible with their delusion. The most characteristic hallucinatory symptom they may experience is formication. Many also complain of pruritus.

It is important early on in diagnosis to make an explicit distinction between primary and secondary DOP. Primary DOP happens spontaneously. Secondary DOP results from many varied causes, including illicit drug use (especially cocaine, narcotics, amphetamines), primary psychotic disorders (schizophrenia, psychotic depression), organic brain injury, and dementia, among other causes. If the patient has a suspected or confirmed history of illicit drug use, then a toxicology screen is useful as confirmation. If the patient has a confirmed or suspected history of an underlying broader mental health disorder, then referral to a psychiatrist is necessary. Secondary DOP are difficult to manage adequately in a dermatology practice. Treatment of the underlying disorder may resolve the DOP. Primary DOP can only be diagnosed once secondary causes have been ruled out.

The condition has a bimodal age distribution, occurring in younger adults (where there is an equal distribution of men and women) and the elderly (mostly women). Primary DOP are

mostly prevalent in older women, whereas secondary DOP are seen in any age group without a predilection for gender. There can be comorbid psychopathologies in DOP, such as depression and anxiety; these can be severe enough to cause the patient to commit suicide.

MANAGEMENT STRATEGY

The management strategy for secondary DOP is a referral to psychiatry. For suspected primary DOP, it is still imperative that the dermatologist carry out a detailed medical history to exclude a bona fide skin condition (e.g., scabies incognito) or other possible organic conditions, such as substance abuse, neurologic, endocrine, hematologic/oncologic, nutritional (e.g., B₁₂ or folate deficiency), or renal (e.g., uremic pruritus) disorders. The condition can also develop after the patient, relative, or pet has had a true parasitic infection, and so ruling out the presence of a real infestation is warranted.

Second, a thorough physical examination should be performed, including examining 'specimens' that the patient may bring. These specimens can be observed under the microscope, which help demonstrate to the patient that his or her concerns are being taken seriously. One should not make any comments that may reinforce their delusional ideation; this may ultimately render the patient more difficult to deal with by making him or her even more firmly fixated on the erroneous beliefs. On the other hand, by definition, rational argument or trying to talk a patient out of a delusion is both not possible and counterproductive. Dermatologists can acknowledge the patient's sensations and suffering as real and that they will do everything they can to help.

It is also important for the dermatologist to treat secondary skin damages in these patients to create a therapeutic alliance with the patient. Dermatologists should consider *soothing baths* and topical agents such as *creams with menthol* or the use of *occlusive dressings* to enhance healing and limit access to involved parts of the skin.

The most effective way to reverse delusional ideation is to start the patient on an *antipsychotic medication*. If this option is offered in a neutral way, emphasizing possible symptom reduction, such as reduced crawling, biting, or stinging sensations, while avoiding discussing pathophysiology or the mechanism of action of these medications, patients may be willing to accept the medication on a 'trial and error' basis.

The medication historically used to treat DOP is pimozide. The fact that pimozide is US Food and Drug Administration (FDA)-indicated only for Tourette syndrome with no psychiatric indications makes pimozide uniquely acceptable to those patients who are often intensely opposed to accepting a psychiatric medication. This medication generally works very well, whether patients have classic DOP or formication without delusions. The trapezoid dosing plan is used to describe the use of pimozide with regard to its dose titrations when treating DOP. The dose of pimozide can be increased by as little as 0.5 mg increments and as slowly as on a biweekly to monthly basis until significant clinical response is noted, which is usually evident at a dose of 3 mg daily or less. It is very rare that a patient will require a dose of more than 5 mg daily. If the patient continues to experience improvement, the dosage of pimozide can eventually be gradually reduced by as little as 0.5 mg every 2–4 weeks until the minimum necessary dosage is determined, or the patient is slowly tapered off the pimozide altogether.

If the clinical state deteriorates again in the future with a new episode of a delusional belief and formication, the patient can be restarted on pimozide and again treated on a time-limited

fashion to control the particular episode. Most patients can be treated on an episodic basis.

Because pimozide blocks dopaminergic receptors, there is the possibility that extrapyramidal side effects such as stiffness or akathisia may develop. If they do develop, however, they can usually be controlled with anticholinergic agents such as benztropine (Cogentin) 1–2 mg up to four times a day as needed, or diphenhydramine (Benadryl) 25 mg up to four times a day as needed. Side effects are not a reason for discontinuing treatment provided they are well controlled. Acute dystonic reaction and tardive dyskinesia are other potential adverse consequences associated with pimozide, although with the relatively low dosages used, these are extremely rare.

The metabolism of pimozide is catalyzed mainly by the cytochrome P450 3A4 (CYP 3A4) enzymatic system and, to a lesser extent, by cytochrome P450 1A2 (CYP 1A2) and cytochrome P450 2D6 (CYP 2D6). Individuals with genetic variations resulting in poor CYP 2D6 metabolism (approximately 10% of the population) exhibit higher pimozide concentrations than extensive CYP 2D6 metabolizers. The time to achieve steady-state pimozide concentrations is expected to be longer (about 2 weeks) in poor CYP 2D6 metabolizers because of the prolonged half-life. Alternative dosing strategies are recommended in patients who are genetically poor CYP 2D6 metabolizers. At doses above 4 mg/day, CYP 2D6 genotyping should be performed. In poor CYP 2D6 metabolizers, pimozide doses should not exceed 4 mg/day, and doses should not be increased earlier than 14 days (see FDA package insert for further information).

Because pimozide can theoretically prolong the QT interval or cause arrhythmias, it is advisable to consider checking electrocardiograms (ECGs) pretreatment and, periodically, during treatment, especially in older patients or those with a history of cardiac arrhythmia. Caution must also be exercised in prescribing pimozide for those with hepatic or renal dysfunction. Hypokalemia or hypomagnesemia is a contraindication to therapy. Therefore, a basic metabolic panel and magnesium (Mg) level should be checked before starting therapy.

Do not prescribe pimozide if a patient has a history of hypersensitivity to it or any components. Further contraindications include history of central nervous system (CNS) depression, history of cardiac arrhythmias, congenital long QT syndrome, and concurrent use with QTc-prolonging agents. Drugs that are inhibitors of CYP3A4 should not be used concurrently. Do not prescribe pimozide if a patient is on a selective serotonin reuptake inhibitor (SSRI) or stimulant.

Atypical antipsychotics, such as *risperidone* and *olanzapine*, have also been used successfully to treat patients with DOP. Atypical antipsychotics block more 5-HT₂ (serotonin) receptors than D₂ receptors. Serotonin has been shown to be a key player in some states of psychosis, most cases of obsessive-compulsive disorder, and self-mutilation, which can all potentially manifest in patients with DOP. Thus, atypical antipsychotics, by blocking both serotonin and dopaminergic receptors, are thought to be an effective choice for treating this condition. Furthermore, the burden of side effects with atypical antipsychotics may be reduced compared with that of older typical antipsychotics. Having the patient agree to go on risperidone or olanzapine, however, may be more difficult than pimozide; the primary indication for risperidone and olanzapine is schizophrenia, with the latter indication likely being unacceptable to many patients with DOP.

Nevertheless, over the past several years, clinicians have reported many successful cases using atypical antipsychotics. It is usually advisable to start at low doses and titrate upward as needed. For example, for risperidone, start from 0.5 mg once to

twice daily, and work up to the effective dose for that particular patient with the usual maximal dose of 5 mg daily. While not widely studied in DOP, the recommended dose for olanzapine ranges from 2.5 mg/day to 7.5 mg/day. The dose should not exceed 10 mg/day.

Even with a skillful interpersonal approach, as described earlier, patients may be reluctant to take a psychotropic medication. It may be helpful to emphasize to them that these medications have worked well with patients with similar symptoms and that, in light of their intense suffering and misery, they are encouraged to try the medication with the spirit of 'trial and error'. Even though managing psychotic patients in dermatologic settings has many challenges, when a dermatologist succeeds in connecting with these patients and dramatically reversing their very miserable situation, these patients often turn out to be the most grateful patients a dermatologist can have in their career.

Specific Investigations

These additional tests may be considered, depending on the patient's clinical presentation:

- Complete blood count
- Complete metabolic panel, including liver function tests
- Thyroid function tests
- Serum B₁₂, ferritin
- ECG before initiation of pimozide and periodically while on pimozide, if indicated
- Drug screen
- Magnesium level
- BMI and waist circumference
- HbA1c and fasting plasma glucose
- Fasting lipid panel

Delusions of parasitosis: a brief review of the literature and pathways for diagnosis and treatment. Laidler N. *Dermatol Online J* 2018; 24(1): 13030/qt1fh739nx.

This review article analyses 17 case reports examining the use of risperidone and olanzapine in the treatment of DOP. These findings are synthesized into a clinical pathway designed to assist dermatologists in effectively managing patients with DOP.

Delusions of parasitosis; suggested dialogue between dermatologist and patient. Patel V, Koo JY. *J Dermatolog Treat* 2015; 26: 456–60.

This article is a practical guide that suggests verbatim how a dermatologist might talk to a delusional patient in order to develop a strong therapeutic rapport. Strategies on how to optimize the initial encounter, build rapport, and prescribe antipsychotic medications that are likely to be accepted by the patient are discussed.

Contemporary diagnosis and management in advanced psychodermatology. Nguyen CM, Beroukhim K, Danesh MJ, et al. *Longboat Key: Handbooks in Health Care*, 2015.

This is a comprehensive handbook on psychodermatology, including diagnosis and management of patients with DOP.

Delusions of parasitosis: ethical and clinical considerations. Fabbro S, Aultman JM, Mostow N. *J Am Acad Dermatol* 2013; 69: 156–9.

A case is presented that demonstrates the dermatologist's dilemma when treating patients with primary psychiatric disease. There is a discussion on the best clinical and ethical action, using principle- and narrative-based approaches in ethical reasoning.

Delusional infestation is typically comorbid with other psychiatric diagnoses: review of 54 patients receiving psychiatric evaluation at Mayo Clinic. Hylwa SA, Foster AA, Bury JE, et al. *Psychosomatics* 2012; 53: 258–65.

This retrospective study found that 74% of patients with delusional infestation have multiple coexisting or underlying psychiatric disorders. Therefore, evaluation by a psychiatrist, when possible, is advised for all patients with delusional infestation.

Diffuse pruritic lesions in a 37-year-old man after sleeping in an abandoned building. Dunn J, Murphy MB, Fox KM. *Am J Psychiatry* 2007; 164: 1166–72.

This is an excellent case presentation of a patient with DOP and contains a thorough discussion of the differential diagnosis.

First-Line Therapy

- Pimozide B

Pimozide in dermatologic practice: a comprehensive review. Lorenzo CR, Koo J. *Am J Clin Dermatol* 2004; 5: 339–49.

This article reviews the utility of pimozide in dermatologic conditions.

Delusional parasitosis: a dermatologic, psychiatric, and pharmacologic approach. Driscoll MS, Rothe MJ, Grant-Kels JM, et al. *J Am Acad Dermatol* 1993; 29: 1023–33.

Pimozide is suggested as the first line of therapy for this psychodermatologic condition. Relapse often occurs upon discontinuation of the drug.

Second-Line Therapies

- Risperidone D
- Olanzapine D
- Quetiapine E
- Aripiprazole E
- Ziprasidone E
- Trifluoperazine E
- Haloperidol E
- Sulpiride E
- Fluphenazine E
- Flupenthixol E
- Promazine E

Second-generation antipsychotics in primary and secondary delusional parasitosis: outcome and efficacy. Freudenmann RW, Lepping P. *J Clin Psychopharmacol* 2008; 28: 500–8.

The first retrospective case-based analysis of 63 cases from 434 available publications to determine the efficacy and outcome of second-generation antipsychotic agents. It was found that risperidone and olanzapine were the most frequently used of these agents, with full or partial remission in 69% and 72% of cases, respectively.

Therapeutic update: use of risperidone for the treatment of monosymptomatic hypochondriacal psychosis. Elmer KB, George RM, Peterson K. *J Am Acad Dermatol* 2000; 43: 683–6.

The authors discuss risperidone as being highly effective for DOP while avoiding the negative long-term side effects of pimozide (as discussed earlier).

Primary delusional parasitosis treated with olanzapine. Freudenmann RW, Schönfeldt-Lecuona C, Lepping P. *Int Psychogeriatr* 2007; 19: 1161–8.

A case report of an elderly woman with DOP successfully and safely treated with olanzapine monotherapy. A dosing regimen is recommended. The authors also present a review of all articles that report the use of atypical antipsychotics for DOP. Of note, dosing regimens for olanzapine are also offered in the two following publications:

Successful treatment of delusions of parasitosis with olanzapine. Meehan WJ, Badreshia S, Mackley CL. *Arch Dermatol* 2006; 142(3): 352–5.

Delusional parasitosis mimicking cutaneous infestation in elderly patients. Le L, Gonski PN. *Med J Aust* 2003; 179(4): 209–10.

Antipsychotic treatment of primary delusional parasitosis: systematic review. Lepping P, Russell I, Freudenmann RW. *Br J Psychiatry* 2007; 191: 198–205.

This article is a systematic review of the use of typical and atypical antipsychotics in patients with DOP. Analyses showed that both typical and atypical antipsychotics were effective in the majority of patients. Particularly effective antipsychotics resulting in full or partial remission were pimozide, trifluoperazine, haloperidol, sulpiride, fluphenazine, and flupenthixol.

Dermatitis artefacta

Bridget Myers, Quinn Thibodeaux, John Y.M. Koo

Dermatitis artefacta (DA), also known as *factitious dermatitis*, is a rare psychiatric condition in which patients self-induce a variety of skin lesions. The motive for creating the lesions is often a conscious or unconscious psychological need to seek attention or play the 'sick role,' possibly due to childhood feelings of abandonment or neglect. DA is unique from *psychogenic excoriation*, a disorder characterized by excessive scratching or picking of one's skin. While both DA as well as psychogenic excoriation can result in significant disfigurement and distress, psychogenic excoriation is used to describe superficial excoriations caused by nail or finger manipulation only. In contrast, DA is used to diagnose self-inflicted cutaneous wounds that are more severe than simple excoriations; it is often generated using sharp instruments, cigarette butts, or injecting feces into one's skin.

Of patients presenting to dermatology with a primary psychiatric condition, 23% of them have DA. DA occurs in a four-to-one ratio of female-to-male patients, with an average age of onset of 12.5 years old. Certain populations, such as healthcare workers and those of lower socioeconomic class, exhibit greater prevalence of DA versus the general population. DA is associated with both childhood abuse and childhood psychiatric disorders. Recent studies suggest that a large proportion of patients with DA have comorbid anxiety, depression, or borderline personality disorder.

To diagnose DA, a detailed history is necessary to uncover any significant stressors, social issues, or underlying psychological diseases. When DA patients are asked about the nature in which their lesions developed, they will often be vague and deny any responsibility. Their disposition is classically described

as inappropriately unconcerned or pleasantly detached, a unique feature termed *hollow history*.

Appearance of DA lesions is variable and depends on what tool or method is used to harm the skin, such as heat, boiling or ice-cold water, chemicals, injection of foreign materials, or tampering with old lesions, such as existing scars or surgical incision sites. Lesions can range in severity from tiny cuts to large areas of trauma, and may include ulcers, burns, erosions, bullae, purpura, hyperpigmentation, ecchymosis, excoriations, or lichenification. Significant disfigurement may result, with more serious lesions posing risk of abscess formation, gangrenous necrosis, or life-threatening infection. Signs of DA-related lesions are different stages of healing, surrounding normal-appearing skin, location in easy to reach areas, and irregular or bizarre morphology. Patients are often otherwise healthy.

The diagnosis of DA is one of exclusion that is difficult to verify, as patients seldom admit to their involvement in producing the lesions. It is important to have a broad differential diagnosis, as DA is capable of mimicking several conditions. First, it is important to consider malingering. If skin lesions are created deliberately for secondary gain, such as to obtain disability or insurance benefits, then the case is no longer considered psychiatrically-based, but instead an act of fraud. However, if skin lesions are created without an underlying material or personal gain, then it is considered an illness warranting medical and psychiatric intervention.

Second, it is important to consider Munchausen syndrome and Munchausen syndrome by proxy, which involves deceptively presenting one's self or another (a victim), respectively, as ill or injured, without obvious external reward. While similar in presentation, Munchausen patients often have an embellished explanation for their condition, with an extensive history of hospital admits and other organ involvement. In Munchausen by proxy, mentally ill individuals make up or cause illness or injury to another, typically a child or even a baby, who are unable to speak for themselves. Finally, since DA frequently occurs in adolescents, it is important to have a low threshold for suspecting physical or sexual abuse in these patients.

MANAGEMENT STRATEGY

Management of DA can be challenging, with most therapeutic options symptomatic and supportive. Topical treatment is first line, and may include bandages, dressings, emollients, baths, or antibiotics. *Protective dressings*, such as an Unna boot, are used to occlude involved areas and protect against further self-injurious behavior.

The mainstay of DA treatment is addressing the patient's underlying psychopathology and behavioral patterns, which could be done with different types of therapy, such as cognitive behavior therapy or psychotherapy. Psychotropic medications are useful in some cases, with appropriate agents depending on patients' underlying psychological issues. *Antidepressant medications*, such as *selective serotonin reuptake inhibitors*, could be helpful for patients with DA and primary or secondary depression. If there is clinical evidence of a psychotic process, *pimozide* could be considered. There have also been case reports of patients responding to *olanzapine*, an atypical antipsychotic, after other therapies failed. A multidisciplinary approach to management, between dermatologists and mental health professionals, is often necessary.

Physicians should be aware that DA patients have a psychiatric illness, and the skin lesions are often a cry for help. However, suggesting the lesions are psychiatrically based often has a negative effect on patient rapport. Direct confrontation should be avoided,

if possible, and instead, a *supportive environment* and *stable physician–patient therapeutic alliance* should be fostered. This is often done with short and frequent office visits.

With an adolescent patient, the clinician should encourage the parents to become involved in identifying psychosocial stressors and helping to modify the patient's environment to meet his or her needs. Certain parents could be resistant to their child's diagnosis and may become angry or critical toward the clinician. If there is intense antagonism between the adolescent patient and the parents, it may be advisable to see the patient alone to optimize the possibility of developing therapeutic rapport. Once the patient establishes trust in his or her physician, through a stable relationship, the physician may then help the patient recognize the psychosocial nature of their disorder and *recommend psychiatric consultation*.

Most DA patients have a chronic waxing and waning course of disease that fluctuates with life circumstances. Even when DA is under control, physicians should continue to follow patients at regular intervals to prevent a relapse in self-destructive behavior. *Regular visits*, whether or not the lesions are present, will help patients feel cared for and diminish the conscious or unconscious desire to self-harm.

Specific Investigations

- Rule out malingering
- Rule out any organic dermatologic disease
- Assess for associated psychiatric disorders (e.g., depression)

Dermatitis artefacta. Lavery MJ, Stull C, McCaw I, et al. Clin Dermatol 2018; 719–22.

An up-to-date review of DA.

Dermatitis artefacta and artefactual skin disease: the need for a psychodermatology multidisciplinary team to treat a difficult condition. Mohandas P, Bewley A, Taylor R. Br J Dermatol 2013; 169(3): 600–6.

Retrospective review of 28 DA cases. Suggests that a combined approach with both dermatology and mental health professionals results in improved patient outcomes.

First-Line Therapies

• Occlusive dressings	D
• Psychotropic agents	D
• Psychotherapy (even if only supportive)	D
• Management of secondary cutaneous complications	D

Second-Line Therapy

• Olanzapine	D

The current management of delusional parasitosis and dermatitis artefacta. Koblenzer CS. Skin Therapy Lett 2010; 15: 1–3.
Review of DA treatment, including the use of aripiprazole.

Self-inflicted skin diseases. A retrospective analysis of 57 patients with dermatitis artefacta seen in a dermatology department. Nielsen K, Jeppesen M, Simmelsgaard L, et al. Acta Derm Venereol 2005; 85: 512–5.

Retrospective analysis of 57 DA patients.

Treatment of self-mutilation with olanzapine. Garnis-Jones S, Collins S, Rosenthal D. J Cutan Med Surg 2000; 4: 161–3.

Three DA patients successfully treated on low-dose olanzapine therapy following failure of other treatment modalities.

Training future dermatologists in psychodermatology. Van Moffaert M. Gen Hosp Psychiatry 1986; 8: 115–8.

Palliative dermatologic measures such as occlusive bandages, ointments, or placebo drugs can therapeutically impact the psychiatric problem by symbolizing the medical attention and care the patient with DA is craving.

Artefactual skin disease in children and adolescents. Rogers M, Fairley M, Santhanam R. Aust J Dermatol 2002; 42(4): 264–270.

DA lesions often on children's head or neck. Non-confrontation with the child is recommended, but parents should be clearly explained the diagnosis so they understand the child's need for psychiatric help.

Dermatitis herpetiformis

Bridget E. Shields, John J. Zone

Dermatitis herpetiformis (DH) is a cutaneous manifestation of celiac disease (CD). More than 85% of patients with DH have a gluten-sensitive enteropathy (CD) that varies in clinical and histologic severity. The skin and intestinal disease both respond to gluten restriction. DH symptoms range from minimally pruritic papules on the elbows and knees to severe, intensely pruritic vesicles over multiple extensor surfaces (see figure). The prevalence of DH is 10–39 per 100,000 persons in the Caucasian population and occurs most frequently in those of northern European descent. CD is rare in those with DH in the Japanese population. One in six patients diagnosed with CD has DH. DH is distinguished from other bullous diseases by characteristic histologic, immunologic, and gastrointestinal findings. Histologically, vesicle formation at the dermal–epidermal junction and infiltration of dermal papillary tips with neutrophils occurs in two-thirds of cases; however, non-specific inflammation is also frequent. Direct immunofluorescence shows granular or fibrillar IgA localized in the dermal papillary tips or along the basement membrane of perilesional skin.

MANAGEMENT STRATEGY

If patients adhere to a strict gluten-free diet, they are likely to undergo long-term remission. Associated intestinal symptoms are minimized and relapses are usually associated with dietary indiscretions. Elevated levels of IgA antibodies to tissue transglutaminase (TG2) are characteristic of CD. Levels correlate with the degree of intestinal inflammation and decrease with gluten restriction. Elevated levels of IgA epidermal transglutaminase (TG3) antibodies are characteristic of DH and are responsible for the diagnostic IgA deposits in skin. Serum levels of both antibodies correlate with response to a gluten-free diet but are not affected by dapsone. DH can be well controlled with medical therapies such as dapsone or sulfapyridine alone, but intestinal symptoms, if present, will continue unabated and contribute to the risk of small intestine lymphoma. Cutaneous disease recurs in 24–72 hours if dapsone is discontinued. Rare patients will enjoy spontaneous DH remission without medical therapy or dietary restriction.

Dapsone is the drug of choice for DH and is currently the only drug approved by the US Food and Drug Administration for DH. We recommend initial treatment with low-dose dapsone at 25 mg daily. Pruritus will usually improve within 24–48 hours and the papulovesicular lesions within 1 week. Correspondingly smaller doses (0.5–1 mg/kg) should be used in children. Maintenance therapy is then adjusted on a weekly basis to maintain adequate suppression of symptoms. The average maintenance dose is 0.5–1.0 mg/kg daily. Despite adequate dapsone dosages, outbreaks of facial and scalp lesions are common.

Adherence to a gluten-free diet (GFD) improves clinical symptoms in patients with DH. Gluten restriction targets the cause of disease as well as the symptoms. Advantages include a reduction in dapsone dosage, improvement in gastrointestinal symptoms, and reduced risk of lymphoma incident to DH and CD, a benefit not seen with dapsone. Strict adherence to a GFD is challenging, and reintroduction of gluten can exacerbate DH. Rare patients will not respond to gluten restriction. In the author's opinion, a useful therapeutic strategy is the initial control of DH symptoms with dapsone coincident with a GFD with subsequent tapering of dapsone. Oats have been found to be non-toxic in most patients with DH and may broaden gluten-free dietary options.

Sulfapyridine is an alternative in patients intolerant to dapsone and offers significant therapeutic efficacy. Sulfapyridine is started at 500 mg three times a day and is increased to a maximum maintenance dose of 1.5 g three times a day. Virtually all DH patients respond to dapsone, but some patients may not respond to sulfapyridine at any dose.

Nicotinamide, tetracycline (or a combination of the two), heparin, ciclosporin, colchicine, rituximab, and systemic corticosteroids have been reported to provide therapeutic benefit in DH. Topical corticosteroid application is generally inadequate when used alone to control DH symptoms. Potent corticosteroids in gel form applied frequently may provide relief for occasional lesions that develop on otherwise adequate dapsone or GFD therapy. Ultraviolet light may provide symptomatic relief. Patients with refractory disease should be screened for iodide ingestion, which can exacerbate DH and has been found in medications, contrast media, dental packing strips, food sources, and dietary supplements.

Specific Investigations

- Lesional biopsy for histology and perilesional biopsy for direct immunofluorescence
- Complete blood count and liver function tests
- Glucose-6-phosphate dehydrogenase levels
- IgA tissue transglutaminase (TG2) antibodies
- IgA epidermal transglutaminase (TG3) antibodies

Deposition of granular IgA relative to clinical lesions in dermatitis herpetiformis. Zone JJ, Meyer LJ, Petersen MJ. Arch Dermatol 1996; 132: 912–8.

Granular IgA deposition in perilesional, clinically normal-appearing skin is the most reliable diagnostic criterion for DH. The diagnosis of DH should not be made without identification of granular IgA in dermal papillae. Linear IgA disease demonstrates identical histology but does not respond to a GFD. These disorders can only be separated on direct immunofluorescence. If direct immunofluorescence is negative and histology is suggestive of DH, a repeat biopsy for direct immunofluorescence is recommended.

Dermatitis herpetiformis: from the genetics to the development of skin lesions. Bonciani D, Verdelli A, Bonciolini V, et al. Clin Dev Immunol 2012; 2012: 239691.

DH is a cutaneous manifestation of CD. The pathogenesis involves an immune response in genetically susceptible individuals (HLA-DQ2 and -DQ8) to dietary gliadin peptides complexed with tissue transglutaminase (TG2). IgA TG2 antibodies are an index of the severity of intestinal involvement and correlate with response to gluten restriction. IgA epidermal transglutaminase (TG3) antibodies are present in the serum of new DH patients and are complexed with TG3 to form the diagnostic immune complexes in the skin of DH patients.

First-Line Therapies

• Dapsone	B
• Gluten-free diet	B

Suggested guidelines for patient monitoring: hepatic and hematologic toxicity attributable to systemic dermatologic drugs. Wolverson SE, Remlinger K. Dermatol Clin 2007; 25: 195–205.

Dapsone may produce a drug hypersensitivity syndrome with liver toxicity in the first 3–12 weeks. Monitoring of the aspartate transaminase (AST), alanine transaminase (ALT), and eosinophil count is indicated. Hepatocellular toxicity may occur in a dose-related fashion, especially with doses greater than 2 mg/kg. AST and ALT should be monitored when dapsone dosage is increased. There are three main hematologic toxicities of dapsone: hemolysis, methemoglobinemia, and agranulocytosis. Methemoglobinemia is usually mild and not problematic unless the patient has underlying cardiopulmonary problems. Agranulocytosis is rare and usually occurs in the first 3–12 weeks of therapy. Symptoms demanding attention include pharyngitis, fever, and oral ulcerations. Virtually all patients have some degree of hemolysis and a decrease in hemoglobin of 1–3 g/dL is expected. Initiation of small doses of dapsone (25 mg daily) and gradual dose increases will minimize these symptoms. A compensatory reticulocytosis occurs. Hemolysis may be severe in patients with glucose-6-phosphate dehydrogenase deficiency. Glucose-6-phosphate dehydrogenase levels should be evaluated prior to the initiation of therapy to avoid catastrophic hemolytic anemia.

Complete blood count and liver function tests should be checked every 2–3 weeks for the first 3 months, then every 3–6 months thereafter.

A long-term gluten-free diet as an alternative treatment in severe forms of dermatitis herpetiformis. Nino M, Ciacci C, Delfino M. J Dermatolog Treat 2007; 18: 10–2.

The treatment of DH with a GFD alone compared to GFD and dapsone was reported. Eighty-seven percent of patients on GFD alone had a complete remission in 18 months (67% of severe patients). A total of 89% of patients on diet and dapsone had remission of skin disease (70% of severe patients) and 11% were improved.

Second-Line Therapies

• Sulfapyridine and sulfasalazine	E
• Elemental diet	C

Management of dermatitis herpetiformis. Cardones AR, Hall RP. Dermatol Clin 2011; 29(4): 631–5. doi: 10.1016/j.det.2011.06.015.

Sulfapyridine is not readily available in the United States but can be prescribed through compounding pharmacies. Sulfasalazine, which is more readily available, is metabolized to 5-amino-salicylic acid and sulfapyridine. Patients have responded to sulfasalazine, 2–6 g/day, administered three times daily.

The effect of elemental diet with and without gluten on disease activity in dermatitis herpetiformis. Kadunce DP, McMurtry MP, Avots-Avotins A, et al. J Invest Dermatol 1991; 97: 175–82.

In refractory DH, elemental diet therapy is effective and produces dramatic clinical improvement within 2–4 weeks. It involves the ingestion of amino acid and carbohydrate alone and is commercially available as Vivonex. It produces rapid healing of the intestine and relief of cutaneous symptoms but was designed for tube feeding and is considered unpalatable by many.

In this author's experience, an elemental diet containing short chain polypeptides is less effective.

Third-Line Therapies

• Tetracycline and nicotinamide	E
• Heparin	E
• Cyclosporin	E
• Colchicine	E
• Systemic corticosteroids	E
• Rituximab	E
• Topical dapsone	E

Dermatitis herpetiformis effectively treated with heparin, tetracycline and nicotinamide. Shah SAA, Ormerod AD. Clin Exp Dermatol 2000; 25: 204–5.

Case report of a patient with severe DH, intolerant to dapsone and sulfapyridine, who achieved DH resolution with subcutaneous low-dose heparin, nicotinamide 1.5 g daily in divided doses, and tetracycline 2 g daily. The patient was on a GFD.

A rare case of dermatitis herpetiformis requiring parenteral heparin for long-term control. Tan CC, Sale JE, Brammer C, et al. Dermatology 1996; 192: 185–6.

A patient with severe DH, intolerant to dapsone and sulfapyridine, was treated with parenteral heparin with complete resolution of her skin lesions within 1 week of therapy. This treatment is not practical for long-term management.

Efficacy of cyclosporine in two patients with dermatitis herpetiformis resistant to conventional therapy. Stenveld HJ, Starink TM, van Joost T, et al. J Am Acad Dermatol 1993; 28: 1014–5.

Two patients with severe DH who were intolerant and/or unresponsive to conventional therapy were treated with cyclosporin (5–7 mg/kg daily) with resolution of skin lesions.

Dermatitis herpetiformis responsive to systemic corticosteroids. Lang PG. J Am Acad Dermatol 1985; 13: 513–5.

A patient with DH was treated successfully with a short course of prednisone and remained clear 4 months after discontinuation. He was successfully re-treated with systemic corticosteroids for recurrence of the skin lesions.

Treatment of dermatitis herpetiformis with colchicine. Silver DN, Juhlin EA, Berczeller PH, et al. Arch Dermatol 1980; 116: 1373–84.

Oral colchicine resulted in significant improvement of skin lesions in three of four patients with DH. The authors suggest that colchicine may be used when dapsone or sulfapyridine is contraindicated.

Rituximab treatment for recalcitrant dermatitis herpetiformis. Albers LN, Zane JJ, Stoff BK, et al. JAMA Dermatol 2017; 153(3): 315–8.

A man with DH unresponsive to dapsone and conventional immunosuppressive therapies was poorly adherent to a GFD. He underwent treatment with rituximab (4 weekly infusions of 375 mg/m²), which resulted in complete and sustained resolution of symptoms. IgA TG2 and TG3 antibody levels returned to normal.

Rituximab treatment for dermatitis herpetiformis in the setting of type 1 diabetes mellitus, celiac disease, vitiligo,

autoimmune hemolytic anemia, and autoimmune thrombocytopenia. Nguyen KT, Gwinn CC, Vary JC. JAAD Case Rep 2020; 6(2): 122–3.

A man with DH and multiple autoimmune diseases (including hemolytic anemia) precluding the use of dapsone was treated with oral prednisone (1–1.5 mg/kg/day) and rituximab (375 mg/m² per week for 4 weeks). He required the addition of a 4-day course of dexamethasone (40 mg daily) and mycophenolate mofetil (500 mg twice daily), which resulted in DH quiescence. The patient remained clear following steroid taper.

Topical dapsone gel as an effective therapy in dermatitis herpetiformis. Burbidge T, Haber RM. J Cutan Med Surg 2016; 20(6): 600–1.

A 66-year-old woman with intermittent flares of DH treated with topical dapsone 5% gel twice daily as she transitioned to a GFD, resulting in dramatic improvement.

Dermatofibrosarcoma protuberans

*Cristian Navarrete-Dechent, Shoko Mori,
Kishwer S. Nehal*

Dermatofibrosarcoma protuberans (DFSP) is a rare soft tissue tumor that represents 0.1% of all cancers and 1.8% of all soft tissue sarcomas. However, it is the most common type of cutaneous sarcoma, mainly affecting adults (30–50 years). Congenital and pediatric cases are rare. DFSP is slightly more common in females (1.14-fold) and Blacks (twofold compared to Whites). The most frequent location is the trunk (42%–49%), followed by the extremities (37%; typically upper extremities), and the head and neck region (13%–16%).

DFSP typically has an indolent growth pattern; however, it has the potential for subclinical extension, morbidity, and local recurrence. DFSP is also associated with a low (2%–5%) risk of metastasis. The 10-year disease-specific survival is 99.1% (97.6%–99.7%). When fibrosarcomatous changes (FS) are found, it is associated with a higher rate of local recurrence, distant metastasis, and decreased survival.

Dermatofibrosarcoma protuberans. Mendenhall WM, Zlotnicki RA, Scarborough MT. *Cancer* 2004; 101: 2503–8.

In this narrative review, the authors discuss the pathophysiology of DFSP as well as its prognosis and histopathological features.

Dermatofibrosarcoma protuberans: a clinicopathologic analysis of patients treated and followed at a single institution. Bowne WB, Antonescu CR, Leung DH, et al. *Cancer* 2000; 88: 2711–20.

In this study with 159 patients, 84% had the classic DFSP variant and 16% had the more aggressive FS-DFSP type. The overall 5-year local recurrence-free survival rate was 75%. Two patients died of metastatic disease.

Incidence and survival of primary dermatofibrosarcoma protuberans in the United States. Kreicher KL, Kurlander DE, Gittleman HR, et al. *Dermatol Surg* 2016; 42 Suppl 1: S24–31.

In this study with almost 7000 patients using the SEER database from 2000 to 2010, the authors found a stable incidence. The trunk was the most common anatomic site. Incidence among women was 1.14 times higher than men. Incidence among Blacks was almost two times the rate among Whites. Ten-year relative survival of DFSP was 99.1% (95% CI: 97.6–99.7).

Prognostic factors, treatment, and survival in dermatofibrosarcoma protuberans. Criscito MC, Martires KJ, Stein JA. *JAMA Dermatol* 2016; 152: 1365–71.

In this study using the SEER database, older age at diagnosis, male sex, and DFSP tumor size were significantly associated with poorer overall survival in a controlled analysis.

Fibrosarcomatous ('high-grade') dermatofibrosarcoma protuberans: clinicopathologic and immunohistochemical study of a series of 41 cases with emphasis on prognostic significance. Mentzel T, Beham A, Katenkamp D, et al. *Am J Surg Pathol* 1998; 22: 576–87.

The fibrosarcomatous variant of dermatofibrosarcoma protuberans (FS-DFSP) represents an uncommon form of DFSP. In this study including 41 cases, FS-DFSP represented a form of tumor progression and was associated with a significantly more aggressive clinical course.

Specific Investigations

- Skin biopsy including subcutis
- Immunostains (e.g., CD34)
- Genetic studies (e.g., FISH)
- Imaging (e.g., magnetic resonance imaging [MRI], ultrasound, PET-CT) to evaluate local and systemic extent of disease

Clinically, DFSP presents as an indurated, irregular, usually skin-colored, subcutaneous tumor, which may display telangiectasia. Rare, pigmented variants exist (Bednar tumor). Differential diagnosis includes dermatofibroma, scar/keloid, epidermal cyst, and lipoma. Definitive diagnosis should be based on biopsy and histopathologic findings. DFSP is frequently misdiagnosed due to inadequate tissue sampling or superficial biopsy. A biopsy, such as a punch or full-thickness incision, needs to include the subcutaneous tissue. Undermining at the time of biopsy is not recommended due to difficulty in reinterpreting re-excisions and possible tumor seeding.

Dermatofibrosarcoma protuberans is a unique fibrohistiocytic tumour expressing CD34. Aiba S, Tabata N, Ishii H, et al. *Br J Dermatol* 1992; 127: 79–84.

On histopathology, a diffuse infiltration of the dermis and subcutaneous adipose tissue with spindle-shaped, tightly packed, neoplastic cells is seen. These cells are arranged in a classic 'storiform' pattern (reminiscent of a straw mat). On immunostains, DFSP typically is diffusely positive for CD34 and negative for Factor XIIIa (FXIIIa). In contrast, dermatofibroma, a benign dermal tumor, is negative for CD34 and positive for FXIIIa.

Subcutaneous dermatofibrosarcoma protuberans, a rare subtype with predilection for the head: a retrospective series of 18 cases. Lombart B, Serra-Guillen C, Rubio L, et al. *J Am Acad Dermatol* 2017; 77: 503–11 e1.

Recently, a purely subcutaneous variant (without dermal involvement) has been described. This subcutaneous DFSP variant more frequently involves the head and neck area, extends to the periosteum, and requires a greater number of stages to clear on Mohs surgery.

Genetics of dermatofibrosarcoma protuberans family of tumors: from ring chromosomes to tyrosine kinase inhibitor treatment. Sirvent N, Maire G, Pedetour F. *Genes Chromosomes Cancer* 2003; 37: 1–19.

DFSP is characterized genetically by a translocation involving chromosome 17 and 22 in greater than 90% of cases. Most commonly, the translocation is caused by a supernumerary ring chromosome.

Deregulation of the platelet-derived growth factor β -chain gene via fusion with collagen gene *COL1A1* in dermatofibrosarcoma protuberans and giant-cell fibroblastoma. Simon MP, Pedetour F, Sirvent N, et al. *Nat Genet* 1997; 15: 95–8.

The t(17:22) mutation leads to collagen type I alpha (*COL1A1*) and platelet-derived growth factor subunit β (*PDGF β*) gene fusion, resulting in the expression of the *COL1A1*-*PDGF β* fusion protein. *PDGF β* is a potent mitogen for mesenchymal cells with autocrine and paracrine activation of the *PDGF* receptor (*PDGFR*) on tumor cells; *PDGF β* activates the Ras MAPK and PI3K-AKT-mTOR pathway leading to uncontrolled cell growth. The identification of the aberrant activation of the *PDGF* pathway led to the utilization of imatinib, a *PDGFR* inhibitor, in the treatment of locally advanced and metastatic DFSP cases.

There is a lack of optimal imaging to assess tumor extension and monitor treatment in DFSP, as evaluation on clinical grounds alone may be inaccurate. This limitation is particularly problematic in patients who do not undergo surgery, either due to significant tumor extension or due to high risk of cosmetic deformity or functional impairment, and who may be eligible for treatment with tyrosine kinase inhibitors.

Correlation between preoperative magnetic resonance imaging and surgical margins with modified Mohs for dermatofibrosarcoma protuberans. Serra-Guillen C, Sanmartin O, Llobart B, et al. *Dermatol Surg* 2011; 37: 1638–45.

MRI with contrast is the likely imaging of choice as it provides better sensitivity than palpation for detecting deep invasion (67% vs 58%); however, MRI can underestimate the depth and area of involvement compared with histopathology. In cases of metastatic disease, a PET-CT may be useful to evaluate systemic dissemination.

MANAGEMENT STRATEGY

Surgery is the standard of care for the majority of DFSP cases. Surgical approaches include wide local excision (WLE), *Mohs micrographic surgery* (MMS), and other modified surgical approaches with comprehensive margin assessment (e.g., Tubingen technique). National Comprehensive Cancer Network (NCCN) guidelines recommend meticulous planning of the surgical approach. Every effort should be made to obtain negative margins as inadequate initial resection may result in local recurrence or increased risk of metastasis. Exhaustive surgery is recommended until margins are clear even if reexcision is required. Resection may be achieved by either WLE with 2–3 cm margins down to the fascia or with surgical techniques that entail a complete circumferential margin assessment (such as MMS or the Tubingen

technique). Reconstruction and tissue rearrangement/flap should be delayed until negative margins are confirmed.

Surgery (either WLE or MMS) is the cornerstone of treatment for DFSP according to the NCCN and every attempt should be made to obtain clear margins. There are cases, however, in which DFSP is unresectable due to tumor extension/size, or risk of cosmetic or functional impairment, such as tumors located on the head and neck, genitalia, or hands and feet. Similarly, some patients may be inoperable due to medical comorbidities.

For larger tumors where surgical resection in the office with local anesthesia is not feasible, surgery with general anesthesia in the operating room may be needed. These cases tend to have a higher recurrence rate and a worse prognosis due to larger size, multiple recurrences, and more aggressive pathology. Differences in cohorts between patients treated in an outpatient setting versus operating room may not be comparable and subject to referral/selection bias.

Radiation therapy (RT) might be considered as a treatment alternative for DFSP. This tumor is considered to be radiosensitive and RT may be used for cases with a high risk of recurrence (microscopic or macroscopic positive margins; adjuvant RT).

Radiation is not recommended in younger patients (under the age of 50 because of increased risk of radiodermatitis, scarring, and second malignancies) or in patients with a previous history of RT. Radiation may be contraindicated in patients with connective tissue diseases or genetic conditions predisposing to skin cancer (e.g., patients with Gorlin syndrome or xeroderma pigmentosum). Combined conservation resection and postoperative radiation could be considered for situations where adequate wide excision alone would result in major cosmetic or functional morbidity. Inoperable, recurrent, and metastatic tumors show significant responses to *imatinib*.

First-Line Therapies

• Mohs micrographic surgery	B
• Wide local excision (2–3 cm)	B

A comparison of Mohs micrographic surgery and wide local excision for treatment of dermatofibrosarcoma protuberans with long-term follow-up: the Mayo Clinic experience. Lowe GC, Onajin O, Baum CL, et al. *Dermatol Surg* 2017; 43: 98–106.

In this non-randomized study, 67 patients treated with MMS and 91 patients with WLE were included. Twenty-eight patients (30.8%) treated with WLE had recurrence (mean time to recurrence, 4.4 years), whereas only two (3.0%) patients treated with MMS recurred (at 1.0 and 2.6 years). Recurrence-free survival rates at 1, 5, 10, and 15 years was significantly higher with MMS ($p < .001$). Mean preoperative lesion sizes were similar between the WLE and MMS groups. Two Mohs layers typically were required for margin control. Surgical excision with meticulous histologic evaluation of all surgical margins is needed for DFSP treatment to achieve long-term high cure rates and low morbidity.

Relapse in dermatofibrosarcoma protuberans: a histological and molecular analysis. Molina AS, Duprat Neto JP, Bertolli E, et al. *J Surg Oncol* 2018; 117: 845–50.

A retrospective study including 61 DFSP patients. There was a recurrence in six patients (9.8% recurrence rate). All recurrences occur in patients who underwent WLE with margins of 2 cm or less. No recurrences were observed when margins of at least 3 cm were used.

Efficacy of Mohs micrographic surgery for the treatment of dermatofibrosarcoma protuberans: systematic review. Foroozan M, Sei JF, Amini M, et al. *Arch Dermatol* 2012; 148: 1055–63.

A systematic review of 23 studies showed that recurrence rate was lower with MMS (1.1%) vs. WLE (6.3%). The mean follow-up period ranged from 26 to 127 months. The mean time to recurrence was 68 months.

Dermatofibrosarcoma protuberans (DFSP): predictors of recurrence and the use of systemic therapy. Fields RC, Hameed M, Qin L-X, et al. *Ann Surg Oncol* 2011; 18: 328–36.

In this large retrospective study, including 244 patients evaluated by oncologic surgery, 70% of patients with primary DFSPs had no evidence of disease (NED) at a median follow-up of 50 months. For recurrent cases, only 47% had NED at the last time of follow-up. On multivariate analysis, depth was associated with disease-free survival (DFS) in primary DFSP. DFS was related to margin status (R1 vs. R0) in the recurrent DFSP group. A total of 22 patients required additional therapy (e.g., RT, systemic therapy).

Second-Line Therapies

- Radiation therapy 50–66 Gy (unresectable, adjuvant if micro- or macroscopic margin involvement) **C**
- Imatinib 400–800 mg (locally advanced, metastatic, unresectable) **C**

S1 guidelines for dermatofibrosarcoma protuberans (DFSP) – update 2018. Ugurel S, Kortmann RD, Mohr P, et al. *J Dtsch Dermatol Ges* 2019; 17: 663–8.

RT can also be considered as a primary treatment modality when there is contraindication for surgery or there is a high risk of cosmetic and functional impairment. A total dose of 60–70 Gy and a 3–5 cm safety margin is used. A lower dose may be used with palliative intent. Adjuvant RT of the tumor bed following a complete surgical excision with negative margins is not recommended.

Dermatofibrosarcoma protuberans: long-term outcomes of 53 patients treated with conservative surgery and radiation therapy. Castle KO, Guadagnolo BA, Tsai CJ, et al. *Int J Radiat Oncol Biol Phys* 2013; 86: 585–90.

The study included 53 consecutive DFSP patients treated with surgery and preoperative or postoperative RT between 1972 and 2010. Radiation dose ranged from 50 to 66 Gy (median dose, 60 Gy). Local control was 98% and 93% at 5 and 10 years, respectively. DFS was 98% and 93% at 5 and 10 years, respectively.

Molecular targeting of platelet-derived growth factor B by imatinib mesylate in a patient with metastatic dermatofibrosarcoma protuberans. Rubin BP, Schuetze SM, Eary JF, et al. *J Clin Oncol* 2002; 20: 3586–91.

In 2002, the first case report showing the efficacy of imatinib in a 25-year-old patient with metastatic DFSP of the lower limb was reported. The patient was severely impaired but was able to walk 2 weeks after initiating treatment; surgery was performed 1 month later. Due to this initial efficacy, numerous case series subsequently evaluated the utility of imatinib in the treatment of DFSP.

Imatinib mesylate in advanced dermatofibrosarcoma protuberans: pooled analysis of two phase II clinical trials. Rutkowski P, Van Glabbeke M, Rankin CJ, et al. *J Clin Oncol* 2010; 28: 1772–9.

The study included a cohort of 24 DFSP patients with tumor size ranging from 1.2 to 49 cm and metastases in seven patients (mainly lungs). Imatinib 400–800 mg/day obtained a partial response in 45.9% of DFSP patients, stable disease in 25% of cases, and progressive disease in 16.6% of patients. Clinical benefit (partial response plus stable disease) from imatinib was 70.9%. The 1-year overall survival rate was 87.5% (range, 66.08%–95.79%). After this phase II study published in 2010 evaluating two different cohorts, the NCCN guidelines incorporated imatinib into their treatment recommendations.

National Comprehensive Cancer Network. Dermatofibrosarcoma protuberans (Version 1.2018) 2017.

The NCCN guidelines recommend imatinib for metastasis/recurrences when ‘disease is unresectable, or unacceptable functional or cosmetic outcomes with resection are predicted’.

Diagnosis and treatment of dermatofibrosarcoma protuberans. European consensus-based interdisciplinary guideline. Saiag P, Grob JJ, Lebbe C, et al. *Eur J Cancer* 2015; 51: 2604–8.

The European consensus-based interdisciplinary guidelines also recommend imatinib for inoperable primary tumors, inoperable locally recurrent disease, and metastatic DFSP.

Imatinib treatment for locally advanced or metastatic dermatofibrosarcoma protuberans: a systematic review. Navarrete-Dechent C, Mori S, Barker CA, et al. *JAMA Dermatol* 2019; 155: 361–9.

A recent systematic review showed a complete response of 5.2% and a partial response of 55.2% when using imatinib in locally advanced or metastatic DFSP. The same study showed no difference between a daily dose of 400 mg or 800 mg. Adverse events were found in 73.5% of cases; severe adverse events were found in 15.1% of cases.

Dermatomyositis

Ruth Ann Vleugels, Scott A. Elman,
Jeffrey P. Callen

Dermatomyositis (DM) is an idiopathic inflammatory myopathy characterized by cutaneous disease, including a heliotrope eruption, Gottron papules, photodistributed erythema and poikiloderma, and/or periungual changes. Patients with cutaneous lesions of DM often have weakness of the proximal muscles; elevated enzymes such as creatine kinase or aldolase; or abnormal electromyogram, magnetic resonance imaging (MRI), or muscle biopsy findings. Some, however, have cutaneous disease that either precedes the onset of demonstrable muscle disease or occurs in its absence (clinically amyopathic DM). In addition, many patients have persistent cutaneous manifestations long after their muscle disease is adequately controlled. DM in children and adolescents may be complicated by calcinosis, particularly when treatment is delayed. Adults with DM have an increased risk of having or developing a malignancy, usually within the first 3 years after diagnosis.

MANAGEMENT STRATEGY

Before treatment the patient should be thoroughly evaluated to assess the severity of both skin and muscle disease; the presence of systemic involvement such as pulmonary, cardiac, or gastrointestinal involvement; and the presence of malignancy.

The goal of management is to *reverse the weakness, prevent contractures*, and allow the patient to return to normal functional status. The *prevention or treatment of calcinosis* is usually an issue in the management of children and adolescents but may occur in adults as well. Cutaneous disease has a large impact on quality of life; they are troubled by intense *pruritus*, *photosensitivity*, and the *appearance of their skin* and may therefore require treatment even when the muscle disease has been effectively managed or is absent.

For the myopathy, *systemic corticosteroids in conjunction with an immunosuppressive agent* is standard treatment. Most patients respond to this strategy, but for those who do not, *high-dose*

intravenous immune globulin (IVIG) or rituximab may be of benefit. Patients with cutaneous disease are photosensitive and are treated with *photoprotective clothing and wide-brimmed hats, sunscreens, behavior modification, topical corticosteroids*, and occasionally *topical calcineurin inhibitors, oral antimalarials*, and very often an *immunosuppressive agent*. *High-dose IVIG* may also be used for recalcitrant cutaneous disease. Ultimately, the therapeutic goal is to provide relief from the cutaneous inflammation and associated symptoms utilizing a combination of medications selected after considering comorbidities.

Assessment of response of cutaneous dermatomyositis has been hampered by a lack of validated assessment tools. To this end, three such measures have been developed: the Cutaneous Dermatomyositis Area and Severity Index (CDASI) (Arch Dermatol Res 2008; 300: 3–9, and Br J Dermatol 2012; 162: 669–73), the Dermatomyositis Skin Severity Index (DSSI) (Br J Dermatol 2008; 158: 345–50), and a cutaneous assessment tool in juvenile dermatomyositis (Arthritis Rheum 2008; 59: 352–6); however, the tools are being utilized more frequently and will ideally become incorporated as standard practice in the future as a means to assess cutaneous disease response.

Specific Investigations

- A thorough evaluation to exclude other causes of myopathy
- Malignancy evaluation, including computed tomography (CT) scans of chest, abdomen, and pelvis; transvaginal pelvic ultrasound; stool occult blood testing and age-appropriate endoscopy; Papanicolaou smear; mammography; complete blood count; comprehensive metabolic panel; CA-125; CA 19-9; urinalysis; and full physical examination
- Serum creatine kinase and aldolase
- Electromyogram, MRI, or ultrasound of muscle
- Muscle biopsy
- Assessment for the presence of systemic involvement (e.g., pulmonary, esophageal, and cardiac)
- Myositis-specific antibodies

Treatment

Scalp involvement in dermatomyositis. Often overlooked or misdiagnosed. Kasteler JS, Callen JP. JAMA 1994; 272: 1939–41.

Skin lesions in patients with DM, particularly those of the scalp, are often confused with psoriasis or seborrheic dermatitis. Additionally, DM skin disease may simulate cutaneous lupus erythematosus or lichen planus.

Influence of age on characteristics of polymyositis and dermatomyositis in adults. Marie I, Hatron PY, Levesque H, et al. Medicine (Baltimore) 1999; 78: 139–47.

This group compared characteristics of younger versus older adults and found that the incidence of malignancy was much higher in the older population, resulting in a poorer prognosis for this subset of patients.

Frequency of specific cancer types in dermatomyositis and polymyositis: a population-based study. Hill CL, Zhang Y, Sigurgeirsson B, et al. Lancet 2001; 357: 96–100.

This study demonstrated that malignancies of the ovaries, pancreas, stomach, colon, and rectum and non-Hodgkin lymphoma were overrepresented in patients with DM. The malignancy

risk decreased with each passing year after DM diagnosis and approached background levels at 3 years.

Malignancy evaluations should be repeated annually for at least 3 years. For details on suggested malignancy screening, please see specific investigations above.

A new approach to the classification of idiopathic inflammatory myopathy: myositis-specific autoantibodies define useful homogeneous patient groups. Love LA, Leff RL, Fraser DD, et al. *Medicine* (Baltimore) 1991; 70: 360–74.

This study compared the usefulness of myositis-specific autoantibodies (anti-aminoacyl-tRNA synthetases, antisignal recognition particle [anti-SRP], and anti-Mi-2) to the standard clinical categories (polymyositis, DM, overlap myositis, cancer-associated myositis, and inclusion body myositis) in predicting clinical signs and symptoms and prognosis in 212 adult patients. Compared with those without these antibodies, patients with anti-aminoacyl-tRNA synthetase autoantibodies ($n=47$) had significantly more frequent arthritis, fever, interstitial lung disease, and ‘mechanic’s hands’; higher mean prednisone dose at survey; higher proportion of patients receiving cytotoxic drugs; and higher death rates. Those with anti-SRP antibodies ($n=7$) had more frequent palpitations, myalgias, severe refractory disease, and higher death rates. Patients with anti-Mi-2 antibodies ($n=10$) had increased ‘V-sign’ and ‘shawl-sign’ rashes and cuticular overgrowth, as well as a good response to therapy. These findings suggest that myositis-specific autoantibody status is a more useful guide than clinical group in assessing patients with myositis.

Dermatomyositis: an update on diagnosis and treatment. Cobos GA, Femia A, Vleugels RA. *Am J Clin Dermatol* 2020 Feb 24 [Epub ahead of print].

This review takes an in-depth look at myositis-specific autoantibodies, many of which are associated with specific phenotypes, which may help the clinician prognosticate as well as identify more common DM systemic manifestations.

Currently, the anti-aminoacyl-tRNA synthetase autoantibodies are those antibodies most frequently incorporated into clinical practice. The recently described antibodies are becoming more widely available although interlaboratory concordance is thought to be highly variable.

A novel dermato-pulmonary syndrome associated with MDA-5 antibodies: report of 2 cases and review of the literature. Chaisson NE, Park J, Orbai AM, et al. *Medicine* (Baltimore) 2012; 91: 220–8.

This work describes the clinical features typically associated with a novel autoantibody termed *melanoma differentiation-associated protein 5* (MDA-5), including interstitial lung disease that can be rapidly progressive, arthritis, and a characteristic cutaneous phenotype, including ulcerations in Gottron papules; Gottron sign; and along the lateral nailfold, painful palmar papules, and prominent alopecia (this phenotype was first described in 2011 by Fiorentino et al. The mucocutaneous and systemic phenotype of dermatomyositis patients with antibodies to MDA5 (CADM-140): a retrospective study. *J Am Acad Dermatol* 2011; 65: 25–34). Most patients with the MDA-5 antibody have clinically amyopathic DM. Although this entity was first recognized in Asian populations, it has since been described in others.

Most patients with cancer-associated dermatomyositis have antibodies to nuclear matrix protein NXP-2 or transcription intermediary factor 1- γ . Fiorentino DF, Chung LS, Christopher-Stone L, et al. *Arthritis Rheum* 2013; 65: 2954–62.

In two large DM cohorts, reactivity against either transcription intermediary factor-1 γ (TIF-1 γ) or NXP-2 identified 83% of patients with cancer-associated DM. In these cohorts, malignancy was associated with older age, male sex, and antibodies to either TIF-1 γ or NXP-2 on multivariate analysis (OR 3.78).

The MDA-5 and TIF-1 γ autoantibodies are not yet routinely available in all commercial laboratories. They define distinct clinical subsets and therefore may be useful in predicting patient outcomes in DM. Specific antibodies may potentially help prognosticate and alter screening practices for patients with DM in the future.

Interstitial lung disease in classic and skin-predominant dermatomyositis: a retrospective study with screening recommendations. Morganroth PA, Kreider ME, Okawa J, et al. *Arch Dermatol* 2010; 146: 729–38.

In this retrospective cohort study, 23% of patients had interstitial lung disease (ILD) based on CT findings, and all of these had a reduced diffusion capacity (DLCO) on pulmonary function tests as well. Prevalence of ILD was not statistically different between patients with and without muscle disease. The authors conclude that serial DLCO testing is reasonable in all patients with DM to screen for pulmonary involvement.

Incidence of dermatomyositis and clinically amyopathic dermatomyositis: a population-based study in Olmstead County, Minnesota. Bendewald MJ, Wetter DA, Li X, et al. *Arch Dermatol* 2010; 146: 26–30.

This retrospective population-based study found that 20% of the dermatomyositis cases were amyopathic in this population.

This epidemiologic study supports other data demonstrating that 20%–30% of adult DM patients lack muscle involvement.

First-Line Therapies

1 For cutaneous disease

- Sunscreens E
- Topical corticosteroids E
- Antimalarials – hydroxychloroquine (HCQ) or chloroquine (CQ) D
- Combination antimalarial therapy (quinacrine plus either HCQ or CQ) E
- Methotrexate D

2 For muscle disease

- Systemic corticosteroids B
- Immunosuppressive agents – methotrexate, mycophenolate mofetil, azathioprine A

The use of pulse corticosteroid therapy for juvenile dermatomyositis. Paller AS. *Pediatr Dermatol* 1996; 13: 347–8.

This report notes that pulse administration of systemic corticosteroids might result in less toxicity, and further that this therapy aids in the prevention of calcinosis.

Cutaneous lesions of dermatomyositis are improved by hydroxychloroquine. Woo TY, Callen JP, Voorhees JJ, et al. *J Am Acad Dermatol* 1984; 10: 592–600.

Seven patients with cutaneous lesions of DM that had not responded to therapy with corticosteroids and/or immunosuppressive agents were treated with hydroxychloroquine 200 mg once or twice daily in an open study. The response to the

addition of hydroxychloroquine was good in all patients, and three had total resolution of their skin lesions. In two patients the corticosteroid dosage could be tapered. Therapy with hydroxychloroquine did not appear to have any beneficial effect on the myositis.

Combination antimalarials in the treatment of cutaneous dermatomyositis: a retrospective study. Ang GC, Werth VP. Arch Dermatol 2005; 141: 855–9.

In this retrospective analysis, seven of 17 patients experienced at least near clearance of cutaneous symptoms with the use of antimalarial therapy alone: four of them required combination therapy (hydroxychloroquine 200 mg once or twice daily + quinacrine 100 mg daily; or chloroquine 250 mg daily + quinacrine 100 mg daily), and three of them responded well to antimalarial monotherapy. The median time required to efficacy was 3 months.

When considering combination antimalarial agents as a therapeutic option, it is critical to use quinacrine in addition to either hydroxychloroquine or chloroquine, given that quinacrine lacks ocular toxicity. Hydroxychloroquine and chloroquine both have ocular toxicity and should not be given concurrently.

Systemic treatment for clinically amyopathic dermatomyositis at 4 tertiary care centers. Pinard J, Femia AN, Roman M, et al. JAMA Dermatol 2019; 155(4): 494–6.

In this study, patients with cutaneous dermatomyositis rarely responded sufficiently to antimalarial therapy alone (10/88 or 11.4% responded adequately). Therefore, patients with moderate-to-severe skin disease were treated more aggressively, either with methotrexate or mycophenolate mofetil as initial therapy, alone or in conjunction with hydroxychloroquine.

Adverse cutaneous reactions to hydroxychloroquine are more common in patients with dermatomyositis than in patients with cutaneous lupus erythematosus. Pelle MT, Callen JP. Arch Dermatol 2002; 138: 1231–3.

In this case-control study, 31% of patients with dermatomyositis developed a cutaneous reaction to hydroxychloroquine, compared with 2.5% of those with cutaneous lupus.

Given the fact that hydroxychloroquine is utilized as a first-line therapy for cutaneous DM, awareness of the increased risk of cutaneous reactions in approximately one-third of DM patients is critical, as this can lead to worsening of the cutaneous DM and warrants cessation of hydroxychloroquine. A pretreatment warning is helpful in order to allow patients to alert the clinician to the development of a cutaneous reaction.

Second-Line Therapies

3 For cutaneous disease

- Topical calcineurin inhibitors (tacrolimus or pimecrolimus) **D**
- Mycophenolate mofetil **D**

4 For muscle disease

- IVIG **A**
- IVIG **A**
- Rituximab **A**
- Other immunosuppressive agents – cyclophosphamide, chlorambucil, cyclosporin, tacrolimus **D**

Topical tacrolimus 0.1% ointment for refractory skin disease in dermatomyositis: a pilot study. Hollar CB, Jorizzo JL. J Dermatol Treat 2004; 15: 35–9.

This open-label study of six patients with cutaneous DM treated with topical tacrolimus noted a very good to excellent response in two patients, a moderate response in one, and essentially no response in three.

This agent is worthy of a trial but does not seem to be highly effective.

Low-dose methotrexate administered weekly is an effective corticosteroid-sparing agent for the treatment of the cutaneous manifestations of dermatomyositis. Kasteler JS, Callen JP. J Am Acad Dermatol 1997; 36: 67–71.

The records of 13 patients who received oral methotrexate in doses ranging from 2.5 mg to 30 mg weekly were reviewed. Their skin lesions had not been completely responsive to sunscreens, topical corticosteroids, oral prednisone, oral antimalarial therapy, or, in one patient each, chlorambucil and azathioprine. Four of these 13 patients had complete clearance of cutaneous manifestations, and another four had almost complete clearance. In the remaining five patients, methotrexate induced moderate clearing of their cutaneous lesions. In all patients, the addition of methotrexate allowed a reduction in or discontinuation of other therapies, including prednisone.

Mycophenolate mofetil as an effective corticosteroid-sparing therapy for recalcitrant dermatomyositis. Edge JC, Outland JD, Dempsey JR, et al. Arch Dermatol 2006; 142: 65–9.

Mycophenolate mofetil in dermatomyositis: is it safe? Rowin J, Amato AA, Deisher N, et al. Neurology 2006; 66: 1245–7.

These two open-label studies suggest that in 60%–75% of patients with myositis, mycophenolate mofetil 1–1.5 g twice daily is an effective steroid-sparing agent for skin and muscle disease. Toxicity was noted in these relatively small case series, including in the former study an Epstein–Barr virus–associated lymphoma of the central nervous system, which resolved upon cessation of therapy, and opportunistic infections in the latter study, one of which was fatal.

This agent appears to be useful in some patients with refractory DM yet needs careful monitoring for the development of infection and potentially neoplasia.

Mycophenolate mofetil for interstitial lung disease in dermatomyositis. Morganroth PA, Kreider ME, Werth VP. Arthritis Care Res 2010; 62: 1496–501.

In this study, all three patients with at least one year of follow-up on mycophenolate mofetil experienced complete normalization of pulmonary functions tests and resolution of dyspnea.

This agent appears to be useful in patients with DM-associated ILD. It is often used as the steroid-sparing agent of choice in DM patients with ILD or at high risk of ILD based on phenotype (ex: MDA-5 DM patients).

A controlled trial of high-dose intravenous immune globulin infusions as treatment for dermatomyositis. Dalakas MC, Illa I, Dambrosia JM. N Engl J Med 1993; 329: 1993–2000.

These authors conducted a double-blind, placebo-controlled trial of IVIG in 15 patients with biopsy-proven treatment-resistant DM. The patients continued to receive prednisone (mean daily dose 25 mg) and were randomly assigned to receive one infusion of immunoglobulin (2 g/kg body weight) or placebo monthly for 3 months, with the option of crossing over to the alternative

therapy for three more months. The eight patients assigned to immunoglobulin showed significant improvement in scores of muscle strength ($p < 0.018$) and neuromuscular symptoms ($p < 0.035$), whereas the seven patients assigned to placebo did not. With crossovers, a total of 12 patients received immunoglobulin. Of these, nine with severe disabilities showed a major improvement to near-normal function. Of 11 placebo-treated patients, none had a major improvement, three had a mild improvement, three had no change in their condition, and the condition of five worsened. Skin disease also responded in the treated patients, with 8 of 12 demonstrating 'marked clearance' of cutaneous disease as assessed through clinical photographs.

Intravenous immunoglobulin for refractory cutaneous dermatomyositis: a retrospective analysis from an academic medical center. Femia AN, Eastham AB, Lam C, et al. *J Am Acad Dermatol* 2013; 69: 654–7.

Clinical efficacy of intravenous immunoglobulins for the treatment of dermatomyositis skin lesions without muscle disease. Bounfour T, Bouaziz JD, Bezier M, et al. *J Eur Acad Dermatol Venereol* 2014; 28: 1150–7.

Since the time of the small, randomized, controlled trial by Dalakas et al., two retrospective studies investigated the role of IVIG specifically in refractory cutaneous DM. The first study (Femia et al.) included 13 patients who received IVIG to specifically treat cutaneous DM. All patients, except two, had previously been treated with various systemic immunosuppressive and immunomodulatory therapies, photoprotection, and topical agents. The validated CDASI was utilized when available to determine treatment response, in addition to review of clinical photography. All 13 patients demonstrated improvement on IVIG, with a complete clinical response noted in eight patients. IVIG allowed for discontinuation of all concurrent immunosuppressive medications except in two patients.

A second retrospective study (Bounfour et al.) of 27 patients treated with IVIG for refractory cutaneous DM also found promising results. Utilizing clinical examination and photography, 19 of 27 patients were determined to have a major response to therapy, four demonstrated a partial response, and four had no response.

Cyclosporine A and intravenous immunoglobulin treatment in polymyositis/dermatomyositis. Danieli MG, Malcangi G, Palmieri C, et al. *Ann Rheum Dis* 2002; 61: 37–41.

This is a retrospective review of 20 patients, including 12 with DM. It suggests that combining prednisone, cyclosporin, and IVIG was the most useful regimen.

A pilot trial of rituximab in the treatment of patients with dermatomyositis. Chung L, Genovese MC, Fiorentino DF. *Arch Dermatol* 2007; 143: 763–7.

In this open-label pilot study with seven evaluable patients who received 1-g infusions administered 2 weeks apart, only three had partial response of their muscle disease. Skin disease using the validated DSSI did not demonstrate notable improvement over the study period.

Rituximab in the treatment of refractory adult and juvenile dermatomyositis (DM) and adult polymyositis (PM): a randomized, placebo-phase trial (the RIM Study). Oddis CV, Reed AM, Aggarwal R, et al. *Arthritis Rheum* 2013; 65: 314.

This multicenter, randomized, controlled trial of 200 participants, including 76 with DM, 48 with juvenile DM, and 76 with

polymyositis, randomized participants to either a 'rituximab early' arm, receiving the drug at weeks 0 and 1 and placebo at weeks 8 and 9, or a 'rituximab late' arm, receiving placebo at weeks 0 and 1 and rituximab at weeks 8 and 9. The primary end point, time to achieve improvement based on specifically defined muscle parameters, was not met, nor were the secondary end points, which were also based on muscle involvement. Despite this, 83% of patients met the definition of improvement (DOI) by week 44. In addition, a steroid-sparing effect of rituximab was noted in both groups. The authors propose that the trial design, particularly the short placebo phase of 8 weeks, may have reduced the ability to detect differences between the groups given the median time to DOI from rituximab. Of note, a validated DM skin index was not used.

Cutaneous improvement in refractory adult and juvenile dermatomyositis after treatment with rituximab. Aggarwal R, Loganathan P, Koontz D, et al. *Rheumatology* 2017; 56: 247–54.

Using the same subjects and methodology of the RIM Study, cutaneous disease activity was assessed on a visual analog scale (VAS), which is not a validated DM skin index. The VAS improved in both adult and juvenile DM, with erythroderma, erythematous rashes without secondary changes, heliotrope eruption, and Gottron sign/papules improving most significantly.

Although design concerns with the RIM Study make recommendations regarding the use of rituximab in DM challenging, it is used for refractory muscle disease. At this time, however, the data to support the use of rituximab for cutaneous DM is weaker, especially without the use of a validated DM skin index in this study.

Third-Line Therapies

• Rituximab for cutaneous disease	D
• Tofacitinib, ruxolitinib (JAK inhibitors)	D
• Leflunomide	D
• Diltiazem for calcinosis	D
• Total body irradiation	D
• Stem cell transplantation	D
• Anakinra	D
• Sirolimus	E
• Tocilizumab	E
• Antiestrogen medication for cutaneous disease	E
• Thalidomide for cutaneous disease	E
• Apremilast	E
• Dapsone for cutaneous disease	E

Calcinosis cutis occurring in association with autoimmune connective tissue disease: the Mayo Clinic experience with 78 patients, 1996 to 2009. Balin SJ, Wetter DA, Andersen LK. *Arch Dermatol* 2012; 148: 455–62.

This retrospective study found that DM and systemic sclerosis were the most common autoimmune connective tissue diseases associated with calcinosis cutis. Therapy with diltiazem resulted in partial benefit in nine of 17 patients. Of 28 patients who had surgical excision of one or more lesions, 22 noted complete response, five had partial response, and one patient did not respond.

A wide variety of agents have been used in the treatment of DM-associated calcinosis, although none is uniformly effective.

A randomized, pilot trial of etanercept in dermatomyositis. Amato A. *Ann Neurol* 2011; 70: 427–36.

In this randomized, double-blind, placebo-controlled trial of 16 participants with DM on prednisone (11 randomized to etanercept arm 50mg subcutaneously weekly for 52 weeks and 5 to placebo arm), a steroid-sparing effect was demonstrated in five patients in the treatment arm. There was no statistically significant difference in skin disease response assessed by CDASI between the groups. In addition, cutaneous disease worsened in five etanercept-treated patients.

In addition to the potential worsening of muscle disease in patients with DM treated with anti-TNF- α therapy, there were reports of TNF inhibitor-associated DM. For these reasons, anti-TNF therapy is not typically utilized in patients with DM.

Improvement in dermatomyositis rash associated with the use of antiestrogen medication. Sereda D, Werth VP. Arch Dermatol 2006; 142: 70–2.

In this report, two women experienced improvement in their DM-associated skin eruptions while taking antiestrogen medication, either tamoxifen, a selective estrogen receptor modulator, or anastrozole, an aromatase inhibitor. When tamoxifen therapy was discontinued after 4 years of use in the first patient, her cutaneous DM worsened and remained difficult to control with conventional immunosuppressive agents.

This observation offers a novel approach to consider for women with DM; however, no further reports of either medication have appeared in the literature.

Efficacy and safety of leflunomide as an adjuvant drug in refractory dermatomyositis with primarily cutaneous activity. de Souza RC, de Souza FHC, Miossi R, et al. Clin Exp Rheumatol 2017; 35:1011–3.

In this retrospective, single-center cohort study of 18 adults, patients were started on leflunomide and followed for 6 months. Leflunomide proved effective and safe in 66.6% of patients with control of cutaneous activity and the ability to taper oral glucocorticoids. Two patients with muscle involvement had improved strength with leflunomide. Importantly, no validated skin index was used.

Rapamycin (sirolimus) as a steroid-sparing agent in dermatomyositis. Nadiminti U, Arbiser JL. J Am Acad Dermatol 2005; 52: 17–9.

A single case of dermatomyositis that was recalcitrant to prior therapies responded to this antirejection agent 5mg/day for 2 weeks, then 2mg/day. Both muscle disease and skin manifestations were noted to improve.

Anakinra treatment in patients with refractory inflammatory myopathies and possible predictive response biomarkers: a mechanistic study with 12 months of follow-up. Zong M, Dorph C, Dastmalchi M, et al. Ann Rheum Dis 2014; 73: 913–20.

An open-label trial of 15 patients with refractory myositis, four of whom had DM, received anakinra for a 12-month period. Three of the four DM patients had improvement in their cutaneous disease, but no validated skin index was used.

Remission of recalcitrant dermatomyositis treated with ruxolitinib. Hournung T, Janzen V, Heidgen FJ, et al. J. N Engl J Med 2014; 371: 2537–8.

A case of refractory DM was incidentally noted to have complete resolution of both muscle weakness and cutaneous disease based on CDASI scores after being treated with ruxolitinib, a JAK 1 and 2 selective inhibitor, for concurrent myelofibrosis. The patient was able to discontinue systemic corticosteroids, mycophenolate mofetil, and IVIG while taking ruxolitinib.

Tofacitinib citrate for refractory cutaneous dermatomyositis: an alternative treatment. Kurtzman DJ, Wright NA, Lin J, et al. JAMA Dermatol 2016; 152: 944–5.

Three patients with refractory DM were identified and treated with tofacitinib. Clinical response was observed after 4 weeks; mean treatment period was 9.6 months. Mean improvement in CDASI activity scores was 12 points. All patients reported decreased pruritus, and two patients reported subjective improvement in strength and fatigue.

Successful treatment of extensive calcifications and acute pulmonary involvement in dermatomyositis with the Janus-Kinase inhibitor tofacitinib – a report of two cases. Wendel S, Venhoff N, Frye BC, et al. J Autoimmun 2019; 100: 131–6.

In two cases of patients observed over 28 weeks, both patients had no progression of calcinosis and also had either stability or regression in their disease. One patient had improvement in ILD. Both patients were able to taper concomitant glucocorticoids.

Larger studies of JAK inhibitors might add another agent to our therapeutic armamentarium for DM.

Apremilast as a potential treatment for moderate to severe dermatomyositis: a retrospective study of 3 patients. Bitar C, Maghfour J, Ho-Pham H, et al. JAAD Case Rep 2019; 5: 191–4.

Three patients with refractory cutaneous DM were treated with apremilast. All patients were treated with 30mg twice daily; overall, patients had 85% improvement in CDASI score at 3 months of therapy. Two patients were able to discontinue all other medications. One patient with muscle involvement had normalization in CK values.

Larger studies or observations of PDE4 inhibition may add another agent to our therapeutic ladder.

Efficacy of allogeneic mesenchymal stem cell transplantation in patients with drug-resistant polymyositis and dermatomyositis. Wang D, Zhang H, Cao M, et al. J Ann Rheum Dis 2011; 70: 1285–8.

An open study of 10 patients with refractory DM ($n=4$) or polymyositis who underwent stem cell transplantation (SCT) noted recurrence of disease in three patients and death in two patients. The remaining patients had improvement in muscle disease, pulmonary disease, and chronic cutaneous ulcers.

Other reports of patients with adult and juvenile DM have noted improvement in both skin disease and calcinosis after SCT in severe cases. Given infection risks, SCT is considered only in highly refractory cases.

Diaper dermatitis

Dawn Z. Eichenfield, Lawrence F. Eichenfield

Diaper (napkin) dermatitis encompasses a broad set of conditions, although the most common form is irritant contact dermatitis (ICD). ICD usually presents as erythema and mild scaling on the convex surfaces of the inner upper thigh, lower abdomen, and buttock, classically sparing the inguinal folds where the skin is not in contact with irritants. It may present as early as a few days after birth to as late as several years of age. Diaper use in older disabled and geriatric patients may be identical in pathogenesis and physical findings. Many other dermatoses such as psoriasis, seborrheic dermatitis, allergic contact dermatitis, acrodermatitis enteropathica, infections (*Candida*, *Staphylococcus*, and *Streptococcus*), and Langerhans cell histiocytosis can affect the diaper area and need to be excluded. Prevalence and severity of infant and toddler diaper dermatitis varies greatly internationally, influenced

by age of toilet-training, regional diaper care habits, frequency of diaper changes, time spent overnight without diaper changes, and prophylactic use of topical products.

MANAGEMENT STRATEGY

ICD is triggered by irritants present in the area covered by the diaper, which acts as an occlusive surface. Moisture from urine and feces causes damage from friction, increased pH from urine and fecal enzymes, and physical erosion. Skin barrier dysfunction and increase in pH contribute to the increased susceptibility to infections with microorganisms such as *C. albicans*. Management is aimed at preventing overhydration and frictional damage, and addressing inflammation or infection.

Prevention

Frequent diaper changes, particularly after defecation, reducing moisture, and minimizing irritants are important steps in managing diaper dermatitis. Disposable diapers containing superabsorbent gelling materials and breathable backsheets are preferred. The evolving diaper technology, including mesh-like apertures, variable topsheet construction, and use of 'natural' or 'organic' materials, has prompted development of 'enhanced' disposable diapers, which can be associated with a lower incidence of diaper dermatitis. Cloth diapers are associated with an increased incidence of irritant diaper dermatitis compared with disposable diapers.

The skin in an area of active diaper dermatitis may be cleaned with water alone, with mild soap, or with commercial wipes. Optimally, wipes should not contain fragrance, isothiazolinones, iodopropynyl butylcarbamate, or alcohol. Rubbing of the area can cause damage to the skin and should be avoided.

A *barrier cream* such as zinc oxide cream maybe applied at every diaper change. This can provide a barrier between the skin and irritants in order to reduce friction and contact with stool and urine.

A *low-potency topical steroid* such as hydrocortisone 1% ointment can be used in more severe cases of diaper dermatitis, but should be used sparingly to avoid skin atrophy and systemic absorption. High-potency steroids should be avoided in diaper dermatitis, including the use of compound formulations containing potent steroids and antimicrobial agents.

Topical antifungal preparations are recommended for use in proven or suspected cases of *C. albicans* infection.

Specific Investigations

- Inquiry about recent antibiotic usage (predisposing to *Candida*)

In selected cases:

- KOH preparation, fungal and bacterial cultures
- Serum zinc and biotin levels
- Skin biopsy
- Patch testing

Diaper dermatitis: clinical characteristics and differential diagnosis. Coughlin CC, Eichenfield LF, Frieden IJ. *Pediatr Dermatol* 2014; 31(Suppl 1): 19–24.

This article characterizes three subgroups: skin conditions caused by the presence of the diaper, eruptions exacerbated by the diaper, and rashes present regardless of the presence of the diaper.

Those caused by the presence of the diaper include irritant diaper dermatitis and its different presentations, as well as allergic contact dermatitis. The conditions exacerbated by the diaper include infectious causes (yeast and bacteria), seborrheic dermatitis, and psoriasis. The third group includes infantile hemangiomas, Langerhans cell histiocytosis, zinc deficiency, Kawasaki disease, and Coxsackie virus.

Potential allergens in disposable diaper wipes, topical diaper preparations and disposable diapers: under-recognized etiology of pediatric perineal dermatitis. Yu J, Treat J, Chaney K, Brod B. *Dermatitis* 2016; 27: 110–8.

Botanical extracts, which include members of the Compositae family, were the top potential allergens in both diaper wipes and topical preparations. Others identified include tocopherol, fragrances, propylene glycol, parabens, iodopropynyl butylcarbamate, and lanolin.

The role of allergic contact dermatitis in diaper dermatitis. Smith WJ, Jacob SE. *Pediatr Dermatol* 2009; 26: 369–70.

Allergens include the many chemicals added to diapers, as well as preservatives in baby wipes. For example, sorbitan sesquioleate, fragrances, and disperse dye have been reported to cause contact dermatitis in the diaper area. Rubber additives, cyclohexylthiophthalimide and mercaptobenzothiazole, tend to cause ‘lucky Luke’ dermatitis, a pattern that resembles a cowboy’s holster due to elastic bands coming into contact with the skin. Patch testing is recommended in diaper dermatitis that fails to improve despite treatment.

First-Line Therapies

• Water-repellent barrier cream	A
• Frequent changing of diapers	B
• Superabsorbent disposable diapers	A

Prevention and treatment of diaper dermatitis. Blume-Peytavi U, Kanti V. *Pediatr Dermatol* 2018; 35(Suppl 1): s19–23.

Non-medical skincare practices that support healthy skin barrier function can prevent or alleviate diaper dermatitis. The usage of barrier emollients and improved diaper technology may minimize dermatitis.

Modern diaper performance: construction, materials, and safety review. Dey S, Kenneally D, Odio M, et al. *Int J Dermatol* 2016; 55(Suppl 1): 18–20.

Typical modern diapers do not contain concerning ingredients such as latex and disperse dyes, but use spandex and pigments with a favorable safety profile. Today’s disposable diapers are designed with layers and liners for optimal urine and feces absorption.

Clinical approaches to skin cleansing of the diaper area: practice and challenges. Coughlin CC, Frieden IJ, Eichenfield LF. *Pediatr Dermatol* 2014; 31(Suppl 1): 1–4.

The authors review important factors in diaper area care, including skin pH, the local microbiome, irritant and allergic potential of certain products, and application of topical agents. The use of wet wipes is concluded to be a widespread practice, which is well tolerated and effective in several populations, including preterm infants.

Diaper dermatitis prevalence and severity: global perspective on the impact of caregiver behavior. Carr AN, DeWitt T, Cork MJ, et al. *Pediatr Dermatol* 2020; 37(1): 130–6.

This article compares the prevalence and severity of diaper dermatitis across three countries: China, United States, and Germany. Diaper dermatitis was significantly lower in babies in China, highest in Germany, and intermediate in the United States. Lower prevalence of diaper dermatitis in China was associated with lower skin pH and transepidermal water loss (TEWL) on diapered skin and decreased relative humidity in the diaper. Chinese caregivers had the highest rate of prophylactic topical product usage, the most robust cleaning of the diapered area, lack of cleansing after urine-only diaper changes, and Chinese infants spent the least time in an overnight diaper.

Neonatal skin care: developments in care to maintain neonatal barrier function and prevention of diaper dermatitis. Burdall O, Willgress L, Goad N. *Pediatr Dermatol* 2019; 36(1): 31–5.

This article emphasizes the importance of reducing moisture at skin level and utilization of barrier creams for both prevention and cure, but not as a substitute for frequent diaper changes.

Second-Line Therapies

• 1% hydrocortisone ointment	D
• Topical antifungal agent (miconazole, clotrimazole, nystatin, ketoconazole)	A

A prospective two-year assessment of miconazole resistance in *Candida* spp. with repeated treatment with 0.25% miconazole nitrate ointment in neonates and infants with moderate to severe diaper dermatitis complicated by cutaneous candidiasis. Blanco D, van Rossem K. *Pediatr Dermatol* 2013; 30: 717–24.

This multicenter, open-label, long-term, phase IV study investigated the potential resistance of *Candida* spp. to repeated topical use of 0.25% miconazole nitrate in infants age 15 months and younger with moderate-to-severe candidal diaper dermatitis. Results showed that about half of the patients achieved clinical cure, 45.8% mycologic cure, and 29.2% overall cure (clinical and mycologic). The treatment with 0.25% miconazole nitrate ointment was effective and generally well tolerated. There was no evidence of candidal resistance to miconazole.

Efficacy and safety of two different antifungal pastes in infants with diaper dermatitis: a randomized, controlled study. Hoeger PH, Stark S, Jost G. *J Eur Acad Dermatol Venereol* 2010; 24: 1094–8.

This double-blinded, multicenter trial compared 1% clotrimazole versus nystatin with 20% zinc oxide for the treatment of diaper dermatitis complicated by *Candida* infection. Clotrimazole was superior to nystatin in symptom reduction. Both clotrimazole and nystatin had microbiologic cure rates of 100%, and were safe and well tolerated.

Absorption and efficacy of miconazole nitrate 0.25% ointment in infants with diaper dermatitis. Eichenfield LF, Bogen ML. *J Drugs Dermatol* 2007; 6: 522–6.

Twenty-four infants with moderate-to-severe diaper dermatitis were evaluated for relative safety from systemic absorption of topical miconazole. Nineteen received 0.25% miconazole nitrate ointment, and five received 2% miconazole nitrate cream for 7 days. Blood concentrations in the 0.25% miconazole nitrate treatment group were undetectable in 83% and minimal in 17%, demonstrating its safety as a treatment for diaper dermatitis.

Pediatricians who prescribe clotrimazole-betamethasone dipropionate (Lotrisone) often utilize it in inappropriate settings regardless of their knowledge of the drug's potency. Railan D, Wilson JK, Feldman SR, et al. *Dermatol Online J* 2002; 8: 3.

High-potency topical corticosteroids can cause skin atrophy and systemic absorption. Products combining antibiotics with high-potency corticosteroids should be avoided in the diaper area.

Third-Line Therapies

- Continuous administration of petrolatum and zinc oxide by disposable diaper **A**
- Oral antifungal agent **E**

Skin benefits from continuous topical administration of a zinc oxide/petrolatum formulation by a novel disposable diaper. Baldwin S, Odio MR, Haines SL, et al. *J Eur Acad Dermatol Venereol* 2001; 1: 5–11.

A double-blind, randomized trial comparing regular diapers to diapers designed to continuously deliver zinc oxide and petrolatum in 268 infants over a 4-week period. The ointment formulation was effectively transferred to the skin, and a significant reduction in skin erythema and rash was observed in the treatment group compared with controls.

Consultation with the Specialist: Contact dermatitis. Friedlander SF. *Pediatr Rev* 1998; 19: 166–71.

Some diaper dermatitis persists despite first- and second-line therapies. In these recalcitrant cases, oral Mycostatin may be beneficial. In addition, an evaluation of the mother for infections of the nipples or genital tract should be considered, as continuous reinoculation of the infant is possible. If positive, a short course of oral fluconazole (5–7 days) can help eradicate the infection.

Discoid (nummular) eczema

Ian H. Coulson

Discoid eczema comprises relatively well-defined, usually multiple, coin-sized plaques. In the acute stages they often weep or ooze; in the chronic phase lesions are discrete, hyperkeratotic, or lichenified. Itching is usual. It primarily affects the limbs (especially the legs), sometimes the trunk, and rarely the face or flexures.

MANAGEMENT STRATEGY

Discoid eczema (nummular dermatitis) has many causes. It is usually idiopathic in older patients, but similar lesions may occur due to contact allergic reactions, as a pattern of hand and foot eczema, in atopic dermatitis (AD), as an 'id' eruption related to venous eczema, or locally (e.g., after trauma, insect bite reactions, 'halo eczema' around melanocytic nevi, and after breast reconstruction). Discoid eczema has been reported as a manifestation of drug reaction to gold, tumor necrosis factor antagonists, interferon, and retinoids. Comparisons among studies may be limited if the site(s) and etiology are not stated or represent a mixed spectrum.

There are few publications on the pathophysiology of discoid eczema to inform treatment. An association with dry skin (xerosis) is documented, and discoid lesions may appear during treatment with isotretinoin (which reduces sebum secretion). However, dry skin is not consistently present, and the morphology of discoid eczema differs from that of xerosis or asteatotic eczema.

One study suggested that patients with discoid eczema have a degree of xerosis similar to that of age-matched controls but have stronger delayed hypersensitivity to allergens that permeate the skin as a result of scratching. A link with atopy has been proposed, but serum IgE levels are generally normal.

Occult infections (e.g., dental abscess) and infections causing dry skin (e.g., leprosy) have rarely been linked with discoid eczema. *Helicobacter pylori* has been implicated, but the evidence is weak.

It is difficult to provide specific therapeutic strategies because of the various different causes and the paucity of pertinent publications; most reports are retrospective from individual departments or are anecdotal, rather than formal, trials. The main therapeutic issues are:

- Other disorders may need to be excluded, especially mycoses, psoriasis, Bowen disease, mycosis fungoides, and sarcoidosis
- A medication and alcohol history should be taken
- Patch testing may be useful; metals and medicaments (such as fusidic acid, lanolin, neomycin, and cetostearyl alcohol) are most implicated
- The management of discoid eczema is generally similar to that of other eczemas; *emollients* appear to be helpful due to the link with dry skin
- The mainstay of treatment is *topical corticosteroids*. Severe itch in discoid eczema usually dictates that strong agents are applied; this is safe because the individual lesions are small, rarely affect thin skin sites such as the face or flexures, and usually respond to this approach. Chronic lichenified lesions may respond better to steroid-impregnated tapes or by using a potent steroid with hydrocolloid dressing or paste bandage occlusion
- *Calcineurin antagonists* have been used successfully both as monotherapy and in combination with topical steroids, but trials specifically looking at efficacy in discoid eczema exclusively, rather than atopic eczema generally, are lacking
- If weeping is present, the use of soaks (with, e.g., 1 in 10,000 *potassium permanganate* solution) will help dry lesions up and prevent lesions from sticking to clothes or dressings
- Secondary impetiginization, particularly in the exudative phase, is common, and combining with a *topical antibiotic or antiseptic*, or the use of an *oral antistaphylococcal antibiotic*, helps
- *Tar-based treatments* and impregnated bandages to minimize the effects of scratching may help
- *Sedating antihistamines* before retiring will help nocturnal scratching and minimize excoriation
- *Phototherapy and systemic immunosuppressive therapies* are usually not required, but there is a literature relating to ultraviolet B (UVB) and methotrexate

Newer drugs such as *biological agents* (dupilumab) and small molecules such as *apremilast* and *topical PDE 4 antagonists*, and *Janus kinase (JAK) inhibitors* show efficacy in atopic eczema, but specific reports relating to discoid eczema are lacking to date.

Specific Investigations

- None usually required, except to exclude differential diagnoses
- Consider medications as a cause
- Consider mycology
- Consider patch testing
- Bacteriology if secondary infection likely
- Consider occult infections in resistant cases

Pityriasis rosea and discoid eczema: dose related reactions to treatment with gold. Wilkinson SM, Smith AG, Davis MJ, et al. *Ann Rheum Dis* 1992; 51: 881–4.

Discoid eczematous lesions occur in up to 30% of patients on gold therapy and may be dose related.

Severe, generalized nummular eczema secondary to interferon alpha-2b plus ribavirin combination therapy in a patient with chronic hepatitis C virus infection. Moore MM, Elpern J, Carter DJ. Arch Dermatol 2004; 140: 215–7.

Study on dermatoses and their prevalence in groups of confirmed alcoholic individuals in comparison to a non-alcoholic group of individuals. Bruno MC, Vilela MA, Oliveira CA. An Bras Dermatol 2013; 8: 368–75.

Discoid eczema, along with psoriasis, pellagra, and pigmented purpuric eruptions, were felt to be potential indicators of alcoholism.

Nummular eczema of breast: a potential dermatologic complication after mastectomy and subsequent breast reconstruction. Iwahira Y, Nagasao T, Shimizu Y, et al. Plast Surg Int 2015, Article ID 209458, 6 pages, 2015. <https://doi.org/10.1155/2015/209458>.

Almost 3% of postmastectomy reconstructions resulted in peri-wound or breast discoid eczema.

Patch testing in discoid eczema. Fleming C, Parry E, Forsyth A, et al. Contact Dermatitis 1997; 36: 261–4.

Retrospective study of persistent and severe discoid eczema; 24 of 48 cases were positive (16 relevant) to rubber chemicals, formaldehyde, neomycin, chromate, and nickel.

Nummular eczema and contact allergy: a retrospective study. Bonamonte D, Foti C, Vestita M, et al. Dermatitis 2012; 23: 153–7.

Nickel, cobalt, and chromate allergy was found in 32% of discoid eczema patients. Irritants may also be relevant as perpetuating factors.

Dental infection associated with nummular eczema as an overlooked focal infection. Tanaka T, Satoh T, Yokozeki H. J Dermatol 2009; 36: 462–5.

Thirteen cases of extensive discoid eczema with moderate-to-severe odontogenic infections detected by panoramic X-ray screening test. In 11 patients, skin lesions partially or completely improved after the dental treatment.

First-Line Therapies

• Topical corticosteroids ± antibacterial agents	C
• Emollients	C
• Tar-based preparations	C
• Oral antibiotics	C
• Oral antihistamines	C
• Topical doxepin	A

Most of these are standard treatments for discoid eczema; however, in terms of evidence grading, most studies include a variety of different eczemas, few specifically identify results for discoid eczema, and no comparative trials have been identified. *Potent and ultrapotent topical steroids are needed short term; maintenance therapy may only need 1 or 2 applications a week.* Chronically lichenified lesions may benefit from topical steroid occlusion under hydrocolloid dressings.

The use of antibacterial agents (e.g., clioquinol) or antibiotics is based on the fact that lesions are often moist and crusted. Secondary staphylococcal infection, as in AD, may aggravate the eczematous process.

Occlusion over a topical corticosteroid has been reported to lead to lesion clearance in previously therapy-resistant patients with discoid lesions due to AD; soaking in water for 20 minutes before treatment application has been recommended for a range of eczemas.

As with other itchy dermatoses, *sedating antihistamines* may help symptoms; the increase in mast cells in lesions provides the rationale for this approach. However, histamine itself has not been shown to be important.

Successful treatment of therapy-resistant atopic dermatitis with clobetasol propionate and a hydrocolloid occlusive dressing. Volden G. Acta Derm Venereol 1992; 176: 126–8.

Nummular AD lesions cleared rapidly.

Topical corticosteroids are the usual first-line therapy. Trial evidence is limited to pharmaceutically sponsored studies that are not specific to discoid eczema. Alternate day treatment left on for 24 h can be used; often only three or four treatments will transform symptoms.

Nummular eczema. A review, follow-up and analysis of a series of 325 cases. Cowan MA. Acta Derm Venereol 1961; 41: 453–60.

5–10% Crude coal tar preparations were the main treatment. Recurrent crops of lesions occurred in 25% of cases, and relapse occurred when treatment was discontinued in 53% of patients, presumably representing the natural history of the disease, but possibly reflecting the limitations of therapy available at the time (other options were hydrocortisone or superficial X-ray therapy).

Tar preparations, historically used in the treatment of discoid eczema, have been largely superseded by potent topical corticosteroids as first-line therapy.

The antipruritic effect of 5% doxepin cream in patients with eczematous dermatitis. Drake LA, Millikan LE. Arch Dermatol 1995; 131: 1403–8.

Significant improvement in itch after 1 day, not at 7 days.

Studies suggest that twice daily doxepin has a short-term effect on itch only.

Second-Line Therapies

• Phototherapy (broadband or narrowband ultraviolet B [NB-UVB], 311 nm)	E
• Photochemotherapy (psoralen plus UVA [PUVA])	E
• Topical immune modulators	E
• Ciclosporin	E
• Intralesional corticosteroid injection	E
• Oral corticosteroids	E

Formal trials of these treatments in discoid eczema are lacking, and therefore the evidence gradings are weak; however, all are useful in AD or other dermatitis (see gradings in Atopic dermatitis, Chapter 17) and are therefore likely to be effective in discoid eczema. Personal experience is that NB-UVB or ciclosporin is useful if required.

Photochemotherapy beyond psoriasis. Honig B, Morison WL, Karp D. J Am Acad Dermatol 1994; 31: 775–90.

Review article. Nothing specific to discoid eczema, but several eczemas respond to PUVA.

Half-side comparison study on the efficacy of 8-methoxypsoralen bath-PUVA versus narrow-band ultraviolet B phototherapy in patients with severe chronic atopic dermatitis. Der-Petrossian M, Seeber A, Honigsmann H, et al. Br J Dermatol 2000; 142: 39–43.

Both were equivalent (at equi-erythemogenic doses) in AD.

Phototherapies also reduce staphylococci and superantigens and therefore may improve eczema with weeping and infection.

Antimicrobial effects of phototherapy and photochemotherapy in vivo and in vitro. Yoshimura M, Namura S, Akamatsu H, et al. *Br J Dermatol* 1996; 135: 528–32.

Antimicrobial effects are apparent after a single exposure.

Suppressive effect of ultraviolet (UVB and PUVA) radiation on superantigen production by *Staphylococcus aureus*. Yoshimura-Mishima M, Namura S, Akamatsu H, et al. *J Dermatol Sci* 1999; 19: 31–6.

Hand dermatitis: a review of clinical features, therapeutic options, and long-term outcomes. Warshaw E, Lee G, Storrs FJ. *Am J Contact Dermat* 2003; 14: 119–37.

One review recommends topical tacrolimus or pimecrolimus twice daily for nummular hand dermatitis. No evaluable evidence presented.

Long-term efficacy and safety of ciclosporin in severe adult atopic dermatitis. Berth-Jones J, Graham-Brown RA, Marks R, et al. *Br J Dermatol* 1997; 136: 76–81.

An open study of 100 patients with AD, with mostly good responses at 3–5 mg/kg/day.

Side effects (drug interactions, hypertension, nephrotoxicity) limit ciclosporin therapy in older patients with discoid eczema, compared with AD. It is possibly useful for intermittent short-term treatment.

Oral corticosteroids are generally unnecessary. Intralesional corticosteroid injection is impractical, except in patients who have a small number of persistent thickened lesions.

Third-Line Therapies

• Azathioprine	E
• Methotrexate	C
• Mycophenolate mofetil	E
• Hypnosis	D
• Relaxation therapy	D

As for second-line therapies, formal trials of these treatments in discoid eczema are lacking, and therefore the evidence gradings are weak; however, all are useful in AD or other dermatitis (see gradings in Atopic dermatitis, Chapter 17) and are therefore likely to be effective in discoid eczema.

Azathioprine in dermatologic practice. An overview with special emphasis on its use in nonbullous inflammatory dermatoses. Scerri L. *Adv Exp Med Biol* 1999; 445: 343–8.

Documents the efficacy of azathioprine in AD and pompholyx.

Azathioprine in dermatology: a survey of current practice in the UK. Tan BB, Lear JT, Gawkrödger DJ, et al. *Br J Dermatol* 1997; 136: 351–5.

A questionnaire to 248 dermatologists showed that none was using azathioprine for discoid eczema.

Azathioprine is used in the treatment of several dermatoses, including various eczemas. It is likely to be beneficial in discoid eczema, although a study of azathioprine prescribing by UK dermatologists did not identify this as a current indication.

Methotrexate for severe nummular eczema in children: efficacy and tolerability in a retrospective study of 28 patients. Knöpfel N, Noguera-Morel L, Hernández-Martín, et al. *Pediatr Dermatol* 2018; 35: 611–5.

In this retrospective study, 35% had greater than 90% improvement; 46% had moderate improvement. The standard dose of oral methotrexate in children is 0.4 mg/kg once weekly. Treatment was well tolerated; 18% had mild transaminitis.

Hypnosis in dermatology. Shenefelt PD. *Arch Dermatol* 2000; 136: 393–9.

Hypnosis as a complementary therapy may improve lesions or itch in discoid eczema.

Treatment of atopic dermatitis: a comparison of psychological and dermatologic approaches to relapse prevention. Ehlers A, Stangier U, Gieler J. *Consult Clin Psychol* 1995; 63: 624–35.

Although this study is related to adults with atopic eczema, it may be applicable to discoid eczema too. Relaxation therapy produced a sustained benefit over a year and significantly reduced topical steroid use.

Discoid lupus erythematosus

Spandana Maddukuri, Daisy Yan, Victoria P. Werth

Discoid lupus erythematosus (DLE) is the most common type of chronic cutaneous lupus erythematosus (CCLE). Lesions typically occur on the scalp, face, and ears, although they can be generalized. The lesions are photodistributed and are scaly, erythematous plaques and papules, which can be hypertrophic/hyperkeratotic. Late-stage lesions result in atrophy and scarring accompanied by dyspigmentation and permanent alopecia.

MANAGEMENT STRATEGY

Although the chance of progression of DLE to systemic lupus erythematosus (SLE) is low, a thorough workup is needed to rule out systemic disease. SLE is also more likely to occur with generalized DLE lesions. This includes inquiring about symptoms of systemic disease such as fever, fatigue, arthralgia, arthritis, myalgia, weight loss, and loss of appetite. Laboratory workup should include urinalysis, complement levels, CBC, and autoantibodies such as antinuclear antibodies (ANA) and double-stranded DNA (dsDNA). Primary counseling includes smoking cessation and sun avoidance and protection.

In localized disease, topical and intralesional steroids are first line. Intralesional injection of corticosteroids can also treat alopecia due to early-stage lesions on the scalp. However, if new lesions are appearing despite local treatment or are widespread, systemic treatment is warranted. Antimalarials are first-line systemic therapy and afford a measure of photoprotection and are highly effective, despite their relatively slow onset of action. Calcineurin inhibitors are also considered a first-line therapy and are important for use on delicate skin, where corticosteroids may not be used.

For refractory DLE, there is a lack of rigorous, randomized studies. However, immunosuppressive agents such as methotrexate (MTX) and mycophenolate mofetil (MMF) clear lesions and act

as steroid-sparing agents for SLE. Retinoids are effective in hypertrophic DLE. Thalidomide, and its derivative lenalidomide, are also effective but can have serious adverse effects.

Specific Investigations

- Autoantibodies
- Indicators of systemic disease: urinalysis, complement levels, CBC

First-Line Therapies

• Sunscreen	B
• Topical or intralesional steroids	A
• Calcineurin inhibitors	A

Review of treatment for discoid lupus erythematosus. Garza-Mayers AC, McClurkin M, Smith GP. *Dermatol Ther* 2016; 29: 74–83.

Potential allergenicity of commonly sold high SPF broad spectrum sunscreens in the United States; from the perspective of patients with autoimmune skin disease. Keyes E, Werth VP, Brod B. *Int J Womens Dermatol* 2019; 5: 227–32.

DLE can be precipitated and exacerbated by ultraviolet (UV) light exposure. Generous sunscreen use with regular reapplication has been shown to be efficacious in preventing UV-induced DLE lesions. A retrospective study confirmed that sunscreen prevented photoprovocation and pigment changes of lesions. Data suggests that higher sun protection factor (SPF 70 or greater) with broad-spectrum UVA and UVB coverage or physical blockers are effective in prevention of UV-induced DLE lesions. Although sunscreen usage is crucial in patients with autoimmune skin conditions, these patients have an increased risk of reaction to allergenic ingredients and developing contact dermatitis. Most sunscreens found on Amazon, Target, and CVS are not allergen-free, but many have no high-prevalence allergens.

Drugs for discoid lupus erythematosus. Jessop S, Whitelaw DA, Grainge MJ, et al. *Cochrane Database Syst Rev* 2017; 5: CD002954.

Topical steroids can be used for localized DLE lesions. In a study comparing fluocinonide 0.05% (potent steroid) and hydrocortisone 1% (low-potency steroid) there was complete resolution of skin lesions in 27% of participants using fluocinonide and 10% using hydrocortisone. Side effects included skin irritation and burning.

Effectiveness of topical calcineurin inhibitors as monotherapy or in combination with hydroxychloroquine in cutaneous lupus erythematosus. Avgerinou G, Papafragkaki DK, Nasiopoulou A, et al. *J Eur Acad Dermatol Venereol* 2012; 26: 762–7.

Review of treatment for discoid lupus erythematosus. Garza-Mayers AC, McClurkin M, Smith GP. *Dermatol Ther* 2016; 29: 74–83.

The macrolactam immunosuppressive agents, tacrolimus and pimecrolimus, are steroid-sparing agents that are effective in the topical treatment of lesions of DLE lesions. Tacrolimus 0.03% or 0.1% and pimecrolimus 1% cream are important in thin-skinned areas where corticosteroids are not appropriate, such as the

eyelids and in areas of atrophy resulting from the disease itself. Hypertrophic lesions may not respond well to calcineurin inhibitors or to other topical therapies because of limited penetration. Topical calcineurin inhibitors can also be used in combination with systemic therapy (e.g., hydroxychloroquine).

Second-Line Therapy

- Hydroxychloroquine

A

Update on recommendations for screening for hydroxychloroquine retinopathy. Couturier A, Giocanti-Aurégan A, Dupas B, et al. *J Fr Ophtalmol* 2017; 40: 793–800.

At recommended doses, the risk of retinopathy is <1% at 5 years and <2% at 10 years but increases to about 20% after 20 years of treatment. Current guidelines for hydroxychloroquine call for a baseline visual field exam and again after 5 years, followed by yearly exams. Although the guidelines are the same for chloroquine, consider more frequent visual field exams (every 4–6 months) due to increased risk of retinopathy.

The effect of increasing the dose of hydroxychloroquine (HCQ) in patients with refractory cutaneous lupus erythematosus (CLE): an open-label prospective pilot study. Chasset F, Arnaud L, Costedoat-Chalumeau N, et al. *J Am Acad Dermatol* 2016; 74: 693–9.

Effects of hydroxychloroquine in patients with cutaneous lupus erythematosus: a multicenter, double-blind, randomized, parallel-group trial. Yokogawa N, Eto H, Tanikawa A, et al. *Arthritis Rheumatol* 2017; 69: 791–9.

Antimalarial drugs are favored for long-term treatment of DLE and are effective in many patients for whom topical therapy alone is unsuccessful or impractical. Hydroxychloroquine is dosed at <5 mg/kg actual body weight/day and chloroquine is dosed at <2.3 mg/kg/day. Quinacrine was widely used in the past but is currently not available in the United States. Antimalarials typically take 2 months before improvement is noticed.

Third-Line Therapies

- Immune response-modifying agents
- Systemic retinoids
- Thalidomide
- Lenalidomide
- Azathioprine

B

B

B

D

D

Efficacy and safety of methotrexate in recalcitrant cutaneous lupus erythematosus: results of a retrospective study in 43 patients. Wenzel J, Brähler D, Bauer R, et al. *Br J Dermatol* 2005; 153: 157–62.

Therapeutic options for cutaneous lupus erythematosus: recent advances and future prospects. Chang J, Werth V. *Expert Rev Clin Immunol* 2016; 12: 1109–21.

MTX and MMF are second-line immunosuppressive agents for refractory DLE. A study by Gammon et al. found nearly all patients responded to MMF, with 37% of patients demonstrating a complete response. For MTX, Wenzel et al. found that 98%

of CLE patients experienced significant improvement. Clinical response to MTX is seen within weeks, and some potential side effects include oral ulcers, transaminitis, nausea, and cytopenias. MTX is titrated up to an average of 15–25 mg/week and MMF can be dosed up to 1500 mg twice daily. Screening of latent infections such as tuberculosis and hepatitis is necessary before treatment initiation.

Isotretinoin for refractory lupus erythematosus. Shornick J, Formica N, Parke A. *J Am Acad Dermatol* 1991; 24: 49–52.

Efficiency of acitretin in the treatment of cutaneous lupus erythematosus. Ruzicka T, Meurer M, Bieber T. *Arch Dermatol* 1988; 124: 897–902.

Oral retinoids, either isotretinoin 1 mg/kg/day or acitretin 25–50 mg/day, are useful in the hypertrophic DLE subtype. Patient counseling must include the teratogenic effects. Long-term adverse effects like hypertriglyceridemia and possible bony abnormalities are especially relevant, as lesions can recur after drug discontinuation.

Thalidomide therapy: an open trial. Naafs B, Faber WR. *Int J Dermatol* 1985; 24: 131–4.

Thalidomide in the treatment of refractory cutaneous lupus erythematosus: prognostic factors of clinical outcome. Cortés-Hernández J, Torres-Salido M, Castro-Marrero J, et al. *Br J Dermatol* 2012; 166: 616–23.

Thalidomide in the treatment of sixty cases of chronic discoid LE. Knop J, Bonsmann G, Happle R, et al. *Br J Dermatol* 1983; 108: 461–6.

Efficacy and tolerance profile of thalidomide in CLE: a systemic review and meta-analysis. Chasset F, Tounsi T, Cesbron E, et al. *J Am Acad Dermatol* 2018; 78: 342–50.

Lenalidomide in treatment-refractory cutaneous LE: efficacy and safety in 52-week trial. Okon L, Rosenbach M, Krathen M, et al. *J Am Acad Dermatol* 2014; 70: 583–4.

Thalidomide has been used in the treatment of cutaneous lupus refractory to other modalities. Thalidomide is dosed at 100 mg daily, decreasing to a lower maintenance dose when lesions are well controlled. A derivative, lenalidomide, can be dosed at 5 mg/day. Patients must be counseled on their teratogenic potential, increased risk of clotting, and peripheral neuropathy. Response rate for thalidomide can be as high as 90%, but lesion clearance is dependent on drug continuation.

Azathioprine. An effective, corticosteroid-sparing therapy for patients with recalcitrant cutaneous lupus erythematosus or with recalcitrant cutaneous leukocytoclastic vasculitis. Callen JP, Spencer LV, Burruss JB, et al. *Arch Dermatol* 1992; 127: 515–22.

Successful treatment of generalized discoid skin lesion with azathioprine. Tsokos GC, Caughman SW, Klippel JH. *Arch Dermatol* 1985; 121: 1323–5.

There is limited data for azathioprine as a CLE treatment. However, azathioprine is one of the few suitable alternatives for refractory CLE treatment during pregnancy.

Dissecting cellulitis of the scalp

Donna Cummins, Matthew Harries

Dissecting cellulitis (*perifolliculitis capitis abscedens et suffodiens*) is a rare inflammatory disease of the scalp characterized by multiple fluctuant nodules and abscesses over the vertex and occipital region associated with interconnecting sinus tract formation and purulent discharge. Dissecting cellulitis of the scalp (DCS) follows a progressive relapsing course eventually resulting in permanent hair loss and hypertrophic scarring. The condition predominantly affects men aged 20–40 and is more common in those of African descent. Dissecting cellulitis may occur in association with hidradenitis suppurativa, pilonidal sinus, and acne conglobata to form the ‘follicular occlusion tetrad’. The suggested common pathogenic mechanism is of follicular occlusion triggering a folliculitis with neutrophilic or granulomatous inflammation in the dermis and subcutis, leading to formation of sinus tracts, abscesses, and progressive fibrosis. An abnormal host response to (possibly commensal) bacteria may also be a factor in disease development.

MANAGEMENT STRATEGY

Dissecting cellulitis is characterized by a chronic, progressive course with temporary improvement on treatment followed by relapses when treatment is discontinued. There are no large therapeutic clinical trials, and recommendations for therapy are based on case reports or case series. Inflammatory tinea capitis and the very rare complication of squamous cell carcinoma should be excluded. Although no specific pathogenic organisms have been isolated, swabs should be obtained for cultures and the antibiotic sensitivity of organisms reviewed.

In mild cases or when disease is limited, improved scalp hygiene and the use of antiseptics, topical antibiotics, intralesional corticosteroid injections, and aspiration of fluctuant lesions may be adequate. At an early stage, systemic antibiotics

such as tetracyclines or azithromycin reduce inflammation and can control disease. In more severe cases a combination of systemic antibiotics, such as clindamycin with rifampicin, may be effective. However, recognition that oral isotretinoin (with or without corticosteroids) can provide sustained remission has led many to now regard it as first-line therapy in DCS. Recent reports highlight success with anti-tumor necrosis factor (TNF) therapy in those unresponsive to standard treatment. Alitretinoin, finasteride, compression therapy and photodynamic therapy are new additions to the therapeutic armamentarium.

In those unresponsive to medical therapy, a surgical approach may be considered. *X-ray epilation* of affected areas has largely been superseded by *laser epilation* techniques. The most resistant cases may require *surgical excision and skin grafting*.

Specific Investigations

- Swabs for bacteriology
- Scrapings and plucked hairs for mycology
- Scalp biopsy for histology and fungal culture

Tinea capitis mimicking dissecting cellulitis in three children. Shastry J, Ciliberto H, Davis DM. *Pediatr Dermatol* 2018; 35: e79–83.

Three cases of inflammatory tinea capitis mimicking DCS are reported. As fungal elements are not always visible on histology, the authors advise that fungal microscopy and culture should be performed in all inflammatory alopecias.

Squamous cell carcinoma arising in dissecting perifolliculitis of the scalp. Curry SS, Gaither DH, King LE. *J Am Acad Dermatol* 1981; 4: 673–8.

The rare complication of squamous cell carcinoma arising in DCS is presented.

First-Line Therapy

- Isotretinoin (oral)

C

Dissecting cellulitis of the scalp: response to isotretinoin. Scerri L, Williams HC, Allen BR. *Br J Dermatol* 1996; 134: 1105–8.

Three patients with DCS showed a sustained response to isotretinoin. The authors recommend isotretinoin initially at 1 mg/kg daily and maintained at 0.75 mg/kg daily for at least 4 months after clinical remission is achieved.

Dissecting cellulitis of the scalp: a retrospective study of 51 patients and review of literature. Badaoui A, Reygagne P, Cavelier-Balloy B, et al. *Br J Dermatol* 2016; 174: 421–3.

A retrospective analysis of 51 patients with DCS treated from 1996 to 2013. Thirty-five patients received treatment with isotretinoin at 0.5–0.8 mg/kg/day with complete remission being achieved in 92%.

Approach to treatment of refractory dissecting cellulitis of the scalp: a systematic review. Thomas J, Aguh C. *J Dermatolog Treat.* 2021; 32: 144–149.

A systematic review summarizing 57 published articles. The authors propose isotretinoin as first-line treatment for DCS, although they highlight that the response can be inconsistent and relapse is common.

Second-Line Therapies

• Systemic antibiotics	C
• Intralesional corticosteroid injection	D
• Incision and drainage	D
• Adalimumab/anti-TNF therapy	D
• Topical antibiotic/retinoid	E

Dissecting cellulitis (perifolliculitis capitis abscedens et suffodiens): a comprehensive review focusing on new treatments and findings of the last decade with commentary comparing the therapies and causes of dissecting cellulitis to hidradenitis suppurativa. Scheinfeld N. *Dermatol Online J* 2014; 20: 22692.

Various treatment strategies for DCS are reviewed. Oral antibiotics and oral isotretinoin, either as monotherapy or in combination, represent the mainstay of treatment. Addition of intralesional corticosteroids or incision and drainage may improve local control. Reported antibiotic regimens include rifampicin 300 mg BID and clindamycin 300 mg BID, tetracyclines (e.g., doxycycline 100–200 mg/day), ciprofloxacin 250–500 mg BID, and trimethoprim-sulfamethoxazole 960 mg BID. Responses and relapse rates are variable and depend on the regimen chosen.

Epidemiology, clinical presentation and therapeutic approach in a multicenter series of dissecting cellulitis of the scalp. Segurado-Miravalles G, Camacho-Martínez FM, Arias-Santiago S, et al. *J Eur Acad Dermatol Venereol* 2017; 31: e199–200.

A retrospective series of 21 patients with DCS. Successful monotherapy included doxycycline (100 mg daily), azithromycin (500 mg 3 × week), isotretinoin, and finasteride (1 mg daily).

Dissecting folliculitis (dissecting cellulitis) of the scalp: a 66-patient case series and proposal of classification. Lee CN, Chen W, Hsu CK, et al. *J Dtsch Dermatol Ges* 2018; 16: 1219–26.

The authors present a classification system for disease severity assessment. Oral tetracyclines or isotretinoin, with intralesional or oral corticosteroids used as short-term adjunctive therapies, were the main treatments used.

Three cases of dissecting cellulitis of the scalp treated with adalimumab. Navarini AA, Trüeb RM. *Arch Dermatol* 2010; 146: 517–20.

Rapid improvement with adalimumab, but relapse occurred on stopping treatment due to persistent underlying structural disease. The authors suggest continuous therapy or surgical excision of involved areas to prevent recurrence.

Perifolliculitis capitis abscedens et suffodiens successfully controlled with topical isotretinoin. Karpouzis A, Giatromanolaki A, Sivridis E, et al. *Eur J Dermatol* 2003; 13: 192–5.

A case of DCS controlled with topical isotretinoin and clindamycin gel.

Third-Line Therapies

• PDT	D
• Excision surgery	D
• Laser epilation	D
• Radiotherapy epilation	E
• Dapsone	E
• Alitretinoin	E
• Oral zinc	E
• Finasteride	E
• Compression therapy	E

Treatment of dissecting cellulitis of the scalp with 10% ALA-PDT. Feng Y, Zhang Y, Guo H, et al. *Lasers Surg Med* 2019; 51: 332.

The authors report using 10% ALA-PDT (plus microneedling) 2-weekly for three sessions in seven males. At 3-month follow-up, two patients achieved remission, four patients had significant improvement, and one had minor improvement.

Dissecting cellulitis of the scalp. Williams CN, Cohen M, Ronan SG, et al. *Plast Reconstruct Surg* 1986; 77: 378–82.

Four patients with extensive scalp disease responded to wide excision and split-thickness skin grafting.

Cutting out the tracts: staged excisions for dissecting cellulitis of the scalp. Powers MC, Mehta D, Ozog D. *Dermatol Surg* 2017; 43: 738–40.

Two patients with extensive scarring and sinus tract disease responded to multiple staged excisions under local anesthetic using a pulley-suture closure technique.

Dissecting cellulitis treated with the long-pulsed Nd:YAG laser. Krasner BD, Hamzavi FH, Murakawa GJ, et al. *Dermatol Surg* 2006; 32: 1039–44.

Four patients achieved sustained improvement at 1 year, with some regrowth of hair at treated sites.

Modern external beam radiation therapy for refractory dissecting cellulitis of the scalp. Chinnalayan P, Tena LB, Brenner MJ, et al. *Br J Dermatol* 2005; 152: 777–9.

Rapid improvement in four cases treated with electron beam therapy. No relapses reported after 4- to 13-year follow-up.

Successful treatment with alitretinoin of dissecting cellulitis of the scalp in keratitis-ichthyosis-deafness (KID) syndrome. Prasad SC, Bygum A. *Acta Derm Venereol* 2013; 93: 473–4.

Alitretinoin was given at 10 mg daily for 2 months followed by 20 mg daily in a patient with DCS and KID syndrome. Significant improvement was noted after 5 months of therapy.

Successful treatment of dissecting cellulitis and acne conglobata with oral zinc. Kobayashi H, Aiba S, Tagami H. *Br J Dermatol* 1999; 141: 1136–8.

A patient with DCS and acne conglobata responded to oral zinc sulfate 135 mg three times a day for 12 weeks followed by a reduced maintenance dose.

Innovative management of recalcitrant dissecting cellulitis with compression therapy. Asemota E, Chang YC, Goldberg LJ. *JAMA Dermatol* 2016; 152: 1280–1.

A bespoke compression dressing was used by one patient that promoted drainage and accelerated healing, possibly by reducing the potential space within the tissue.

DRESS syndrome: drug reaction with eosinophilia and systemic symptoms/ drug-induced hypersensitivity syndrome (DiHS)

Roni P. Dodiuk-Gad, Nidhi Shah, Neil H. Shear

Drug reaction with eosinophilia and systemic symptoms (DRESS), also known as drug-induced hypersensitivity syndrome (DiHS), is considered to result from complex interactions between genetic predisposition, exposure to drug, and viral reactivation. DRESS is characterized by multiorgan involvement with cutaneous, mucosal, hematological, and solid organ manifestations. The cutaneous involvement in DRESS is typically extensive and symptomatic. Delayed onset of 2–8 weeks after drug administration followed by a stepwise development of manifestations is characteristic. Two types of diagnostic criteria are available: the Japanese study group of severe cutaneous adverse reactions to drugs and the RegiSCAR network. Symptoms are usually present for several weeks even after discontinuation of the offending agent and appropriate treatment. Late complications, including mostly

autoimmune diseases and end-organ failure, should be closely monitored. Mortality in DRESS has been estimated at 10%, with most patients dying from liver failure.

MANAGEMENT STRATEGY

DRESS/DiHS is a severe adverse drug reaction with multiorgan involvement that is potentially fatal. Hence, prompt diagnosis and management are essential.

Initial management of DRESS/DiHS requires withdrawal of the culprit drug and assessment of the extent and severity of cutaneous, mucosal, and systemic involvement (hematological and solid organs).

DRESS presents with a combination of fever, diffuse rash, and signs of systemic involvement (any internal organ can be affected) – this triad is often the key to diagnosis. Delayed onset of 2–8 weeks after drug administration followed by a stepwise development of manifestations is characteristic. Fever is the most common sign, followed by a skin rash. The cutaneous involvement in DRESS is typically extensive and symptomatic (pruritus, burning, and pain), with morbilliform eruption being most common. However, various dermatological features may appear. Facial edema and diffuse lymphadenopathy are observed in most patients and mucosal involvement, mainly of the lips and oral cavity, may be demonstrated.

DRESS is considered to occur as a result of complex interactions between genetic predisposition (such as HLA-B*13:01 with dapsone hypersensitivity), exposure to drug, and viral reactivation.

According to the above, thorough investigations are to be conducted by history-taking, skin and full body exam (including assessment of mucous membranes and lymph nodes), blood work, and additional assessment for systemic involvement, viral reactivation, and to exclude alternative diagnosis.

Differential diagnosis must be done with other diseases that may present with skin rash, systemic symptoms, hematologic abnormalities, adenopathy, and fever. These include other severe drug reactions, viral and bacterial infections, autoimmune diseases, hypereosinophilic syndromes, Sézary syndrome, pseudolymphoma, and lymphomas.

Histological assessment is mandatory. Histopathology of cutaneous lesions in DRESS syndrome are variable. However, most commonly include perivascular dense lymphocytic infiltrate in the papillary dermis, with eosinophils, atypical lymphocytes, and spongiosis of the epidermis.

The RegiSCAR group developed a validated and practical scoring system for the diagnosis of DRESS. A severity score is an additional clinical tool to guide treatment options and assist in predicting outcomes.

Proper identification of the culprit drug is of utmost importance for avoiding it and all drugs that may cross-react with this agent and for providing the patient with reassurance to use other drugs that are safe.

The following methods are helpful to establish whether there is a causal relationship between the suspected drug and the clinical event: 1) patient history: the patient should be questioned about former drug eruptions and whether discontinuing the drug improved the eruption; 2) analysis of the literature: PubMed (<http://www.ncbi.nlm.nih.gov/pubmed/>) and Litt's D.E.R.M. Drug Eruptions and Reactions Manual and database (<http://www.drugeruptiondata.com/>); and 3) in vitro and in vivo diagnostic assessments, including human leukocyte antigen (HLA) genetic tests.

Specific Investigations

- Assessment of skin: extent of cutaneous involvement and morphology of the primary lesion based on four main categories: maculopapular (exanthem, enanthem), urticarial, bullous, and pustular
- Assessment of mucous membranes involvement: ocular, oral, genital
- Assessment of systemic involvement based on patient's signs and symptoms: fever, facial edema, enlarged lymph nodes, malaise, dysphagia, appetite loss, chills, dyspnea, cough, palpitations, nausea, vomiting, diarrhea, sore throat, and arthralgia
- Assessment of systemic involvement based on patient's laboratory screen: full blood count, peripheral blood smear for evaluation of atypical lymphocytes, liver function tests (AST, ALT, GGT, alkaline phosphatase, total bilirubin), kidney function tests (creatinine, serum urea), blood electrolytes, amylase and lipase, serum creatine phosphokinase (CPK), C-reactive protein, and urine analysis. Further laboratory evaluation to be conducted based on patient's signs and symptoms
- Assessment of systemic involvement based on additional evaluation: chest X-ray, ECG, and further investigations based on patient's signs and symptoms
- Assessment of viral reactivation: viral serology and polymerase chain reaction for HHV-6, HHV-7, CMV, EBV
- Assessment to exclude alternative diagnosis according to clinical relevance: serology for hepatitis (A, B, C) and *Mycoplasma/Chlamydia pneumoniae*, blood cultures, and ANA
- Skin biopsy for histopathology and, if relevant, direct immunofluorescence studies
- Usage of RegiSCAR DRESS validation score (classification into definite, probable, possible, or no diagnosis of DRESS)
- Establishment of a differential diagnosis that considers all possible diagnoses
- Usage of DRESS severity score to guide treatment options and assist in predicting outcomes
- Drug exposure analysis: determination of the lag period and creation of a timeline
- Determination of probabilities for the associations between the suspected drug and the clinical event according to the patient's history, literature, and in vitro and in vivo diagnostic assessments, including HLA genetic tests

Variability in the clinical pattern of cutaneous side-effects of drugs with systemic symptoms: does a DRESS syndrome really exist? Kardaun SH, Sidoroff A, Valeyrie-Allanore L, et al. *Br J Dermatol* 2007; 156: 609–11.

RegiSCAR DRESS validation score is presented.

Drug-induced hypersensitivity syndrome/drug reaction with eosinophilia and systemic symptoms severity score: a useful tool for assessing disease severity and predicting fatal cytomegalovirus disease. Mizukawa Y, Hirahara K, Kano Y, et al. *J Am Acad Dermatol* 2019; 80(3): 670–8.

DRESS severity score is presented with implications regarding treatment options and predicting outcomes, including CMV-related complications.

Sensitivity and specificity of the lymphocyte transformation test in drug reaction with eosinophilia and systemic symptoms causality assessment. Cabañas R, Calderón O, Ramírez E, et al. *Clin Exp Allergy* 2018; 48(3): 325–33.

An observational retrospective analysis was performed on 41 patients diagnosed with DRESS syndrome and 35 additional patients with non-immediate drug-induced reactions in which a re-exposition drug test was performed. Sensitivity and specificity of the lymphocyte transformation test (LTT) in the recovery phase of DRESS were 73% and 82%, respectively, whereas in the acute phase, they were only 40% and 30%, respectively. The data indicate that LTT has a good sensitivity and specificity and is a reliable tool for diagnosis of drug causality, mainly when performed in the recovery phase in DRESS syndrome.

A combined approach using a detailed case history, LTT, and skin tests is advised to identify the causative drug.

Making a diagnosis in severe cutaneous drug hypersensitivity reactions. Ardern-Jones MR, Mockenhaupt M. *Curr Opin Allergy Clin Immunol* 2019; 19(4): 283–93.

Diagnostic algorithm for drug allergy testing in cutaneous drug hypersensitivity reactions is presented.

First-Line Therapies

• Discontinue the offending drug and avoidance of cross-reacting medications	B
• Supportive care: fluid and electrolyte replacement, nutritional supplementation, hemodynamic balance, and pain control	B
• Skin care and treatment with topical high potency corticosteroids	C
• Systemic corticosteroids	C
• Ciclosporin	C
• Antivirals	D

Therapeutic management of DRESS: a retrospective study of 38 cases. Funck-Brentano E, Duong TA, Bouvresse S, et al. *J Am Acad Dermatol* 2015; 72(2): 246–52.

In this retrospective, single-center, observational study of 50 consecutive patients with DRESS, topical steroid treatment alone was initiated in 66% of cases. The treatment protocol included topical steroids (betamethasone or clobetasol applied once or twice daily) for symptoms of DRESS-related skin disorders in the absence of life-threatening organ involvement; otherwise, systemic steroids were given (orally or intravenously). Complications of DRESS, such as relapse, viral reactivation, and sepsis, were less frequent with topical steroid than with systemic steroids. None of the patients died during their stay in hospital. It was found that systemic steroids may not be required for the management of mild forms of DRESS and may thus be reserved for more severe cases.

Drug reaction with eosinophilia and systemic symptoms (DRESS): how far have we come? Martínez-Cabrales SA, Rodríguez-Bolaños F, Shear NH. *Am J Clin Dermatol* 2019; 20(2): 217–36.

A very comprehensive review including detailed causality assessment tests, treatment guidelines, and summary of all original articles reporting patients with DRESS treated with systemic corticosteroids.

Management of drug reaction with eosinophilia and systemic symptoms (DRESS). Descamps V, Ben Saïd B, Sassolas B, et al. *Ann Dermatol Venerol* 2010; 137(11): 703–8.

This management protocol for DRESS of the French Society of Dermatology was tailored according to the severity and extent of systemic involvement, and the diagnosis of viral reactivation of herpesviruses (mostly HHV-6). The protocol includes four visceral involvement severity categories and corresponding treatment:

1. No severe systemic involvement: topical corticosteroids (potent or very potent), emollients, H1-antihistamines
2. Severe systemic involvement (transaminases >5 times normal, renal involvement, pneumonia, hemophagocytosis, cardiac, etc.): systemic corticosteroids equivalent to 1 mg/kg/day of prednisone and multidisciplinary evaluation
3. Life-threatening signs (hemophagocytosis with bone marrow failure, encephalitis, severe hepatitis, renal failure, and respiratory failure): systemic steroids with intravenous immunoglobulin (IVIG) at a dose of 2 g/kg over 5 days. The IVIG should not be used without associated steroids. The treatments are to be conducted under multidisciplinary supervision
4. Severe systemic involvement and confirmation of a major viral reactivation: combining steroids and antiviral (such as ganciclovir) and/or IVIG

The management of DRESS was not assessed in a prospective study. These guidelines are clinically practical. Systemic steroids need to be slowly tapered over 6–8 weeks to prevent a flare of the disease.

Spanish guidelines for diagnosis, management, treatment and prevention of DRESS syndrome. Cabañas R, Ramírez E, Sendagorta E, et al. *J Investig Allergol Clin Immunol* 2020; 30(4): 229–53.

A comprehensive review including drugs reported in association to DRESS, causality assessment for identifying the culprit drug by the Spanish Pharmacovigilance System, in vitro and in vivo tests, treatment guidelines (consensus of experts) of acute interstitial nephritis and liver injury in DRESS, management of anti-TB DRESS, and Spanish guidelines for the treatment of DRESS including consensus of experts.

Evaluation of cyclosporine for the treatment of DRESS syndrome. Nguyen E, Yanes D, Imadojemu S, et al. *JAMA Dermatol* 2020 Mar 11 [Epub ahead of print].

This retrospective case-control study of adult patients with DRESS compared treatment with intravenous or oral ciclosporin (3–5 mg/kg divided twice daily for 7 days, tapered to 1.5–2.5 mg/kg divided twice daily for 7 days) and four age- and sex-matched controls treated with intravenous methylprednisolone, 1–2 mg/kg daily, with variable prednisone taper dose. The cohort included five patients on treatment with ciclosporin and 21 patients that received systemic corticosteroids. Ciclosporin treatment was associated with shorter time from treatment initiation to cessation of progression and erythema. Ciclosporin treatment resulted in shorter duration of hospitalization and faster normalization of fevers and systemic involvement. Patients in the control group experienced eruption recrudescence on prednisone taper, requiring dosage escalation.

In the following clinical settings, treatment with ciclosporin as first- or second-line treatment is to be considered: when systemic steroids are contraindicated; when there is an inadequate response to steroids; or when a prolonged course of steroids is not ideal. Renal function is important to assess prior and during this treatment.

Second-Line Therapies

• Intravenous immunoglobulin G	E
• Plasmapheresis	E
• Cyclophosphamide	E

Drug reaction with eosinophilia and systemic symptoms (DRESS) in the pediatric population: a systematic review of the literature. Kim GY, Anderson KR, Davis DMR, et al. *J Am Acad Dermatol* 2000; 83: 1323–30.

This systematic literature review on pediatric DRESS found that the majority of patients experienced skin involvement and that the liver was the second most common organ involved. Regarding treatment, the majority were treated with systemic steroids, IVIG alone failed to improve symptoms, and those treated with IVIG and steroids showed rapid clinical improvement. The mortality rate was low, and complications included multiorgan failure and acute respiratory distress syndrome.

Severe DRESS syndrome managed with therapeutic plasma exchange. Alexander T, Iglesia E, Park Y, et al. *Pediatrics* 2013; 131(3): e945–9.

A pediatric case of DRESS syndrome leading to multiorgan involvement and life-threatening complications of respiratory failure and cardiac arrest. After failing to improve with systemic corticosteroids, the patient showed dramatic, sustained clinical response to therapeutic plasma exchange.

Cyclophosphamide therapy for corticoreistant drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome in a patient with severe kidney and eye involvement and Epstein–Barr virus reactivation. Laban E, Hainaut-Wierzbicka E, Pourreau F, et al. *Am J Kidney Dis* 2010; 55(3): e11–4.

A case of severe DRESS with acute tubulointerstitial nephritis in the context of reactivation of Epstein–Barr virus infection. Owing to resistance of the skin and kidney manifestations to prolonged corticosteroid therapy, a 6-month course of oral cyclophosphamide was given and resulted in complete recovery.

Other Therapies

• Counsel the patient and family	C
• Report the event to the patient's healthcare provider, the manufacturer, and regulatory agencies	C
• Conduct medical follow-up to assess long-term emotional and physical complications	C

Long-term sequelae of drug reaction with eosinophilia and systemic symptoms: a retrospective cohort study from Taiwan. Chen YC, Chang CY, Cho YT, et al. *J Am Acad Dermatol* 2013; 68(3): 459–65.

This retrospective cohort study of patients for at least 1 year following DRESS found that the sequelae of DRESS can be divided into two major types occurring in different age groups: young patients tend to develop autoimmune diseases, whereas elderly patients are more vulnerable to end-organ failure.

Post-traumatic stress disorder following drug reaction with eosinophilia and systemic symptoms. Lew TT, Creamer D, Mackenzie J, et al. *Br J Dermatol* 2015; 172(3): 836–7.

This retrospective pilot study on a cohort of 19 patients with DRESS found that most patients experience psychological symptoms consistent with posttraumatic stress disorder, anxiety, and depression following DRESS.

Drug eruptions

Roni P. Dodiuk-Gad, Nidhi Shah, Neil H. Shear

Drug eruptions are among the most frequent adverse reactions in patients receiving drug therapy. They have a wide spectrum of clinical manifestations, are caused by various drugs, and result from varied pathophysiologic mechanisms. Hence, their diagnosis and management are challenging. Drug eruptions can range from a mild, simple eruption involving only the skin to severe complex eruptions with systemic involvement, such as toxic epidermal necrolysis. Systemic involvement should be explored even in a mild cutaneous eruption due to a drug because the severity of skin manifestation does not necessarily mirror the severity of the systemic involvement. The figure above shows a widespread eruption of erythematous macules and papules coalescent into ill-defined plaques on the trunk – maculopapular (exanthem, enanthem) morphology of cutaneous drug eruption. This can be localized to the skin with no systemic involvement (simple drug eruption) or be associated with systemic involvement (complex drug eruption).

MANAGEMENT STRATEGY

The following is the authors' protocol to approaching a patient with a drug eruption: the **4Ds**.

Diagnosis

Diagnosis of the adverse event is based on three key clinical elements:

1. Appearance: the morphology of the drug eruption based on four main categories of the primary lesion: maculopapular (exanthem, enanthem), urticarial, bullous, and pustular.

2. Systemic signs that differentiate between a simple reaction involving only the skin and a complex reaction that comprises systemic involvement in addition to the skin. Systemic involvement is evaluated by assessing the patient's symptoms such as fever, facial edema, malaise, chills, dyspnea, cough, palpitations, nausea, vomiting, diarrhea, sore throat, and arthralgia, and a basic laboratory screen, which includes a full blood count, liver and renal function tests, and urine analysis.

3. Histology: histopathology and, if relevant, direct immunofluorescence studies of skin biopsies to confirm the clinical impression and to distinguish between a drug eruption and other skin diseases.

In addition, it is valuable to use validated diagnostic criteria of specific types of drug eruptions, if available. Currently, only acute generalized exanthematous pustulosis (AGEP) and drug reaction with eosinophilia and systemic symptoms (DRESS) have published validated diagnostic criteria.

Differential Diagnosis

Establishing a differential diagnosis, which considers all possible diagnoses, is essential.

Drug Exposure (Timing)

All medications, regardless of route of administration, must be considered, particularly new drugs taken in the 8 weeks before the drug eruption. Assessment of the lag period, the time between initiation of the drug and onset of the cutaneous reaction, is essential in view of the different lag times for different drug eruptions. A recommended method for drug exposure analysis is to chart a timeline to visualize the chronology and facilitate comprehension of the event.

Determine Probabilities

An important step in assessing a drug eruption is to establish whether there is a causal relationship between the suspected drug and the clinical event. The following methods are helpful:

1. Patient history: the patient should be questioned about previous drug eruptions and whether dechallenging with the drug improved the eruption.
2. Analysis of the literature: PubMed (<http://www.ncbi.nlm.nih.gov/pubmed/>) and Litt's DERM (*Drug Eruptions and Reactions Manual*) and database (<http://www.drugeruptiondata.com/>).
3. In vitro and in vivo diagnostic assessments, including human leukocyte antigen (HLA) genetic tests.

An important progress in understanding the underlying mechanisms of several types of drug eruptions has been achieved by the discovery of an association between a specific HLA allele, a drug, an ethnic background, and a drug eruption. These tests are best utilized as genetic screening before drug prescription. However, they may serve as a simple, safe, and reliable method for establishing causality in specific cases of drug eruptions such as toxic epidermal necrolysis and DRESS induced by specific drugs, such as carbamazepine and allopurinol. In some countries in Asia, genetic tests are performed prior to prescription of high-risk drugs, and this strategy was proven to reduce the incidence of severe drug eruptions caused by these drugs. Unfortunately, although available in other places, these tests are not yet incorporated as a genetic screening tool to assess the risk of developing a severe drug eruption. In vitro tests, such as the lymphocyte transformation test and basophil activation test, exhibit varying

sensitivity depending on the drug involved and clinical phenotype. In vivo tests, such as patch test and delayed intradermal testing, may also be used in assessment of a drug eruption. Caution should always be exercised regarding false-positive and false-negative results of these in vitro and in vivo tests.

After the diagnosis of a drug eruption, the physician must provide the patient with clear information on the drug eruption, the name of the offending drug, potential cross-reacting drugs, and drugs that can be safely taken as an alternative to the offending drug. In cases of complex reactions, it is also necessary to explain to the patient the need for long-term medical follow-up, to provide information on support groups, and to conduct family counseling because the predisposition may be genetic. The physician must also report the event to the patient's healthcare provider, the manufacturer, and regulatory agencies.

Specific Investigations

- Determination of the morphology of the primary lesion based on four main categories: maculopapular (exanthem, enanthem), urticarial, bullous, and pustular
- Assessment of mucous membrane involvement: ocular, oral, genital
- Assessment of systemic involvement based on patient's signs and symptoms: fever, facial edema, malaise, chills, dyspnea, cough, palpitations, nausea, vomiting, diarrhea, sore throat, and arthralgia
- Assessment of systemic involvement based on patient's basic laboratory screen: full blood count, liver and renal function tests, and urine analysis
- Skin biopsy for histopathology and, if relevant, direct immunofluorescence studies
- In cases of complex drug eruptions, further investigations by multidisciplinary medical team based on the patient's signs and symptoms
- Usage of validated diagnostic criteria, if available (AGEP and DRESS)
- Establishment of a differential diagnosis that considers all possible diagnoses
- Drug exposure analysis: determination of the lag period and creation of a timeline
- Determination of probabilities for the associations between the suspected drug and the clinical event according to the patient's history, literature, and in vitro and in vivo diagnostic assessments, including HLA genetic tests

Phenotype standardization for immune-mediated drug-induced skin injury. Pirmohamed M, Friedmann PS, Molokhia M, et al. Clin Pharmacol Ther 2011; 89: 896–901.

A drug-induced skin injury (DISI) expert working group defined the minimum phenotypic criteria for selected forms of DISI (Stevens–Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN), AGEP, and DRESS). In addition, an algorithm to aid appropriate clinical categorization is presented.

Severe cutaneous adverse reactions to drugs. Duong TA, Valeyrie-Allanore L, Wolkenstein P, et al. Lancet 2017; 28: 390(10106): 1996–2011.

This review summarizes the clinical approach to patients with severe cutaneous adverse reactions to drugs.

Acute generalized exanthematous pustulosis (AGEP) – a clinical reaction pattern. Sidoroff A, Halevy S, Bavinck JN, et al. J Cutan Pathol 2001; 28: 113–9.

AGEP validation score is presented in this manuscript.

Variability in the clinical pattern of cutaneous side-effects of drugs with systemic symptoms: does a DRESS syndrome really exist? Kardaun SH, Sidoroff A, Valeyrie-Allanore L, et al. Br J Dermatol 2007; 156: 609–11.

Scoring system for classifying DRESS cases is presented in this manuscript.

Controversies in drug allergy: in vitro testing. Mayorga C, Ebo DG, Lang DM, et al. J Allergy Clin Immunol. 2019; 143: 56–65.

International consensus on in vitro testing to assess drug allergy.

Controversies in drug allergy: testing for delayed reactions. Phillips EJ, Bigliardi P, Bircher AJ, et al. J Allergy Clin Immunol. 2019; 143: 66–73.

International consensus on in vitro testing to assess delayed immunologically mediated adverse drug reactions, which includes a summary table on the various tests available for different types of reactions.

HLA association with drug-induced adverse reactions. Fan WL, Shiao MS, Hui RC, et al. J Immunol Res 2017; 2017: 3186328.

This review summarizes the alleles of HLA genes, which have been proposed to have association with adverse drug reactions induced by different drugs.

First-Line Therapies

• Discontinue the offending drug	B
• Supportive care	B
• Simple drug eruption (involving only the skin): oral antihistamines and topical corticosteroids	C
• Complex drug eruption (systemic involvement in addition to the skin): specific treatments based on the type of the drug eruption	C

Clinical practice. Exanthematous drug eruptions. Stern RS. N Engl J Med 2012; 366: 2492–501.

Identifying and discontinuing the causative drug are the most important steps in management of a drug eruption. In simple drug eruptions, symptomatic treatment with antihistamines and potent topical glucocorticoids may be helpful. A decision can be made to continue the drug and offer symptomatic treatment if the drug is of paramount importance, but the risk:benefit ratio of this option must be carefully weighed, and the evolution of the eruption must be meticulously monitored. In cases of complex drug eruptions, it is always essential to discontinue the drug.

Severe delayed cutaneous and systemic reactions to drugs: a global perspective on the science and art of current practice. Peter JG, Lehloeny R, Dlamini S, et al. J Allergy Clin Immunol Pract 2017; 5: 547–63.

The review summarizes various types of delayed cutaneous and systemic reactions to drugs including common offending drugs, images of different clinical phenotypes, and management.

Second-Line Therapies

• Cyclosporine	B
• Systemic steroids	C
• TNF inhibitors	E
• Intravenous immunoglobulin G	E
• Mucous membrane treatment	E
• Skin treatment	E
• Pain control	E

Open trial of cyclosporine treatment for Stevens–Johnson syndrome and toxic epidermal necrolysis. Valeyrie-Allanore L, Wolkenstein P, Brochard L, et al. *Br J Derm* 2010; 163: 847–53.

Death rate and progression of detachment appeared lower than expected in 29 patients with a diagnosis of SJS or TEN who received ciclosporin (3 mg/kg/day for 10 days and tapered over a month).

A meta-analysis of cyclosporine treatment for Stevens–Johnson syndrome/toxic epidermal necrolysis. Ng QX, De Deyn MLZQ, Venkatanarayanan N, et al. *J Inflamm Res* 2018; 11: 135–42.

A meta-analysis of ciclosporin treatment for Stevens–Johnson syndrome/toxic epidermal necrolysis found improved mortality with efficacy, safety, and beneficial effects in SJS/TEN patients.

Randomized, controlled trial of TNF- antagonist in CTL-mediated severe cutaneous adverse reactions. Wang CW, Yang LY, Chen CB, et al. Taiwan Severe Cutaneous Adverse Reaction (TSCAR) Consortium. *J Clin Invest* 2018; 128: 985–96.

In this randomized trial, participants with SJS/TEN were consecutively enrolled and randomly assigned at a 1:1 ratio to receive either etanercept by subcutaneous injection 25 mg (or 50 mg administered to patients who weighed more than 65 kg) twice a week or 1–1.5 mg/kg/day prednisolone by intravenous injection until their skin lesions were healed. Etanercept was found to improve clinical outcomes in patients with SJS/TEN.

Stevens–Johnson syndrome and toxic epidermal necrolysis: risk factors, causality assessment and potential prevention strategies. Lin CC, Chen CB, Wang CW, et al. *Expert Rev Clin Immunol* 2020; 2: 1–15.

This review presents the current therapeutic approaches to SJS and TEN and includes a summary of studies using ciclosporin and TNF- α antagonist for SJS/TEN.

Spanish guidelines for diagnosis, management, treatment and prevention of DRESS syndrome. Cabañas R, Ramírez E, Sendagorta E, et al. *J Investig Allergol Clin Immunol* 2020; 30(4): 229–53.

Spanish guidelines on DRESS syndrome including expert consensus protocols for management and treatment. Gives advice on suitable alternatives to causative anticonvulsants and allopurinol, and evidence relating to in vivo and in vitro drug tests.

Other Therapies

- Counsel the patient and family C
- Report the event to the patient's healthcare provider, the manufacturer, and regulatory agencies C
- In cases of DRESS and SJS/TEN, conduct medical follow-up to assess long-term emotional and physical complications C

Health-related quality of life and long-term sequelae in survivors of epidermal necrolysis: an observational study of 57 patients. Ingen-Housz-Oro S, Alves A, Colin A, et al. *Br J Dermatol* 2020; 182: 916–26.

TEN-specific sequelae in survivors 3.6 years after the acute event were cutaneous (77%), ocular (70%), psychological (60%), dental/oral (49%), genital (30%), and respiratory (18). Anxiety and depression were similar to survivors of severe septic shock requiring ITU admission.

Eosinophilic fasciitis

Elizabeth Tkachenko, Alisa Femia, Ruth Ann Vleugels

Eosinophilic fasciitis (EF), also known as *Shulman syndrome*, is a rare fibrosing disorder characterized by the rapid onset of symmetric induration of the extremities. The trunk and neck are affected less commonly; the distal digits and face are typically spared. The condition overlaps with plaque morphea in 35% of patients. Clinically, EF is marked by an early, edematous phase with erythema, followed by progressive sclerosis and a *peau d'orange* appearance. Depressions over superficial veins produce the characteristic 'groove' sign. Ultimately, woody induration and stiffness of the limbs develop, leading to decreased range of motion. Joint contractures are a major cause of morbidity and occur in 50%–56% of patients.

Laboratory investigations may reveal peripheral blood eosinophilia, present in 58% of patients, and an elevated erythrocyte sedimentation rate, but these are not essential in securing a diagnosis. EF has been reported in association with hematologic disorders, including monoclonal gammopathy, aplastic anemia, hemolytic anemia, thrombocytopenia, leukemias, and lymphomas; as such, abnormalities in complete blood count and immunofixation and/or protein electrophoresis may be seen. Histologically, EF presents with fascial thickening associated with a mixed inflammatory infiltrate composed of lymphocytes, plasma cells, histiocytes, and occasionally eosinophils. Dermal sclerosis can be seen in more advanced disease. Although the etiology remains unknown, vigorous physical activity and infection have been reported prior to EF onset in select cases, presumably triggering an aberrant immune response; however, these factors may be present in a minority of patients, with preceding trauma or intense exercise reported in only 28% of cases.

EF is differentiated from systemic sclerosis by the relative absence of sclerodactyly, Raynaud disease, nailfold capillary changes, and serologic markers. In addition, patients with EF traditionally lack visceral involvement. This clinical distinction is critical given that data supports avoiding systemic corticosteroids,

a first-line agent for EF, in systemic sclerosis. EF must also be distinguished from the eosinophilia-myalgia syndrome, which is characterized by diffuse muscle pain and weakness, polyneuropathy, respiratory and pulmonary involvement, and most notably a history of contaminated L-tryptophan ingestion.

MANAGEMENT STRATEGY

The constellation of clinical, laboratory, imaging, and histologic findings establish the diagnosis of EF. Histopathologic examination from a full-thickness skin-to-muscle biopsy has been considered the gold standard for diagnosis. Diagnostic biopsy can be challenging to obtain due to feasibility issues, concerns regarding healing, and sampling error. *Magnetic resonance imaging* (MRI) is increasingly used by experts as a non-invasive modality to establish the diagnosis and monitor the effectiveness of treatment. On MRI, findings typically show high signal intensity of the deep and superficial fasciae on T₁, T₂, and short tau inversion recovery imaging with enhancement after intravenous contrast administration. Ultrasound and positron emission tomography/computed tomography (PET/CT) are additional non-invasive tools to aid in diagnosis, but are utilized less frequently. Serum aldolase levels have also been proposed as a useful indicator of disease activity.

Though spontaneous remission of EF has rarely been reported, treatment is crucial to help prevent the progression of sclerosis and development of contractures and limited mobility. Although a validated skin index does not exist, clinical response is usually defined as resolution of erythema and edema with improvement in skin thickening. As fibrosed tissue becomes softer and looser, it allows for increased range of motion. The primary goal of EF management is to halt disease progression. Softening of recently involved areas of sclerosis is possible with appropriate early treatment. Complete resolution of induration is rare and not routinely expected, particularly in patients with longstanding disease. Importantly, when patients are appropriately diagnosed and treated during the early, edematous phase, avoidance of induration and joint contractures is often possible, underscoring the need for prompt diagnosis and management.

Although responsive to *oral steroids*, EF will typically flare upon taper of steroids, and thus EF requires long-term treatment with a *steroid-sparing immunosuppressive* agent for durable clinical response and to avoid sequelae of prolonged steroid use. The combination of systemic corticosteroids and either *methotrexate* or *mycophenolate mofetil* should be considered first line for EF, initiated simultaneously at the time of diagnosis. This regimen consists of high-dose oral corticosteroids (*prednisone* 1 mg/kg/day, slowly tapered over 3–6 months depending on disease severity) or *pulse methylprednisolone* (1000 mg/day for 3 days, followed by prednisone taper). The authors utilize pulse methylprednisolone in moderate-to-severe cases as there are data to support this results in improved outcomes. Simultaneously, therapy with *methotrexate* (target dose 25 mg weekly) or *mycophenolate mofetil* (target dose 2–3 g daily, often 3 g in moderate-to-severe cases) is initiated. *Pulse methotrexate* has also been efficacious (4 mg/kg/month with 25 mg/day folinic acid 24 hours after administration) with or without systemic corticosteroids for five treatment months. The addition of *hydroxychloroquine* (200–400 mg/day) to this regimen can also be considered.

Although methotrexate has traditionally been considered the steroid-sparing agent of choice for EF, novel data reveals that *mycophenolate mofetil* (2–3 g/day) is efficacious both first line and in cases where methotrexate fails or is contraindicated. *Intravenous immunoglobulin* (2 g/kg over 2 days, monthly) may also be considered in refractory cases as an adjuvant to corticosteroids

and/or methotrexate, or as monotherapy in patients with contraindications to *methotrexate* or *mycophenolate mofetil*. Use of *cyclosporin* monotherapy (3.7–5 mg/kg/day) is supported by several case reports. *Ultraviolet A1 (UVA1)* at cumulative doses of 1750–1930 J/cm² was efficacious in one case as monotherapy and in a second case with concomitant methylprednisolone.

Infliximab, *sirolimus*, *D-penicillamine*, *ketotifen*, *chloroquine*, *psoralen and ultraviolet light (PUVA)*, *azathioprine*, *griseofulvin*, *dapsone*, *rituximab*, *tocilizumab*, *tofacitinib*, and *sulfasalazine* have all been reported to have beneficial effects in case reports or series. *Mepolizumab*, an antiinterleukin-5 antibody, is being evaluated in a clinical trial (NCT04305678) given the role of IL-5 in hyper-eosinophilia. Additionally, physical therapy should be routinely recommended to prevent and/or improve joint contractures and related functional morbidity.

Specific Investigations

- Careful physical examination to differentiate from systemic sclerosis
- Complete blood count with differential
- Wedge excision to muscle (including fascia) and/or MRI
- In select cases, ultrasound or fludeoxyglucose (FDG) PET/CT
- History to exclude tryptophan, simvastatin, or trichloroethylene ingestion

Epidemiology and treatment of eosinophilic fasciitis: an analysis of 63 patients from 3 tertiary care centers. Wright NA, Mazori DR, Patel M, et al. *JAMA Dermatol* 2016; 152: 97–9.

In this large cohort of EF patients, peripheral eosinophilia was present in 58% of cases. Seventy-nine percent of patients were initially misdiagnosed, most frequently with systemic sclerosis. Although 50% of patients had joint contractures, only 37% were referred for physical therapy.

The use of an elevated aldolase in diagnosing and managing eosinophilic fasciitis. Nashel J, Steen V. *Clin Rheumatol* 2015; 34: 1481–4.

In this retrospective review of 15 patients, the aldolase level was the last parameter to normalize and the first to rise during a flare compared with eosinophilia and inflammatory markers.

Eosinophilic fasciitis: spectrum of MRI findings. Moulton SJ, Kransdorf MJ, Ginsburg WW, et al. *Am J Roentgenol* 2005; 184: 975–8.

In this case series of six patients with histologically proven EF, MRI revealed characteristic findings, including thickening, signal abnormalities, and contrast enhancement of the superficial and, to a lesser extent, deep muscle fasciae.

Eosinophilic fasciitis: typical abnormalities, variants and differential diagnosis of fasciae abnormalities using MR imaging. Kirchgessner T, Dallaudiere B, Omoumi P, et al. *Diagn Interv Imaging* 2015; 96: 341–8.

This review summarizes the MRI findings in EF and other subcutaneous conditions on the differential diagnosis of entities that produce abnormal fascial signal intensities.

Ultrasound assessment of subcutaneous compressibility: a potential adjunctive diagnostic tool in eosinophilic fasciitis. Kissin EY, Garg A, Grayson PC, et al. *J Clin Rheumatol* 2013; 19: 382–5.

A cross-sectional study of 12 patients with EF revealed a significant reduction in subcutaneous compressibility quantified by ultrasound.

Usefulness of FDG PET/CT in the diagnosis of eosinophilic fasciitis. Kim HJ, Lee SW, Kim GJ, et al. *Clin Nucl Med* 2014; 39: 801–2.

In one case report, increased uptake of FDG on PET/CT along the superficial and deep fasciae suggested FDG PET/CT may be a non-invasive tool to illustrate more detailed anatomic involvement of the disease, especially if MRI is contraindicated.

Eosinophilic fasciitis. A pathologic study of twenty cases. Barnes L, Rodnan GP, Medsger TA, et al. *Am J Pathol* 1979; 96: 493–517.

Deep fascia and subcutaneous tissue are infiltrated with lymphocytes, plasma cells, histiocytes, and eosinophils early in the course of the disease. Sclerosis of the dermis with increased collagen occurs later in the course of the disease.

Clinicopathologic and immunophenotypic features of eosinophilic fasciitis and morphea profunda: a comparative study of 27 cases. Onajin O, Wieland CN, Peters MS, et al. *J Am Acad Dermatol* 2018; 78: 121–8.

While EF and morphea profunda share clinical and pathologic features, EF patients are more likely to have forearm involvement and peripheral eosinophilia. Histopathologically, fascia in patients with EF is more likely to reveal eosinophils and focal loss of CD34 staining.

Baseline characteristics and long-term outcomes of eosinophilic fasciitis in 89 patients seen at a single center over 20 years. Mango RL, Bugdayli K, Crowson CS, et al. *Int J Rheum Disease* 2020; 23(2): 233–9.

This retrospective review of 89 EF patients revealed complete treatment response in 60% of patients at 3 years. While diagnostic delay was inversely associated with treatment response, no baseline characteristics correlated with response, although there was a trend toward positive association with elevated aldolase, hypergammaglobulinemia, and hematologic disorders.

First-Line Therapies

• Systemic corticosteroids and methotrexate	B
• Systemic corticosteroids	B
• Pulsed methylprednisolone	D
• Methotrexate	D
• Mycophenolate mofetil	D
• Adjunctive physical therapy	Expert opinion (no studies have evaluated this)

Epidemiology and treatment of eosinophilic fasciitis: an analysis of 63 patients from 3 tertiary care centers. Wright NA, Mazori DR, Patel M, et al. *JAMA Dermatol* 2016; 152: 97–9.

A retrospective review of 63 EF patients revealed that complete response was more likely in those treated with a combination of corticosteroids and methotrexate (64%), compared with corticosteroid monotherapy (30%), other treatment combinations (29%), and without steroids (17%).

Eosinophilic fasciitis: clinical spectrum and therapeutic response in 52 cases. Lakhanpal S, Ginsburg WW, Michet CJ, et al. *Semin Arthritis Rheum* 1988; 17: 221–31.

Of the 52 patients, 34 were treated with prednisone (40–60 mg/daily). The remaining 18 were treated with hydroxychloroquine, colchicine, D-penicillamine, or no medication. Twenty of the 34 patients treated with prednisone had a partial response, and five had complete resolution. Eight of the nine patients who had a poor response were treated with the addition of hydroxychloroquine (200–400 mg/daily). Two responded completely, two had an improvement of over 50%, and three were lost to follow-up. Eight patients also responded to treatment with hydroxychloroquine alone. Relapses occurred in some patients.

Eosinophilic fasciitis (Shulman disease): new insights into the therapeutic management from a series of 34 patients. Lebeaux D, Francés C, Barete S, et al. *Rheumatology (Oxford)* 2012; 51: 557–61.

Prednisone served as a first-line therapy for all 34 patients. Before treatment initiation, 15 patients received methylprednisolone pulses (MPPs), which increased the probability of complete remission. After treatment initiation, 12 patients received methotrexate as a second-line therapy. A poor outcome was present in 10 patients and was associated with a diagnosis time delay of more than 6 months and a lack of MPPs at treatment initiation. Overall, complete remission was achieved in 69% of patients.

Eosinophilic fasciitis: clinical characteristics and response to methotrexate. Berianu F, Cohen MD, Abril A, et al. *Rheum Dis* 2015; 18: 91–8.

Of 15 prednisone-dependent patients with biopsy-proven EF, 13 (87%) were able to discontinue prednisone after receiving methotrexate for a mean of 14.5 months, with 9/13 (69%) achieving disease remission after a mean of 31.4 months on methotrexate.

High-dose intravenous pulse methotrexate in patients with eosinophilic fasciitis. Mertens JS, Zweers MC, Kievit W, et al. *JAMA Dermatol* 2016; 152: 1262–5.

In this study, 12 patients with biopsy-proven EF received intravenous methotrexate (4 mg/kg) monthly for 5 months with folinic acid rescue 24 hours after administration. Median modified skin scores improved significantly from baseline on this regimen.

Mycophenolate mofetil for eosinophilic fasciitis: a retrospective analysis from 3 tertiary care centers. Tkachenko E, Steuer AB, Lo K, et al. *JAMA Dermatol* 2020; 156: 595–7.

Fourteen EF patients were treated with mycophenolate mofetil (2–3 g daily), with 13 responding favorably and eight ultimately achieving complete clinical response. Concomitant systemic corticosteroids were discontinued in the majority (69%) of patients and tapered from an average of 48 mg to average 11.25 mg daily in the remaining 31%. Gastrointestinal distress was the only adverse event noted.

Four prolonged cases of eosinophilic fasciitis in children. Hui-Yuen J, Lauren C, Garzon M, et al. *Arthritis Rheumatol* 2014; 66: S85.

Four pediatric patients with EF confirmed the efficacy of corticosteroids as a first-line therapy. All patients required either methotrexate or mycophenolate mofetil, and three required both, suggesting a more severe course within the pediatric population.

Second-Line Therapies

• Hydroxychloroquine	C
• Prednisone and D-penicillamine	C
• Intravenous immunoglobulin	D
• Ciclosporin	E

Eosinophilic rheumatic disorders. Clauw DJ, Crofford LJ. *Rheum Clin North Am* 1995; 21: 231–46.

Hydroxychloroquine at a dose of 200–400 mg daily can be used either alone or in combination with corticosteroids.

Eosinophilic fasciitis successfully treated with cyclosporine. Bukiej A, Dropiński J, Dyduch G, et al. *Clin Rheumatol* 2005; 24: 634–6.

A 45-year-old female unresponsive to treatment with prednisone followed by cimetidine experienced clinical remission after a regimen of ciclosporin at 5 mg/kg daily for 4 weeks tapered to 2.5 mg/kg daily.

Severe eosinophilic fasciitis: comparison of treatment with D-penicillamine plus corticosteroids vs. corticosteroids alone. Mendoza FA, Bai R, Kebede AG, et al. *Scand J Rheumatol* 2015; 73: 1010.

A prospective, non-randomized, open-label trial of 16 patients with a clinicohistopathologic diagnosis of severe EF revealed that the combination treatment of D-penicillamine plus corticosteroids was more efficacious than corticosteroids alone. Proteinuria was the most common adverse event in both groups. Four of 10 patients in the D-penicillamine-arm had to discontinue treatment due to adverse events.

Intravenous immunoglobulin for refractory eosinophilic fasciitis: a retrospective analysis from 3 tertiary care centers. Tkachenko E, Steuer AB, Lo K, et al. *J Am Acad Dermatol* 2019; S0190-9622(19)33297-9.

Five patients with recalcitrant EF were successfully treated with intravenous immunoglobulin (IVIG) (2 g/kg divided evenly over 2–3 consecutive days, every 4 weeks). All patients were able to discontinue oral corticosteroids once receiving IVIG. Adverse effects were headache in two patients.

Third-Line Therapies

• PUVA	E
• Ultraviolet A1 (UVA1) phototherapy	E
• Combination UVA1–retinoid–corticosteroid	E
• Extracorporeal photochemotherapy	E
• D-penicillamine	E
• Azathioprine	E
• Chloroquine	E
• Sulfasalazine	E
• Surgery	E
• Infliximab	E
• Rituximab	E
• Dapsone	E
• Cimetidine	C
• Tocilizumab	E
• Sirolimus	E
• Tofacitinib	E
• Mepolizumab	E

Eosinophilic fasciitis treated with psoralen-ultraviolet A bath photochemotherapy. Schiener R, Behrens-Williams SC, Gottlob P, et al. *Br J Dermatol* 2000; 142: 804–7.

After 35 sessions of PUVA, induration and mobility improved in a 56-year-old patient, with resolution of induration after 50 sessions.

Extracorporeal photochemotherapy in the treatment of eosinophilic fasciitis. Romano C, Rubegni P, De Aloe G, et al. *J Eur Acad Dermatol Venereol* 2003; 17: 10–3.

Three patients were treated with extracorporeal photochemotherapy on 2 consecutive days at 2-week intervals for 3 months, then every 4 weeks. After 1 year of therapy, two patients showed a considerable improvement in clinical parameters.

Eosinophilic fasciitis: a report of two cases treated with ultraviolet A1 phototherapy. Silny W, Osmola-Mankowska A, Czarnecka-Operacz M, et al. *Photodermatol Photoimmunol Photomed* 2009; 25: 325–7.

In one patient for whom immunosuppression was contraindicated, UVA1 monotherapy improved skin elasticity on the forearms but not the trunk after a cumulative dose of 1750J/cm². A second patient reduced concomitant methylprednisolone dose and experienced clinical improvement with a total UVA1 dose of 1930J/cm².

Surgical management of eosinophilic fasciitis of the upper extremity. Suzuki G, Itoh Y, Horiuchi Y. *J Hand Surg* 1997; 22: 405–7.

All four patients experienced improved mobility a few weeks after fasciectomy with follow-up oral prednisolone.

Infliximab may be effective in the treatment of steroid-resistant eosinophilic fasciitis: report of three cases. Khanna D, Agrawal H, Clements PJ. *Rheumatology (Oxford)* 2010; 49: 1184–8.

Three patients refractory to initial treatment with prednisone (60 mg/daily), two of whom also received methotrexate (20 mg/week), noticed clinical improvement within 8 weeks of starting

infliximab (3 mg/kg every 8 weeks), leading ultimately to drug-free remission.

Rituximab as a therapeutic consideration for refractory eosinophilic fasciitis. Nahhas AF, Alam M, Lim HW. *Int J Dermatol* 2018; 57: 614–5.

A 67-year-old man with biopsy and MRI-proven refractory EF was treated with oral corticosteroids, methotrexate, and rituximab (1 g IV, 2 weeks apart) in two courses 5 months apart. Range of motion and skin thickness improved, and peripheral eosinophilia resolved.

The use of tocilizumab in the treatment of refractory eosinophilic fasciitis: a case-based review. Vilchez-Oya F, Sánchez-Schmidt JM, Agustí A, et al. *Clin Rheumatol* 2020 Jan 23 [Epub ahead of print].

A 60-year-old man who failed corticosteroids, subcutaneous methotrexate, and intravenous immunoglobulins for EF was initiated on 8 mg/kg monthly tocilizumab with improved Rodnan skin scores and functional range of motion after 5 months. This case and two additional cases in the literature used concomitant prednisone and methotrexate with tocilizumab in refractory EF.

Treatment of eosinophilic fasciitis with sirolimus. Oza VS, Walsh R, North J, et al. *JAMA Dermatol* 2016; 152: 488–90.

A man in his 30s failed combined prednisone and methotrexate for biopsy-proven EF. He started sirolimus 2 mg/day (with 5 mg/day prednisone), experiencing improved pain and skin thickening within 6 weeks. Clinical and functional improvement continued throughout 9 months on this regimen.

Treatment of generalized deep morphea and eosinophilic fasciitis with the Janus kinase inhibitor tofacitinib. Kim SR, Charos A, Damsky W, et al. *JAAD Case Rep* 2018; 4: 443–5.

Tofacitinib (5 mg twice weekly) in combination with methotrexate (10 mg weekly) and prednisone (15 mg daily tapered and discontinued over 3 months) resulted in marked improvement of induration and range of motion after 1 year of treatment in a 66-year-old female.

Epidermal nevi

Jeffrey M. Weinberg

Epidermal nevi (EN; OMIM162900) are congenital hamartomas of embryonal ectodermal origin classified on the basis of their major component. The components may be sebaceous, apocrine, eccrine, follicular, or keratinocytic. An estimated one-third of individuals with EN have involvement of other organ systems. In these cases, the condition is termed *epidermal nevus syndrome*.

The most common EN are verrucous epidermal nevi (VEN), which are best treated with an ablative procedure using either surgical or laser technology. Inflammatory EN may respond to topical or systemic therapy.

The pluripotential stem cell in the embryonic ectoderm can develop into any of the cell types found within the epidermis and skin adnexa. Therefore many potential nevi may develop from these cell types. EN may be classified according to the predominant cell type. However, there may be different cell populations or overlap between different areas within the same nevus.

The focus of this chapter will be on nevi derived from keratinocytes. Of these, VEN are the most common. Other forms include an inflammatory linear verrucous epidermal nevus (ILVEN), an acantholytic or Darier-like nevus, an epidermolytic form, and linear porokeratosis. Very rarely an epidermal nevus may be associated with other birth defects, and a number of epidermal nevus syndromes have been described.

VEN may be localized, segmental, and rarely systematized. The individual lesions are verrucous papules, which may be pink, brown, or gray. These may develop as a result of mosaicism, and, if there is gonadal mosaicism, EN may be transmitted to future offspring.

There are very rare case reports of malignant change within EN, including squamous cell carcinoma and basal cell carcinoma.

MANAGEMENT STRATEGY

The major focus of therapy is improved cosmesis. A possible role for the dermis in the development of EN is suggested by the difficulty experienced in ablating these lesions surgically without destroying the underlying dermis. *Surgical management* of these lesions presents challenges. Superficial treatments, which remove only the epidermis, have a high recurrence rate, whereas excision or more aggressive ablative procedures may produce unacceptable scarring. *Laser* technology provides the surgeon with more precise tools to maximize efficacy while minimizing scarring. Alternatively, for very widespread lesions, a variety of *topical regimens*, as well as *systemic retinoids*, have been reported to produce some benefit.

ILVEN presents in early childhood as a pruritic, erythematous, linear plaque. It shares many features with psoriasis, and certain cases respond to antipsoriatic therapies such as *topical vitamin D analogs*, *corticosteroids*, and *dithranol*. This has led some authors to suggest that this condition is a nevusoid form of psoriasis. Epidermolytic and acantholytic nevi are more likely to respond to treatment with *retinoids*.

Specific Investigations

- Skin biopsy
- X-ray, imaging studies (magnetic resonance imaging [MRI], computed tomography scans), and ophthalmologic examinations

An epidermal nevus can most often be diagnosed solely on the clinical presentation and distribution of the lesion. A skin biopsy can be used both to confirm the diagnosis if necessary and to determine the predominant cell type and the presence of inflammatory changes, acantholysis, or dysplasia. This can be helpful in determining which therapeutic modality is most likely to succeed. If histopathology demonstrates an epidermolytic nevus, the individual should be counseled that there is a possibility that the mutation could be transmitted to offspring, with the risk that their children may have generalized cutaneous involvement. Biopsy can also indicate the rare occurrence of squamous or basal cell carcinoma, which can develop in EN.

Epidermal nevus syndromes refer to the association of EN with extracutaneous manifestations involving the central nervous system, eyes, or bones. The evaluation for systemic involvement should be based on the clinical extent of the EN and the presence of any extracutaneous signs and symptoms.

Generalized epidermolytic hyperkeratosis in two unrelated children from parents with localized linear form, and prenatal diagnosis. Chassaing N, Kanitakis J, Sportich S, et al. *J Invest Dermatol* 2006; 126: 2715–7.

The authors report two unrelated children with epidermolytic hyperkeratosis, both born to a parent affected with epidermolytic epidermal nevi (EEN); prenatal diagnosis in two successive pregnancies of one of the patients with EEN is described.

Squamous cell carcinoma arising in a verrucous epidermal naevus. Ichikawa T, Saiki M, Kaneko M, et al. *Dermatology* 1996; 193: 135–8.

A case report of a squamous cell carcinoma arising in a 74-year-old man with an epidermal nevus, plus a review of the literature, which revealed 18 previous reports of malignant change in EN.

Basal cell carcinoma developing in verrucous epidermal nevus. De D, Kanwar AJ, Radotra BD. *Indian J Dermatol Venereol Leprol* 2007; 73: 127–8.

A 58-year-old farmer with a hyperpigmented, soft verrucous plaque on the right temporoparietal region since birth presented with an ulcer of 8 months' duration. A diagnosis of basal cell carcinoma (BCC) arising in a verrucous epidermal nevus was made. Biopsy was consistent with BCC.

Epidermal nevus syndromes: new insights into whorls and swirls.

Asch S, Sugarman JL. *Pediatr Dermatol* 2018; 35 :21–9. The authors review recent genetic discoveries involving EN, including nevus sebaceous, keratinocytic epidermal nevus, nevus comedonicus, congenital hemidysplasia with ichthyosiform nevus and limb defects syndrome, phakomatosis pigmentokeratotic, Becker nevus, porokeratotic adnexal ostial nevus, ILVEN, and cutaneous-skeletal hypophosphatemia syndrome. Several mutations have been identified in EN, including mutations in Ras, fibroblast growth factor receptor 3 (FGFR3), phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (PIK3CA), and keratins.

Epidermal nevus syndromes: clinical findings in 35 patients.

Vidaurre-de la Cruz H, Tamayo-Sanchez L, Duran-Mckinster C, et al. *Pediatr Dermatol* 2004; 21: 432–9. Of patients with EN, 10%–18% may have disorders of the eye and skeletal and nervous systems.

Does inflammatory linear verrucous epidermal nevus represent a segmental type 1/type 2 mosaic of psoriasis?

Hofer T. *Dermatology* 2006; 212: 103–7. The author hypothesizes that inflammatory linear verrucous eruption besides nevoid psoriasis/linear psoriasis represents a further segmental type 1/type 2 mosaic of psoriasis, which, if a (verrucous) epidermal nevus exists, shows a high affinity of occurrence in close context to such a nevus. Heritability is thought to be possible.

Papular epidermal nevus with skyline basal cell layer (PENS): three new cases and review of the literature.

Luna PC, Pannizardi AA, Martin CI, et al. *Pediatr Dermatol* 2016; 33: 296–300. Papular epidermal nevus with skyline basal cell layer (PENS) is a recently described type of epidermal nevus with characteristic histopathologic findings. The authors note that cases of Blaschko distribution, associated extracutaneous manifestations, and familial cases have been reported. The probability of having extracutaneous manifestations is 6.3 times greater in those with more than four lesions. Therefore these patients require closer follow-up.

Verrucous Epidermal Nevus

First-Line Therapies

- Excision under local anesthetic **D**
- Shave or curettage under local anesthetic **D**
- Cryotherapy **C**

Epidermal nevus: surgical treatment by partial-thickness skin excision.

Dellon AL, Luethke R, Wong L, et al. *Ann Plast Surg* 1992; 28: 292–6. A case report of treatment of a systematized epidermal nevus by partial-thickness skin excision. This cleared the nevus but led to extensive hypertrophic and keloidal scarring.

Treatment of VEN: experience with 71 cases.

Lapidoth M, Israeli H, Ben Amitai D, et al. *Dermatology* 2013; 226: 342–6. Of the 71 cases reviewed, 62 responded well to cryotherapy alone, and nine facial VEN required CO₂ laser treatment. Small VEN required relatively few treatments (mean 3.4). Larger lesions required more treatments (mean 7.4) and did not respond as well.

Assessment of cryotherapy for the treatment of verrucous epidermal nevi.

Panagiotopoulos A, Chasapi V, Nikolaou V, et al. *Acta Derm Venereol* 2009; 89: 292–4. Nine patients with VEN and two with extensive unilateral epidermal nevus were treated with cryosurgery. Ten patients had their nevi treated successfully in two to five sessions, in which two cycles of open spray technique were used, 10–15 seconds each, depending on the size and extent of the nevus. The authors reported that the cosmetic result was excellent, with no scarring.

Second-Line Therapies

- Laser ablation **B**
- Dermabrasion **E**
- Ruby laser **E**
- Erbium:YAG laser **C**

Laser treatment of epidermal nevi: a multicenter retrospective study with long-term follow-up.

Alkhalifah A, Fransen F, Le Duff F, et al. *J Am Acad Dermatol* 2019 Jun 13. pii: S0190-9622(19)30976-4. doi: 10.1016/j.jaad.2019.06.013 [Epub ahead of print].

Patients were treated for different types of EN, mostly with ablative lasers, including 23 VEN, 16 nevi sebaceous, 26 Becker nevi, and 2 ILVEN. The follow-up period was a median of 37 months. Better results, fewer recurrences, and higher patient satisfaction were noted in treatments for VEN than for nevi sebaceous.

Epidermal nevi treated by carbon dioxide laser vaporization: a series of 25 patients.

Paradela S, Del Pozo J, Fernández-Jorge B, et al. *J Dermatol Treat* 2007; 18: 169–74.

A total of 25 patients were treated with the CO₂ laser in the superpulsed mode. Good results were achieved in 92% of patients with soft, flattened nevi but in only 33% of patients with keratotic nevi. The authors concluded that the CO₂ laser in the superpulsed mode is an effective and safe treatment for VEN and provides fewer recurrences than other laser therapies. They noted that the main determining factor for the cosmetic result is thickness of the nevus.

Er:YAG laser treatment of verrucous epidermal nevi.

Park JH, Hwang ES, Kim SN, et al. *Dermatol Surg* 2004; 30: 378–81. Twenty patients with VEN were treated with the erbium:YAG laser. After a single treatment, successful elimination of the VEN was observed in 15 patients. Five patients (25%) showed a relapse within the first year after treatment.

Successful treatment of dark-colored epidermal nevus with ruby laser.

Baba T, Narumi H, Hanada K, et al. *J Dermatol* 1995; 22: 567–70. Five darkly pigmented EN were successfully cleared after one to four treatments with a ruby laser in the normal mode. Two patients subsequently had hypopigmentation at the treatment site.

Third-Line Therapies

• Systemic retinoids	D
• Topical retinoids plus 5-fluorouracil	E
• Photodynamic therapy	E
• Sirolimus	E

A case of verrucous epidermal naevus successfully treated with acitretin. Taskapan O, Dogan B, Baloglu H, et al. Acta Derm Venereol 1998; 78: 475–6.

Report of a case of VEN in a 20-year-old patient who responded to acitretin 75 mg daily. The nevus started to recur 6 weeks after cessation of therapy.

Topical tretinoin and 5-fluorouracil in the treatment of linear verrucous epidermal nevus. Kim JJ, Chang MW, Shwayder T. J Am Acad Dermatol 2000; 43: 129–32.

In a 7-year-old boy with an extensive facial epidermal nevus, there was significant improvement using a combination of topical tretinoin 0.1% cream and 5-fluorouracil.

Verrucous epidermal nevus successfully treated with photodynamic therapy. Sim JH, Kang Y, Kim YC. Eur J Dermatol 2010; 20: 814–5.

A 9-year-old girl presented with asymptomatic linear papillomatous and hyperkeratotic papules on the right thigh. She had no history of previous therapy. Treatment with methyl-aminolevulinate–photodynamic therapy (MAL-PDT) was performed. After four treatments, the lesion almost completely resolved, with mild residual hyperpigmentation. At 3 months' follow-up, cosmetic and clinical response was excellent. At 5 months' follow-up, no recurrence had been observed.

Topical sirolimus therapy for epidermal nevus with features of acanthosis nigricans. Dodds M, Maguiness S. Pediatr Dermatol 2019; 36: 554–5.

A 4-year-old male presented with widespread expanding epidermal nevus with features of acanthosis nigricans. He demonstrated a mosaic mutation in FGFR3, the R248C variant. Despite several treatments, there was progressive growth, fissuring, and bleeding of the affected skin. Topical sirolimus was attempted and found to improve thickness and overall symptoms.

Inflammatory/Dysplastic Epidermal Nevi

First-Line Therapy

• Topical corticosteroids	D

Successful treatment of inflammatory linear verrucous epidermal nevus with tacrolimus and fluocinonide. Mutasim DF. J Cutan Med Surg 2006; 10: 45–7.

Successful treatment of ILVEN with potent topical steroid and tacrolimus ointments.

Nevi that have inflammatory, epidermolytic, acantholytic, or dysplastic features may respond more effectively to medical therapy than to surgical treatment. ILVEN is a relatively rare entity that presents during childhood and can be difficult to treat. Topical corticosteroids are often used as first-line therapy, but the response is variable.

Second-Line Therapies

• Topical calcipotriol/tacalcitol	D
• Topical retinoids	E
• Systemic retinoids	E
• Topical dithranol	E

Topical calcipotriol for the treatment of inflammatory linear verrucous epidermal nevus. Zvulunov A, Grunwald MH, Halvy S. Arch Dermatol 1997; 133: 567–8.

A report on the use of calcipotriol in the treatment of an ILVEN.

Acitretin treatment of a systematized inflammatory linear verrucous epidermal nevus. Renner R, Rytter M, Sticherling M. Acta Derm Venereol 2005; 85: 348–50.

In this case treatment with oral acitretin was initiated at a dose of 25 mg daily but was reduced to 20 mg, with increasing erythema on the face and left leg. The dose was slowly increased to 30 mg daily. After 2 weeks, the erythema had almost entirely resolved, and the hyperkeratosis was distinctly reduced. After 8 weeks, the inflammatory and hyperkeratotic lesions had almost disappeared.

Dithranol in the treatment of inflammatory linear verrucous epidermal nevus. De Mare S, van de Kerkhof PC, Happle R. Acta Derm Venereol 1989; 69: 77–80.

Treatment with dithranol resulted in complete relief from pruritus and clearing of all linear lesions, except for a small verrucous band on the shin.

Third-Line Therapies

• Pulsed-dye laser	E
• CO ₂ laser	E
• Surgical excision	D
• Etanercept	E
• Photodynamic therapy	E
• Crisaborole	E
• Excimer laser	E

Inflammatory linear verrucous epidermal nevus responsive to 308-nm excimer laser treatment. Grgurich E, Gupta N, Owen R, et al. Cutis 2018; 102: 111–4.

The authors report a 20-year-old woman with lesions on the right leg since infancy. After failing treatments, including ablative CO₂ laser, the patient was treated with a UV 308-nm excimer laser and showed noticeable clinical improvement.

Inflammatory linear verrucous epidermal nevus treated successfully with crisaborole ointment in a 5-year-old boy. Barney E, Prose NS, Ramirez M. Pediatr Dermatol 2019; 36(3): 404–5. doi: 10.1111/pde.13793. 2019 Mar 5 [Epub ahead of print].

The authors present a case of ILVEN in a 5-year-old-boy, treated successfully with crisaborole 2% ointment.

Pulsed dye laser for inflammatory linear verrucous epidermal nevus. Sidwell RU, Syed S, Harper JL. Br J Dermatol 2001; 144: 1267–9.

Three cases of ILVEN in children (ages 2–8) were treated successfully with the pulsed-dye laser. The authors surmise that the destruction of capillaries by the laser reduces the release of inflammatory mediators.

Carbon dioxide laser therapy for an inflammatory linear verrucous epidermal nevus: a case report. Ulkur E, Celikoz B, Yuksel F, et al. *Aesthet Plast Surg* 2004; 28: 428–30.

A case of ILVEN was treated with the CO₂ laser. All symptoms, including erythema, excoriation, granulation, and pruritus, disappeared, and a pale pigmentation remained.

Full-thickness surgical excision for the treatment of inflammatory linear verrucous epidermal nevus. Lee BJ, Mancini AJ, Renucci J, et al. *Ann Plast Surg* 2001; 47: 285–92.

The authors report four patients with extensive ILVEN treated successfully with full-thickness surgical excision.

Successful treatment of a widespread inflammatory verrucous epidermal nevus with etanercept. Bogle MA, Sobell JM, Dover JS. *Arch Dermatol* 2006; 142: 401–2.

A 55-year-old woman diagnosed with widespread inflammatory epidermal verrucous nevi was presented. She had a history of multiple therapies, including emollients, topical and intramuscular steroids, and isotretinoin.

Etanercept therapy was initiated at 25 mg biweekly. After 1 month, good improvement in pruritus and erythema was observed. Etanercept was increased to 50 mg biweekly, which provided nearly 50% improvement over 3 months. After a total of 6 months, she achieved almost complete resolution of pruritus and a significant improvement in roughness and erythema. The dose was then reduced to 25 mg biweekly, and disease activity remained quiescent at follow-up.

Inflammatory linear verrucous epidermal nevus successfully treated with methyl-aminolevulinate photodynamic therapy. Parera E, Gallardo F, Toll A, et al. *Dermatol Surg* 2010; 36: 253–6.

Treatment with MAL-PDT was performed for a 67-year-old man with ILVEN who had failed multiple modalities. Almost complete resolution of the lesions after three weekly PDT sessions was observed. No recurrence was observed after follow-up of 15 months.

Epidermodysplasia verruciformis

Helen Lee, Anthony A. Gaspari

Epidermodysplasia verruciformis (EV) is a rare genetic disease characterized by an impaired immune response to human papillomavirus (HPV) and HPV-associated cutaneous oncogenesis. The exact prevalence of EV is unknown; however, about 500 cases have been described worldwide. Because of the rarity of EV, there are few controlled trials of therapeutic interventions. Thus, the treatments described herein are predominantly anecdotal. The therapies applied to EV are usually extensions of treatments for HPV infections and skin cancers in the general population, or treatments successfully used for other immunodeficiency diseases in which HPV infections are prominent.

The disease is manifested by development of widespread flat-wart and pityriasis versicolor-like lesions in early childhood, which persist throughout adulthood. Other lesions may be more verrucous or resemble seborrheic keratoses. In the fourth and fifth decades, 50%–70% of patients begin to develop multiple cutaneous malignancies, mainly squamous cell carcinomas (SCCs).

EV has been associated with increased susceptibility to specific HPV types, primarily involving β -human papillomaviruses (β -HPVs). Most β -HPVs are considered non-pathogenic in the general population and viewed as commensal viruses of the human skin. In EV, however, HPV-5 and HPV-8 genotypes account for up to 90% of EV-associated SCC. Malignant transformation has also been associated with HPV subtypes 17, 20, and 47. Other non-oncogenic HPV types commonly seen in EV include 4, 9, 12, 14, 15, 19, 21–25, 36–38, and 50. EV patients generally are concomitantly infected with more than one genotype. Notably, Merkel cell polyomavirus particles have been recently identified in EV lesions as well. Advancement in HPV typing systems has proven to be beneficial in discerning potentially oncogenic HPV types from non-pathologic types. Such HPV detection methods involving polymerase chain reaction protocols can further assist in confirming the diagnosis of EV when histology is unrevealing.

Inherited EV harbors autosomal recessive mutations of two genes located on chromosome 17: *EVER1/TCM6* and *EVER2/*

TCM8, both coding transmembrane proteins located in the endoplasmic reticulum and involved in zinc transportation. However, about 25% of EV cases are not associated with these genetic mutations. Various case reports presenting novel mutations such as *MST-1*, *RHOH*, *CORO1A*, *DOCK8*, *DCLRE1C*, *RASGRP1*, *ANKRD26*, *IL2RG*, and *TPP2* have emerged. Loss of function gene mutation of *CIB1* (calcium and integrin-binding protein 1), which is an integral part of the *EVER1/EVER2* complex, has gained recent notoriety in its role in atypical EV cases. All associated mutations are thought to result in defective cell-mediated immune response to HPV, ultimately leading to formation of skin lesions.

A more novel entity is the occurrence of the EV phenotype in immunosuppressed individuals, which has been coined *acquired epidermodysplasia verruciformis*. This EV-like syndrome has been described in patients with HIV infection, organ transplantation, Hodgkin disease, common variable immunodeficiency, systemic lupus erythematosus, immunoglobulin M deficiency, adult T-cell leukemia, some cases of graft-versus-host reaction, and others. Although this condition affects a diverse range of immunocompromised patients, AEV is reported less frequently than congenital EV, which may be due to a yet unidentified, higher genetic predisposition to EV infections in affected individuals only. The high risk of malignant transformation in genetic EV seems to be reduced in the acquired variety.

MANAGEMENT STRATEGY

There is no definitive treatment for EV that can produce a complete and sustained clearing of both benign wart-like and keratotic lesions that possess potential for oncogenic transformation. In addition, these EV lesions can be locally destructive when left untreated. Arguably the most vital aspect in the management of EV is protection from ultraviolet radiation, which contributes to carcinogenesis. Ultraviolet light-avoiding behavior and topical sunscreens (sun protection factor >50) are indicated. Other cancer cofactors (radiotherapy, immunosuppressive drugs) must be avoided. Premalignant and troublesome benign lesions can be treated by a variety of destructive techniques: surgical (cryotherapy, shave excision, curettage, laser, full excision, Mohs micrographic surgery) or chemical (trichloroacetic acid, 5-fluorouracil, cidofovir, glycolic acid).

For more widespread lesions with signs of premalignancy or malignancy, agents that modify keratinization are indicated, such as oral or topical retinoids, vitamin D₃ analogs, interferons, and imiquimod. Photodynamic therapy (PDT) can be useful in the treatment of early malignant lesions. Larger malignancies can necessitate skin autografts.

The role of HPV vaccination in EV patients has not been fully elucidated. Recent literature has been divided on the therapeutic benefit of HPV vaccines in immunosuppressed patients. Some cases have reported clinical resolution of cutaneous warts with anecdotal use, while others have shown limited results. There are evolving studies examining the effects of investigational vaccinations such as HPV-16-derived L-2 vaccine, which can generate antibodies that exhibit potential to cross-neutralize other cutaneous genotypes including HPV-5 and HPV-8. The efficacy of such vaccines in preventing cutaneous malignancies has not been fully assessed and ongoing work will be needed to confirm the protective and therapeutic potential of HPV vaccination in EV patients.

Specific Investigations

- Family history and examination of other family members
- Skin biopsy
- HPV typing to identify potentially oncogenic and non-oncogenic HPV types
- Evaluation of immune status and the presence of factors producing or enhancing immunosuppression: HIV, congenital and acquired immunodeficiency syndromes, iatrogenic immunosuppression

Generalized verrucosis: a review of the associated diseases, evaluation, and treatments. Sri JC, Dubina MI, Kao GF, et al. *J Am Acad Dermatol* 2012; 66: 2292–311.

Generalized verrucosis and distinct diseases (including EV) associated with generalized warts are defined. The indications for histopathologic examination, HPV typing, and other laboratory tests, as well as potential treatment options, are discussed.

Acquired epidermodysplasia verruciformis: a comprehensive review and proposal for treatment. Zampetti A, Giurdanella F, Manco S, et al. *Derm Surg* 2013; 39: 974–9.

The treatment of acquired EV is not standardized, and several approaches have been described in the literature. Better results have been reported with combination procedures (e.g., photodynamic therapy and retinoids).

Deleterious effect of radiation therapy on epidermodysplasia verruciformis patients. de Oliveira WR, da Cruz Silva LL, Neto CF, et al. *J Cutan Med Surg* 2015; 19: 416–21.

Radiotherapy might be associated with progression of SCC in EV patients, and it is recommended that this method of treatment be avoided in this patient population.

Re-evaluation of epidermodysplasia verruciformis: reconciling more than 90 years of debate. Przybyszewska J, Zlotogorski A, Ramot Y. *J Am Acad Dermatol* 2017; 76(6): 1161–75.

The different characteristics of seemingly clinically similar disorders are highlighted between EV, acquired EV, and generalized verrucosis.

First-Line Therapies

• Sun avoidance/protection	E
• Cryotherapy with liquid nitrogen	E
• Topical retinoic acid 0.05%–0.1% cream for benign, flat, cosmetically troublesome lesions	E
• Shave excision of flat lesions	E
• Surgical excision of malignant lesions	E

Second-Line Therapies

• Interferon- α with retinoids (acitretin)	E
• Systemic isotretinoin	E
• Imiquimod 5% cream	E
• Topical 15% glycolic acid lotion	C
• Topical squaric acid dibutylester 2% solution (SADBE)	E
• Oral zinc sulfate	E
• Topical 1% cidofovir cream	E

Treatment of epidermodysplasia verruciformis with a combination of acitretin and interferon alfa-2a. Anadolu R, Oskay T, Erdem C, et al. *J Am Acad Dermatol* 2001; 45: 296–9.

A patient treated with oral acitretin 50 mg daily and systemic interferon- α_{2a} 3 million IU was subcutaneously injected three times weekly for 6 months. Improvement was followed by relapse after discontinuation of treatment, and the same regimen was reintroduced. The interferon was eventually discontinued after 4 months and the acitretin was reduced to 25 mg for 3 months, then ultimately stopped. Improvement was maintained during the subsequent 12-month follow-up. Used as monotherapy, interferon- α has minimal benefit and is not recommended.

Systemic low-dose isotretinoin maintains remission status in epidermodysplasia verruciformis. Rallis E, Papatheodorou G, Bimpakis E, et al. *J Eur Acad Dermatol Venereol* 2008; 22: 523–5.

In this case isotretinoin 0.8 mg/kg/day for 6 months produced complete clearance, with relapse 4 months after discontinuation of medication. Maintenance treatment with 20 mg/day resulted in sustained remission. EV in this case was associated with HPV-3 – that is, a more benign variant responsive to therapy.

Treatment of a patient with epidermodysplasia verruciformis carrying novel EVER2 mutation with imiquimod. Berthelot C, Dickerson MC, Rady P, et al. *J Am Acad Dermatol* 2007; 56: 882–6.

An EV patient with homozygous gene mutation of the *EVER2* gene with a 10-year history of flat warts underwent treatment with wide, local excision of large SCC on the chest and topical 5% imiquimod 5 days weekly for 3 months to multiple SCCs on face with significant improvement.

Acquired epidermodysplasia verruciformis syndrome in HIV-infected pediatric patients: prospective treatment trial with topical glycolic acid and human papillomavirus genotype characterization. Moore RL, de Schaezen V, Joseph M, et al. *Arch Dermatol* 2012; 148: 128–30.

Topical 15% glycolic acid lotion had a good effect in HIV-infected children; the therapy was regarded as safe and efficacious.

Epidermodysplasia verruciformis: successful treatment with squaric acid dibutylester. Kehdy J, Erickson C, Rady P, et al. *Cutis* 2015; 96: 114–8.

A case of 25-year history of refractory EV that was successfully treated with topical SADBE contact sensitizer agent. SADBE has been used over the years for the treatment of a variety of skin diseases, including alopecia areata and refractory cutaneous warts.

Efficacy of oral zinc therapy in epidermodysplasia verruciformis with squamous cell carcinoma. Sharma S, Barman KD, Sarkar R, et al. *Ind Derm Online J* 2014; 5: 55–8.

A 24-year-old patient with EV was treated with oral zinc sulfate (550 mg/kg/day) with a satisfactory result (clearance of wart-like lesions on the face and upper and lower extremities by 30%–40%). The squamous cell carcinoma of the right hand was removed surgically.

New human papillomavirus (HPV) types involved in epidermodysplasia verruciformis (EV) in 3 HIV-infected patients: response to topical cidofovir. Darwich E, Darwich L, Klaustermeier J, et al. *J Am Acad Dermatol* 2011; 65(2): e43–5.

Two out of three HIV patients with recalcitrant EV-like lesions were treated with topical 1% cidofovir cream for 4–9 weeks with

resolution. Notably, patients who responded were only carriers of a novel genotype HPV-36 and had the most common HLA-II haplotypes associated with EV.

Third-Line Therapies		
• Photodynamic therapy		E
• CO ₂ laser for malignant and premalignant lesions		E
• Skin autografts		E

Photodynamic therapy for human papillomavirus-related diseases in dermatology. Szeimies RM. Med Laser Appl 2003; 18: 107–16.

Topical PDT using 20% 5-aminolevulinic acid was reported to yield excellent results in a case of EV associated with HPV-5, 8, 36, and other strains. Twelve months after PDT the lesions started to reappear but resolved after repeated treatments. The authors suggest annually repeated PDT is safe and will help control EV lesions.

CO₂ laser treatment of warts in immunosuppressed patients. Lauchli S, Kempf W, Dragieva G, et al. Dermatology 2003; 206: 148–52.

Alternative therapies for recalcitrant HPV-induced cutaneous warts in EV may include CO₂ laser or neodymium laser. Laser therapy of recalcitrant warts proved to be efficacious in both immunosuppressed and immunocompetent individuals.

Skin autografts in epidermodysplasia verruciformis: human papillomavirus-associated cutaneous changes need over 20 years for malignant conversion. Majewski S, Jablonska S. Cancer Res 1997; 57: 4214–6.

For very widespread, constantly developing new lesions not responding to any therapy, the only effective method is removal of the most involved skin area (usually on the forehead) and its replacement with skin from non-exposed inner aspects of the arms.

Epidermolysis bullosa

Tobias Welponer, Johann W. Bauer, Martin Laimer

Epidermolysis bullosa (EB) comprises a group of rare, genetically inherited mechanobullous skin disorders. Underlying mutations impair the structural and functional integrity of the epidermis and dermoepidermal basement membrane zone (BMZ) of skin and mucous membranes. The clinical hallmarks include increased mucocutaneous fragility with trauma-induced blistering, erosions, and scarring (see figure). Based upon the level of blister formation within the BMZ, EB is subclassified into four major types: simplex (intraepidermal), junctional (lamina lucida), dystrophic (dermal), and Kindler EB (mixed). Considerable genetic heterogeneity as well as secondary epigenetic, biochemical, and environmental factors constitute for the wide phenotypical variety of the disease. The index genes involved are also expressed in other epithelialized (gastrointestinal, respiratory, urogenital tract) or mesenchymal (skeletal muscle) organs rendering particularly the more severe EB variants a systemic disease with high morbidity and mortality.

MANAGEMENT STRATEGY

Currently no curative treatment options are available in clinical practice. As such, management of EB primarily consists of avoidance of provoking factors, supportive care, and symptomatic therapies (i.e., skin and wound care; avoidance of wound infection; nutritional support; management of extracutaneous manifestations, itch, and pain). Developing individualized care plans for each patient is crucial due to the high geno- and phenotypical

interpatient variance as well as to address changing individual needs and preferences to increase therapy adherence. Milder variants of EB, like localized simplex or mild dystrophic forms, mostly do not require close monitoring and can be seen once a year. Patients suffering from severe forms of EB (severe dystrophic, junctional, and generalized simplex forms) need close monitoring at least every 3–6 months and require a multidisciplinary approach of care.

Skin care and avoidance of trauma are keys to avoid painful blister formation and erosions.

Avoidance of trauma to healthy skin is a difficult task when dealing with everyday life, especially during infancy and childhood. It is crucial not to limit physiological needs and movement patterns, as this would alter the development of bones, tendons, and muscles, causing a non-physiological posture that needs intensive physical therapy or even surgical interventions.

Cleansing: bathing in pure water can be painful for patients with larger wounds. Adding salt to the bathtub approximates isotonic conditions; reduces bacterial colonization, pain, and body odor as well as skin exudate; and facilitates removal of wound dressings.

Moisturizing: regular skin care with soft and non-sticking emollients containing, for example, dexpanthenol, zinc, or glycerine, as well as taking oil baths, increases skin smoothness and improves structural integrity while reducing vulnerability of the skin.

Dressings: non-adherent, flexible, polyurethane foam pads (e.g., Mepilex Transfer, Mepilex Lite) applied on skin areas prone to pressure and shearing forces (knees, elbows, wrists, feet) establish an artificial barrier that absorbs mechanical stress and simultaneously maintains a moist wound bed supporting the healing process. Based on our clinical experience, these wound dressings can easily be removed and reapplied to intact skin or wounds, without inflicting additional trauma.

Individualized *wound care* is essential to restore the barrier function of the skin and to prevent infections, as well as to reduce pain. Wounds need to be assessed on a daily basis by the caregiver or patient considering localization, course, and characteristics (size, exudate, bacterial colonization, infection, and pain) in order to choose an appropriate wound dressing.

Blisters have to be punctured with a sterile needle to prevent further extension. Wounds are cleansed with non-cytotoxic solutions (e.g., 0.9% saline solutions, 0.1% chlorhexidine, 0.1% polyhexanide). In order to promote healing, *avital tissue* needs to be debrided, preferably using non-physical methods (e.g., hydrogels, calcium alginate, tensid-containing polyurethane foams).

Bacterial colonization as well as *infections* primarily caused by *Staphylococcus* spp., *Streptococcus* spp., or *Pseudomonas aeruginosa* have to be treated with topical antibiotics, antimicrobials, or antiseptics (e.g., 2% fusidic acid, 2% mupirocin, 1% silver sulfadiazine, 2–4% chlorhexidine). Topical antibiotics need to be rotated every 2–6 weeks to prevent resistance. Bathing in antiseptic agents (e.g., 100 mL bleach in a bathtub) is very useful to control critically colonized wounds and microbial burden. If cutaneous infections are unresponsive to topical treatment or signs of systemic infections occur, antibiogram-guided systemic therapy has to be initiated. Granulating wounds without signs of infection can be covered with paraffin- or white petrolatum-impregnated gauzes and dry lesions with hydrogels. Non-stick and non-adherent silicone dressings (e.g., UrgoTul, Adaptic, Mepitel) or foams (e.g., Mepilex) minimize traumatization when removing the dressings.

Tissue-engineered *skin grafts* derived from neonatal foreskin or allogeneic composite cultured skin (e.g., Apligraf, OrCel) can promote wound healing in non-infected wounds unresponsive to conservative therapies and for which malignancy has been ruled out.

Management of *itch and pain* is a very important issue in EB due to their chronic course and huge impact on quality of life. Conservative and supportive as well as psychological, therapeutic options should be fully exploited before implementing a pharmacological analgesic treatment. While classical antihistamines do not work sufficiently in EB, the anti-IL-4R α monoclonal antibody dupilumab anecdotally proved some preliminary efficacy. Likewise, differential diagnoses (e.g., contact dermatitis) and other causes of pain and itch should be determined (and repeated at intervals). Special diligence needs to be attributed to the change of wound dressings as a significant measure in pain reduction. If pharmaceutical treatment is necessary, it should adhere to the ladder approach of the World Health Organization and include topical analgesics, if applicable.

Improving nutritional intake – due to structural issues alongside mucosal involvement within the oro-esophageal-gastrointestinal tract, as well as a chronic hypercatabolic state, there is reduced intake and increased nutrient loss caused by an impaired skin and intestinal barrier, especially in dystrophic and junctional EB. Failure to thrive necessitates intake of high caloric formulas. Nasogastric tubes and gastrostomy may be considered in severe cases. Patients with low levels of micronutrients (e.g., iron, albumin, zinc, calcium, selenium, or vitamin D) suffer from poor wound healing, growth deficit, osteoporosis, or anemia, which might increase the risk of severe cardiomyopathies. Supplementation, especially of iron, albumin, vitamin D, and zinc, prevents, diminishes, or delays complications.

Primary and secondary *extracutaneous involvement* especially occurs in the severe forms of EB. Common complications involve ocular, oral, and dental lesions, as well as esophageal or genitourinary strictures and mitten deformities, which often require surgical treatment.

Patients with junctional (JEB) and recessive dystrophic EB (RDEB) are at high risk for developing aggressive mucocutaneous *squamous cell carcinomas* (SCCs). Suspicious skin areas (chronic, non-healing ulcers with excessive pain and rapid growth; hypergranulating tissue; raised borders; hyperkeratotic areas in a wound) should be biopsied or excised for histological examination. Differentiation of malignant lesions from pseudoepitheliomatous hyperplasia or granulation tissue may sometimes be challenging. In case of proven malignancy, regular controls as well as clinical and radiographic (e.g., CT, PET-CT, MRI) follow-up every 3–6 months are necessary due to the aggressive course of these tumors.

In light of the serious morbidity and mortality of EB, therapeutic options are highly needed. Such strategies include genome editing, as well as gene-, protein- and cell-based therapies, which are currently under development.

Specific Investigations

- Rule out differential diagnoses of EB
- Skin biopsy for immunofluorescence microscopy
- Skin biopsy for transmission electron microscopy
- Whole blood in ethylenediamine tetra-acetic acid (EDTA) for genomic DNA extraction and mutational analysis

Clinical practice guidelines for laboratory diagnosis of epidermolysis bullosa. Has C, Liu L, Bolling MC, et al. Br J Dermatol 2020; 182: 574–592.

In patients presenting with skin fragility and blistering, a traumatic, metabolic, hematologic, infectious, drug-induced, and autoimmune etiology has to be ruled out. If history and clinical features are indicative for EB, a skin biopsy from a newly developed blister and peripheral blood sampling should be taken for immunofluorescence mapping and direct genetic testing (Sanger sequencing,

next-generation sequencing), respectively. Thus irregular protein expression, cleavage level, and pathogenic sequence variants can be identified. Immunofluorescence investigation allows a fast and feasible initial diagnostic work-up. Simultaneously, genetic testing should be performed for full molecular characterization to deliver a final diagnosis (and rationale for approaches of molecular therapy). Although rarely necessary, transmission electron microscopy might be helpful in select cases to identify skin cleavage level and ultrastructural anomalies to confirm or refine results obtained from immunofluorescence mapping.

First-Line Therapies

• Wound care and management of extracutaneous manifestations	B
• Treatment of SCC	D
• Management of pain and pruritus	B
• Meeting nutritional requirements	B
• Psychosocial support	B
• Occupational therapy	B

A consensus approach to wound care in epidermolysis bullosa. Pope E, Lara-Corrales I, Mellerio J, et al. J Am Acad Dermatol 2012; 67: 904–17.

Skin and wound care is the backbone of treatment of EB patients. This consensus recommendation guideline for wound care is based on the best evidence available established by EB experts. It takes into account EB (sub-) type, wound localization, and characteristics, as well as patient age, nutritional status, hemoglobin levels, limitations of daily activities, pain, and itch to establish an individualized treatment plan for each patient to improve wound healing and prevent complications like antibiotic resistance by, for example, rotating topical antibiotics. Providing education and support to patients, parents, and treatment circles is obligatory to increase adherence to treatment.

Management of cutaneous squamous cell carcinoma in patients with epidermolysis bullosa: best clinical practice guidelines. Mellerio JE, Robertson SJ, Bernardis C, et al. Br J Dermatol 2016; 174: 56–67.

Severe EB types, especially JEB and RDEB, are associated with the development of aggressive mucocutaneous SCCs, which constitute significant morbidity and mortality and may arise early even in premature patients. These tumors develop at sites of chronic skin blistering, wounds, and scars, which makes clinical detection challenging. Given the low number of patients, no prospective clinical trials are available comparing treatment options. Wide local excision is currently the treatment of choice. Adjuvant or neoadjuvant radio- and/or chemotherapy might be useful for unresectable tumors or at a metastatic stage. Case reports on epidermal growth factor receptor antagonists, PD-1 inhibitors, and tyrosine kinase inhibitors show some favorable results in metastatic disease. Due to the aggressive course of these SCCs, efforts should be directed toward palliative care when tumor progress is inevitable.

Pain care for patients with epidermolysis bullosa: best care practice guidelines. Goldschneider KR, Good J, Harrop E, et al. BMC Med 2014; 12: 178.

Management of pain and pruritus is of special importance in EB as it poses major limitations on quality of life. This guideline grades recommendations regarding safety and harm, health benefit to patient, burden of adherence, and cost-effectiveness, as well as impact on morbidity, mortality, or quality of life. Differentiating acute and chronic pain, as well as pain characteristics,

localization, and origin impact therapeutic decisions. Pain management comprises treatment of the underlying cause, cognitive behavioral therapy, and environmental comfort measures, supportive measures, and pharmacologic therapy taking into account complications of chronic intake. The guideline also attributes special topics and offers recommendations for infants and end-of-life pain care. Management of itch consists in environmental and behavioral interventions, antihistamines, centrally acting medications, and antidepressants.

Nutritional aspects of children and adolescents with epidermolysis bullosa: literature review. Zidorio AP, Dutra ES, Leao DO, et al. *An Bras Dermatol* 2015; 90: 217–23.

Gastrointestinal problems in EB lead to severe nutritional deficits, among which esophageal stenosis hinders swallowing and thus further aggravates nutrient deficits without appropriate intervention. A dietary plan for EB patients takes into consideration evaluation of interfering factors regarding food intake and absorption, biochemical assessment, EB-intrinsic hypercatabolic state, and assessment of nutritional intake compared to healthy individuals. To meet energy requirements for EB patients it is proposed to approach 100%–150% of the estimated energy requirement of sex-, age-, and height-matched healthy individuals.

Natural history of growth and anaemia in children with epidermolysis bullosa: a retrospective cohort study. Reimer A, Hess M, Schwieger-Briel A, et al. *Br J Dermatol* 2019.

This paper demonstrates that nutritional compromise with growth failure and anemia occurs early in RDEB and may therefore require interventions as of the first year or two of life.

Psychosocial recommendations for the care of children and adults with epidermolysis bullosa and their family: evidence based guidelines. Martin K, Geuens S, Asche JK, et al. *Orphanet J Rare Dis* 2019; 14: 133.

The manifold and often severe complications of EB have a big impact on psychosocial life. People and families living with EB need psychological guidance with the aim to improve quality of life and psychosocial wellbeing and to help them cope with the condition. Pain and physical limitations have a big impact on mental health and therefore should be prioritized in the clinical treatment. Psychosocial techniques can support and extend guideline-adherent pain management.

Occupational therapy for epidermolysis bullosa: clinical practice guidelines. Chan JM, Weisman A, King A, et al. *Orphanet J Rare Dis* 2019; 14: 129.

Chronic wounding and inflammation in EB patients induce sustained tissue-remodeling and contractures, which limit activities of daily living. Occupational therapy supports patients to maximize their functional abilities and improve quality of life.

Second-Line Therapies

- Downregulation of IL-1 β in generalized severe epidermolysis bullosa simplex **C**
- Inhibition of phosphodiesterase-4 in generalized severe epidermolysis bullosa simplex **E**
- Induced premature termination codon read-through **C**
- Dapsone as antiinflammatory agent in EB simplex **E**

Diacerein orphan drug development for epidermolysis bullosa simplex: a phase 2/3 randomized, placebo-controlled, double-blind clinical trial. Wally V, Hovnanian A, Ly J, et al. *J Am Acad Dermatol* 2018; 78: 892–901. e897.

Targeting trauma-induced inflammatory pathways, 17 patients suffering from generalized EB simplex who were treated with topical diacerein, an IL-1 β inhibitor, for 6 weeks showed a significant reduction of blisters by more than 70% without any adverse events in the treatment arm.

Epidermolysis bullosa simplex generalized severe induces a T helper 17 response and is improved by apremilast treatment. Castela E, Tulic MK, Rozieres A, et al. *Br J Dermatol* 2019; 180: 357–64.

Treatment with the phosphodiesterase-4 inhibitor apremilast approved for the treatment of psoriasis resulted in an improvement of skin blistering and good tolerance in three adult patients with generalized EB simplex.

Successful dapsone therapy in inherited epidermolysis bullosa. Gibson M, Rogers CL, Murrell DF. *J Eur Acad Dermatol Venereol* 2020; doi: 10.1111/jdv.16301.

One patient with generalized EB simplex receiving 100 mg dapsone daily showed a rapid reduction in number and size of blisters. A second patient with intermediate JEB and end-stage kidney disease received 25 mg dapsone up to three times weekly. After 10 months of treatment, his Quality of Life in EB score and the activity score in the EB Disease Activity and Scarring Index (EBDASI) improved, while the damage score in the EBDASI remained unaffected.

Gentamicin induces functional type VII collagen in recessive dystrophic epidermolysis bullosa patients. Woodley DT, Cogan J, Hou Y, et al. *J Clin Invest* 2017; 127: 3028–38.

Five RDEB patients harboring nonsense mutations received topical gentamicin 0.1% ointment or placebo three times daily for 2 weeks and intradermal injections with 8 mg of gentamicin or placebo for 2 days. Gentamicin treatment restored type VII collagen as well as anchoring fibrils and was associated with a trend toward improved wound closure and a reduction in blister formation.

Third-Line Therapies

- Granulocyte colony-stimulating factor **C**
- Gene replacement **E**
- Transplantation of revertant mosaic skin **E**
- Bone marrow transplantation **C**
- Injection of wild-type allogeneic fibroblasts **C**
- Injections of autologous, gene-corrected fibroblasts **C**
- Allogeneic mesenchymal stromal cell therapy **D**

Overview of the management of epidermolysis bullosa. Murrell DF. 2020; UpToDate; <https://www.uptodate.com> (Accessed 2020 June 6).

Different molecular therapy approaches for EB are currently under investigation involving gene replacement via cDNA delivery, revertant mosaicism, bone marrow transplantation, injection of wild-type allogeneic or autologous gene-corrected fibroblasts, allogeneic mesenchymal stromal cell therapy, and systemic granulocyte colony-stimulating factors. All of the named therapies are at an experimental stage and require further evaluation regarding feasibility, clinical safety, and effectiveness. Moderate overall formal quality of clinical evidence reflects significant methodological limitations to research in rare disease populations.

Epidermolysis bullosa acquisita

Lawrence S. Chan

Courtesy Iris Aronson

Epidermolysis bullosa acquisita (EBA) is an uncommon, chronic, autoimmune blistering disease affecting the skin and mucous membranes. The disorder affects patients of any age, and the skin lesions occur commonly at trauma-prone skin areas (in the non-inflammatory mechanobullous scarring subset) or widespread skin areas (in the generalized inflammatory non-scarring subset). Although IgG (or rarely IgA or IgM) class autoantibodies targeting the skin basement membrane component type VII collagen (anchoring fibrils) are major contributing factors, minor physical trauma also plays an important role in the blister development.

MANAGEMENT STRATEGY

EBA, particularly the non-inflammatory mechanobullous subset, is characteristically very refractory to conventional medical therapies. For an immune-mediated blistering disease associated with autoantibodies that target skin components, the obviously logical approach is to suppress the immune responses, thereby reducing the production and effect of the autoantibodies to their target skin component type VII collagen. Unfortunately, currently there is no target-specific medication available. Thus the presently available non-target-specific immunosuppressive medications not only suppress the immune responses against type VII collagen but also reduce the patient's immune defense to pathogens, leading to a relative immunodeficiency. Therefore, when treating patients with this disease, every effort should be made to use antiinflammatory instead of immunosuppressant agents, to use the lowest possible doses of immunosuppressant for the shortest time frame, and to replace immunosuppressant with antiinflammatory medications whenever feasible. Because of its rarity, well-controlled clinical trials have not been performed for EBA. The therapeutic guidelines in this chapter are derived mainly

from case reports of small groups or single patients. A commonly used start-up regimen consists of a *systemic corticosteroid combined with either mycophenolate mofetil or dapsone or both* as a corticosteroid-sparing agent. For adult patients without major medical problems, a combination of oral prednisone (1 mg/kg daily), mycophenolate mofetil (1–2 g daily), and dapsone (100–200 mg daily) can be initiated.

Other medications also reported to be beneficial for EBA are *colchicine* (1–2 mg daily); *ciclosporin* (5–9 mg/kg daily); *intravenous immunoglobulin (IVIG)* treatment (400 mg/kg daily); and *extracorporeal photochemotherapy*. Most recently, a monoclonal antibody against B-cell-specific target CD20, *rituximab* (usual dose 375 mg/m² body surface area, multiple doses), has been reported to be effective in several cases.

In addition, patients with EBA should *avoid physical trauma* as much as possible. Patients should be informed to *care for open wounds promptly* and to recognize local skin infection and *seek medical attention when infection occurs*.

Specific Investigations

- Skin biopsy and serum for direct and indirect immunofluorescence, respectively, to detect in vivo bound and circulating IgG (or IgA, IgM) class skin basement membrane-specific autoantibodies
- Transmission immune-EM, FOAM analysis, or serration pattern analysis
- Serum for enzyme-linked immunosorbent assay (ELISA) to detect IgG (or IgA, IgM) class type VII collagen-specific autoantibodies
- Gastrointestinal workup for possible inflammatory bowel disease

Epidermolysis bullosa acquisita: ultrastructural and immunologic studies. Yaoita H, Briggaman RA, Lawley TJ, et al. *J Invest Dermatol* 1981; 76: 288–92.

Identification of the skin basement-membrane autoantigen in epidermolysis bullosa acquisita. Woodley DT, Briggaman RA, O'Keefe EJ, et al. *N Engl J Med* 1984; 310: 1007–13.

Direct immunofluorescence typically detects linear IgG deposits at the dermoepidermal junction in all patients. Indirect immunofluorescence detects IgG circulating autoantibodies bound to the dermal side of salt-separated normal skin substrate in approximately 50% of patients.

Development of an ELISA for rapid detection of antitype VII collagen autoantibodies in epidermolysis bullosa acquisita. Chen M, Chan LS, Cai X, et al. *J Invest Dermatol* 1997; 108: 68–72.

ELISA using recombinant protein of the non-collagenous (NC1) domain of human type VII collagen is the most sensitive and specific method for detecting IgG class circulating autoantibodies in patients.

Consensus on EBA diagnostic criteria International Bullous Diseases Group – Consensus on Diagnostic Criteria for Epidermolysis Bullosa Acquisita. Prost-Squarcioni C, Caux F, Schmidt E, et al. *Br J Dermatol* 2018; 179(1): 30–41. doi: 10.1111/bjd.16138 [Epub 2018 May 8].

In case circulating autoantibodies are not detected by indirect immunofluorescence (IIF) or ELISA methods, special techniques including transmission immune-EM, fluorescent overlay antigen

mapping, or serration pattern analysis of direct IF are helpful in delineating the location of autoantibody target.

IgA-mediated epidermolysis bullosa acquisita: two cases and review of the literature. Vodegel RM, de Jong MC, Pas HH, et al. *J Am Acad Dermatol* 2002; 47: 919–25.

In rare incidences, IgA class rather than IgG class autoantibodies were found to target the type VII collagen, resulting in a clinical phenotype indistinguishable from the classic IgG-mediated disease. IgA-mediated disease, however, is less likely to form scars and is more responsive to dapsone treatment.

IgM-type epidermolysis bullosa acquisita. Omeland SH, Gniadecki R. *Br J Dermatol* 2015; 173: 1566–8.

This is a very rare case where the targeting autoantibodies appear to be the IgM class.

Epidermolysis bullosa acquisita and inflammatory bowel disease. Raab B, Fretzin DE, Bronson DM, et al. *JAMA* 1983; 250: 1746–8.

Inflammatory bowel disease, particularly Crohn disease, is strongly associated with EBA. All patients should be questioned for symptoms of inflammatory bowel disease. If symptoms are present, a comprehensive gastrointestinal workup is indicated.

The epidermolysis bullosa acquisita antigen (type VII collagen) is present in human colon and patients with Crohn's disease have autoantibodies to type VII collagen. Chen M, O'Toole EA, Sanghavi J, et al. *J Invest Dermatol* 2002; 118: 1059–64.

The presence of type VII collagen in the gut and autoantibodies to type VII collagen in patients with inflammatory bowel disease without skin manifestations supports an inflammation link between the gut and the skin.

Black patients of African descent and HLA-DRB1*15:03 frequency overrepresented in epidermolysis bullosa acquisita. Zumelzu C, Le Roux-Villet C, Loiseau P, et al. *J Invest Dermatol* 2011; 131: 2386–93.

A higher percentage of patients affected by EBA are Black patients of African descent and that the human leukocyte antigen HLA-DRB1*15:03 allele may contribute to this disease development.

Congenital epidermolysis bullosa acquisita: vertical transfer of maternal autoantibody from mother to infant. Abrams ML, Smidt A, Benjamin L, et al. *Arch Dermatol* 2011; 147: 337–41.

Although EBA rarely occurs in children, it has never been reported in an infant until 2011. This infant case should raise the awareness of maternally transferred EBA by physicians when they encounter blistering disease in a neonate.

Physicians need to recognize the possibility of maternal transfer of autoantibodies and the transient nature of the blisters (with no need for systemic treatment). This case of passive transfer of disease further demonstrates the pathogenic role of the autoantibodies, as was illustrated in a passive transfer animal model of EBA.

In utero development of epidermolysis bullosa acquisita. Dewan AK, Braue J, Danford B, et al. *Pediatr Dermatol* 2019; 36: e46–7.

This is the first reported case of in utero development of an active EBA. Physicians should consider infant-onset EBA in their differential diagnoses of neonatal blistering diseases.

First-Line Therapies

• Systemic corticosteroids	D
• Mycophenolate mofetil	E
• Dapsone	D

Epidermolysis bullosa acquisita – a pemphigoid-like disease. Gammon WR, Briggaman RA, Woodley DT, et al. *J Am Acad Dermatol* 1984; 11: 820–32.

Five patients with the generalized inflammatory subset of disease responded at least partially to prednisone (40–120 mg daily), with or without the addition of immunosuppressive azathioprine 100 mg daily.

Epidermolysis bullosa acquisita. Prost-Squarcioni C, Caux F. In: Murrell DF, ed. *Blistering Diseases: Clinical Features, Pathogenesis, Treatment*. Berlin: Springer-Verlag, 2015; 405–412.

The use of systemic glucocorticosteroids (GCDs) is controversial in EBA.

Childhood IgA-mediated epidermolysis bullosa acquisita responding to mycophenolate mofetil as a corticosteroid-sparing agent. Tran MM, Anhalt GJ, Barrett T, et al. *J Am Acad Dermatol* 2006; 54: 734–6.

Mycophenolate mofetil (700 mg/day) was added to the regimen of prednisolone (25 mg/day) and dapsone (25 mg/day) when the disease flared upon reduction of prednisolone dose in this 2-year-old patient affected by an IgA-mediated EBA. With the addition of mycophenolate mofetil, the systemic corticosteroid was totally tapered off over a 9-month period.

Mycophenolate mofetil in epidermolysis bullosa acquisita. Kowalick L, Suckow S, Zuiegler H, et al. *Dermatology* 2003; 207: 332–4.

Mycophenolate mofetil (1 g twice daily) was used successfully in conjunction with plasmapheresis as a corticosteroid-sparing agent in one patient with EBA not controlled by azathioprine (150 mg daily) and prednisolone (60 mg daily). The clinical improvement was associated with a reduction in autoantibody titers.

Bullous pemphigoid and epidermolysis bullosa acquisita: presentation, prognosis, and immunotherapy in 11 children. Edwards S, Wakelin SH, Wojnarowska F, et al. *Pediatr Dermatol* 1998; 15: 184–90.

A survey of five childhood-onset cases showed good clinical responses to combined corticosteroids and dapsone, as well as a good long-term prognosis.

Epidermolysis bullosa acquisita responsive to dapsone therapy. Hughes AP, Callen JP. *J Cutan Med Surg* 2001; 5: 397–9.

One patient who failed to respond to prednisone (40 mg daily) plus tetracycline and niacinamide achieved complete control of blistering activities after 2 months on dapsone 150 mg daily.

Second-Line Therapies

• Intravenous immunoglobulin	D
• Rituximab	D

Successful adjuvant treatment of recalcitrant epidermolysis bullosa acquisita with anti-CD20 antibody rituximab. Schmidt E, Benoit S, Brocker E-B, et al. *Arch Dermatol* 2006; 142: 147–50.

The patient, who had both skin and oral mucosal involvement, was not controlled with prednisolone (up to 250 mg/day), dapsone (150 mg/day), and subsequently azathioprine (up to 175 mg/day) and colchicine (2.5 mg/day). The regimen was changed to rituximab weekly infusions (375 mg/m² body surface area) for 4 consecutive weeks, with continuous use of azathioprine (175 mg/day) and colchicine (2.5 mg/day) and reducing doses of prednisolone. The patient's lesions completely healed in 11 weeks post-rituximab infusion, allowing the tapering of systemic steroid, colchicine, and azathioprine. Fourteen weeks after the discontinuation of colchicine and prednisolone, the patient remained in clinical remission. No complication was reported except an event of deep vein thrombosis.

A successful therapeutic trial of rituximab in the treatment of a patient with recalcitrant, high-titer epidermolysis bullosa acquisita. Crichlow SM, Mortimer NJ, Harman KE. *Br J Dermatol* 2006; 156: 194–6.

A patient with both oral mucosal and skin lesions and a high titer of IgG autoantibodies to skin basement membrane zone (titer up to 1:3200) was treated with conventional therapeutic agents (prednisolone up to 60 mg/day, mycophenolate mofetil 2 g/day, and subsequently IVIG infusions (2 g/kg body weight/month)) without much success. Moreover, the patient could not tolerate azathioprine (due to liver toxicity) or ciclosporin (due to nephrotoxicity and hypertension). In the meantime, the patient's conditions were worsening, with an increasing autoantibody titer and involvement of the esophagus. Therefore, weekly rituximab infusions (375 mg/m² body surface area) were then given to the patient along with mycophenolate mofetil (2 g/day) and prednisolone (30 mg/day). The patient had slow but progressive improvement of the lesions, and all were healed 5 months after starting rituximab. One year after the rituximab treatment the patient was still in partial remission, suffering only occasional trauma-induced blisters, and the autoantibody titer fell to 1:10.

Epidermolysis bullosa acquisita following bullous pemphigoid, successfully treated with anti-CD20 monoclonal antibody rituximab. Wallet-Faber N, Franck N, Matteux F, et al. *Dermatology* 2007; 215: 252–5.

An interesting patient who initially developed bullous pemphigoid but who upon subsequent flare manifested a generalized skin and mucosal (oral and genital) blistering disease that was confirmed as EBA by target antigen identification. The initial success of treatment (combined prednisone 1.5 mg/kg/day and azathioprine 100 mg/day) did not last, as the reduction of prednisone resulted in rapid worsening of the condition, further complicated by a life-threatening *Legionella pneumophila* infection. Furthermore, the patient could not tolerate mycophenolate mofetil. Therefore, rituximab (375 mg/m² body surface area) was initiated on a weekly interval for 4 consecutive weeks, resulting in dramatic improvement of the patient's condition. At 10 months' follow-up post-rituximab initiation the patient had only a few visible blisters.

Treatment-resistant classical epidermolysis bullosa acquisita responding to rituximab. Sadler E, Schafleitner B, Lanschuetzer C, et al. *Br J Dermatol* 2007; 157: 417–9.

A patient with both skin and multiple mucosal (oral, esophageal, and laryngeal) lesions who failed to respond to multiple conventional immunosuppressive medications subsequently responded to rituximab. Over a 6-year period the patient failed to show complete clinical response to methylprednisolone (up to 5 mg/kg/day), azathioprine (up to 2.5 mg/kg body weight),

ciclosporin (up to 9 mg/kg/day), mycophenolate mofetil (up to 30 mg/kg/day), cyclophosphamide (500 mg/m² body surface area IV, followed by 1 mg/kg/day orally), colchicine (up to 1.5 mg/day), IVIG (up to 2.5 g/kg body weight/cycle), gold (1 mg/kg/week IV, followed by IM and oral preparations), and daclizumab (1 mg/kg body weight, six infusions over 3 weeks). Therefore, a regimen of a reduced dose of rituximab (144 mg/m² infusion per week for 5 weeks) along with azathioprine (2 mg/kg/day) was given; the patient tolerated the treatment without any side effects or infections. A remarkable improvement was noticed 4 weeks after the initiation of rituximab treatment, and all medications were subsequently discontinued. Two years after all medications were tapered, the patient's disease activity remained very low.

Clinical response of severe mechanobullous epidermolysis bullosa acquisita to combined treatment with immunoadsorption and rituximab (anti-CD20 monoclonal antibodies). Niedermeier A, Eming R, Pfitze M, et al. *Arch Dermatol* 2007; 143: 192–8.

Two patients affected by the mechanobullous type of EBA were treated with combined immunoadsorption (daily treatment for 8 consecutive days) and rituximab (375 mg/m² body surface area/week for a total of 4 weeks). Mycophenolate mofetil (1–3 g/day) continued during this period. In both patients, treatment with multiple medications, including ciclosporin, azathioprine, dapsone, dexamethasone pulse, and cyclophosphamide pulse, was unsuccessful. One patient achieved near-complete clinical resolution, but the other could only obtain stable disease status. This report illustrates the treatment-resistant nature of EBA.

Severe, refractory epidermolysis bullosa acquisita complicated by an oesophageal stricture responding to intravenous immune globulin. Harman KE, Whittam LR, Wakelin SH, et al. *Br J Dermatol* 1998; 139: 1126–7.

The patient had the non-inflammatory mechanobullous subset of disease and esophageal stricture and was refractory to prednisone (up to 80 mg daily), dapsone (100 mg daily), cyclophosphamide (150 mg daily), and azathioprine (3 mg/kg daily). The patient was treated with courses of IVIG (0.4 g/kg daily) on 5 consecutive days at 4- to 6-week intervals as a monotherapy, resulting in a dramatic fall in the circulating titers of antibasement membrane IgG autoantibodies, reduction of new blister formation, and disappearance of dysphagia. Not all patients reported in the literature responded to this treatment. The major disadvantage of this regimen is the high cost.

Treatment of epidermolysis bullosa acquisita with intravenous immunoglobulin in patients non-responsive to conventional therapy: clinical outcome and post-treatment long-term follow-up. Ahmed AR, Gürkan HM. *J Eur Acad Dermatol Venereol* 2012; 26: 1074–83.

In this report the authors examined 10 EBA patients (mean age 57.4 years), who received 16–31 cycles (2 g/kg/cycle) of IVIG (mean 23.1 cycles) for 30–52 months (mean 38.8 months), with all other medications tapered off in 5–9 months (mean 7.2 months) and IVIG as monotherapy thereafter. All treated patients had satisfactory improvement. At the time of follow-up, occurring 29–123 months posttreatment (mean 53.9 months), they revealed no disease recurrence. No serious side effects were noted.

Meta-analysis of the clinical and immunopathological characteristics and treatment outcomes in epidermolysis bullosa acquisita. Iwata H, Vorobyev A, Koga H, et al. *Orphanet J Rare Dis* 2018; 13: 153.

In this 2018 meta-analysis on 1159 cases of EBA, the study researchers concluded that EBA is a difficult disease to treat and that IVIG and rituximab are the only two medications associated with complete remission by Chi-square analysis.

Epidermolysis bullosa acquisita: the 2019 update. Koga H, Prost-Squarcioni C, Iwata H, et al. *Front Med (Lausanne)* 2019; 5: 362.

In this 2019 update, the authors concluded that IVIG and rituximab are the two most promising therapeutics currently available.

Third-Line Therapies	
• Colchicine	D
• Ciclosporin	D
• Minocycline	E

Colchicine for epidermolysis bullosa acquisita. Cunningham BB, Kirchmann TT, Woodley DT. *J Am Acad Dermatol* 1996; 34: 781–4.

Four patients with the non-inflammatory mechanobullous subset of disease, some refractory to prednisone treatment, were treated with oral colchicine (1–2 mg daily), with or without additional cyclophosphamide (50 mg daily). In all patients there was substantial clinical improvement in the reduction of skin fragility and spontaneous blister formation. An initial dose of 0.4–0.6 mg

daily is recommended, with an increase by 0.6 mg daily each week until diarrhea develops. The patients are instructed to take the highest tolerable doses. Other than diarrhea, the long-term administration of colchicine (up to 4 years) was well tolerated. However, the side effect of diarrhea makes it difficult for those patients who already have associated inflammatory bowel disease.

Oral cyclosporine in the treatment of inflammatory and noninflammatory cases. A clinical and immunopathologic analysis. Gupta AK, Ellis CN, Nickoloff BJ, et al. *Arch Dermatol* 1990; 126: 339–50.

Two patients with EBA (subset not defined) were treated with oral ciclosporin (6 mg/kg daily) for a total of 8 weeks. These patients experienced a gradual reduction in the frequency of new blister and erosion formation. The known renal toxicity of ciclosporin makes it an unsuitable long-term regimen.

Inflammatory epidermolysis bullosa acquisita effectively treated with minocycline. Kawase K, Oshitani Y, Mizutani Y, et al. *Acta Derm Venereol* 2014; 94: 615–6.

In this report, a patient with generalized inflammatory subtype of the disease was effectively controlled with an antibiotic with antiinflammatory function.

Erosive pustular dermatosis

Bhavnit K. Bhatia, Jenny E. Murase

Erosive pustular dermatosis (EPD) is a rare condition characterized by pustular, erosive, and crusted lesions in areas of alopecia that tend to be atrophic, actinically damaged, or subject to local iatrogenic or external trauma. The condition primarily affects the elderly and is located on the scalp but has also been documented to occur on the legs. EPD lesions tend to be chronic, progressive, and difficult to treat. Laboratory and histopathologic findings are not diagnostic.

MANAGEMENT STRATEGY

Traditionally, *potent topical corticosteroids* have been used in EPD with a generally positive but variable response within a few months of use. Due to steroid-related cutaneous atrophy and residual scarring, *tacrolimus 0.1% ointment*, *calcipotriol cream*, *oral and topical zinc*, *topical dapsone*, and *photodynamic therapy* (PDT) have been introduced as alternative therapies. *Retinoids and oral corticosteroids* have also shown some promise when used in conjunction with topical antibiotics, topical corticosteroids, topical tacrolimus, oral dapsone, and oral zinc therapy. Individual case reports exist for other *immunosuppressants*, *silicone gel*, and *fractional 2940-nm laser*. Topical and systemic antibiotics and antifungals are essentially ineffective.

First-Line Therapy

- High-potency topical corticosteroids

D

Erosive pustular dermatosis of the scalp: clinical, trichoscopic, and histopathologic features of 20 cases. Starace M, Loi C, Bruni F, et al. *J Am Acad Dermatol* 2017; 76(6): 1109–14.

Fourteen of 17 patients responded to clobetasol 0.05% ointment. Two responded to prednisone 25 mg daily tapered over 20 days. All three patients treated with topical tacrolimus responded. Mean duration of treatment before clinical efficacy was 5 months.

Erosive pustular dermatosis of the scalp. Pye RJ, Peachey RD, Burton JL. *Br J Dermatol* 1979; 100: 559–66.

Six cases are presented in the first description of erosive pustular dermatosis of the scalp (EPDS) in the literature. Five of the six cases resolved after potent topical steroids, often used with neomycin or nystatin.

Second-Line Therapies

• Photodynamic therapy	D
• Topical 25% powdered zinc oxide	D
• Topical 5% dapsone gel	E
• Topical 0.1% tacrolimus ointment	E

Aminolevulinic acid photodynamic therapy in the treatment of erosive pustular dermatosis of the scalp: a case series. Yang CS, Kuhn H, Cohen LM, et al. *JAMA Dermatol* 2016; 152: 694–7.

Eight patients with EPDS underwent curettage followed by aminolevulinic acid photodynamic therapy 1–2 weeks later, with complete resolution of lesions in six patients. The remaining two patients had complete resolution after a second cycle of curettage and PDT.

Although this case series shows good results after PDT, the literature also notes that PDT is a risk factor for developing EPD.

Topical zinc oxide: an effective treatment option for erosive pustular dermatosis of the leg. Di Altobrando A, Patrizi A, Vara G, et al. *Br J Dermatol* 2020; 182(2): 495–7.

In 51 patients with leg EPD, 23 patients were treated with topical corticosteroids alone, compared with 28 patients treated with topical corticosteroids for 10 days and transitioned to 25% powdered zinc oxide. Treatment was successful in all patients; however, 10/23 patients in the corticosteroid-only group relapsed, compared with 4/28 in the latter group.

Erosive pustular dermatosis of the scalp: a review with a focus on dapsone therapy. Broussard KC, Berger TG, Rosenblum M, et al. *J Am Acad Dermatol* 2012; 66: 680–6.

Four patients with recalcitrant EPD responded to topical 5% dapsone in an average of 3 months after previously failing topical, intralesional, and oral steroids, antibiotics, silver sulfadiazine cream, topical tacrolimus, salicylic acid, and ultraviolet phototherapy.

Erosive pustular dermatosis of the scalp: treatment with topical tacrolimus. Laffitte E, Kaya G, Piguet V, et al. *Arch Dermatol* 2003; 139: 712–4.

In two patients, topical 0.1% tacrolimus ointment resulted in marked improvement within 2 weeks, with complete resolution and recovery of skin atrophy within 6–8 months.

Multiple case reports exist for topical tacrolimus ointment in the literature. The majority are as monotherapy, few as maintenance therapy after successful short-term treatment with topical steroids, and rare reports in conjunction with oral steroids.

Third-Line Therapies

• Oral dapsone	E
• Oral steroids	E
• Oral zinc	E
• Oral retinoids	E
• Oral tofacitinib	E
• Oral ciclosporin	E
• Topical silicone gel	E
• Topical calcipotriol cream	E
• Fractional 2940-nm laser	E

Disseminated erosive pustular dermatosis also involving the mucosa: successful treatment with oral dapsone. Feramisco JD, George T, Schulz SE, et al. *Acta Derm Venereol* 2012; 92: 91–2.

A patient presented after failing antifungal creams, antiseptic solutions, oral antibiotics, glucocorticoids, oral zinc replacement, and oral fluconazole. Significant improvement was observed in a few days and complete pustule resolution in 6 weeks on oral dapsone 50 mg three times daily with vitamin C 1000 mg daily.

Erosive pustular dermatosis of the scalp successfully treated with oral prednisone and topical tacrolimus. Zahdi MR, Seidel GB, Soares VC, et al. *An Bras Dermatol* 2013; 88: 796–8.

The patient initially experienced significant improvement with prednisone 40 mg daily; however, they had increased purulent discharge when it was tapered. When prednisone was restarted with 0.1% topical tacrolimus, lesions healed completely after 10 weeks, and prednisone was successfully tapered.

Cases for successful treatment with oral steroids are often in combination with oral zinc, topical steroids, or topical tacrolimus.

Erosive pustular dermatosis of the scalp successfully treated with oral zinc sulfate. Ikeda M, Arata J, Isaka H. *Br J Dermatol* 1982; 106: 742–3.

A patient's pustules disappeared after 90 mg zinc sulfate daily for 5 days. The dose was increased to 180 mg daily thereafter, and the patient remained pustule free.

The majority of cases for oral zinc report success when used in combination with topical or oral steroids.

Erosive pustular dermatosis of the scalp responding to acitretin. Darwich E, Muñoz-Santos C, Mascaró JM Jr. *Arch Dermatol* 2011; 147: 252–3.

After failing minocycline, betamethasone 17-valerate, and fusidic acid cream, a patient was started on acitretin 50 mg daily and topical 0.1% tacrolimus ointment. Tacrolimus was discontinued after 10 days due to burning. The lesions healed completely after 3 months.

Oral tofacitinib treatment of erosive pustular dermatosis of the scalp. Leung N, Eldik H, Ramirez MR, et al. *JAMA Dermatol* 2019; 155(6): 752–4.

A patient with poorly controlled rheumatoid arthritis experienced significant improvement after 4 weeks of oral tofacitinib 5 mg twice daily. She had previous limited response to clobetasol, topical tacrolimus, mupirocin, and intralesional Kenalog.

Familial erosive pustular dermatosis of the scalp and legs successfully treated with ciclosporin. Di Lernia V, Ricci C. *Clin Exp Dermatol* 2016; 41(3): 334–5.

Combination ciclosporin 3 mg/kg/day and topical clobetasol resulted in rapid improvement of scalp EPD. Ciclosporin had to be discontinued due to adverse effects, and relapses on the scalp and leg were controlled with clobetasol.

Erosive pustular dermatosis successfully treated with a novel silicone gel. Uva L, Aphale AN, Kehdy J, Benedetto AV. *Int J Dermatol* 2016; 55(1): 89–91.

An elderly male underwent extensive debridement of EPD lesions and Mohs micrographic surgery of a recurrent squamous cell carcinoma on the scalp. A semi-occlusive, gas-permeable, topical silicone gel wound dressing was applied to all granulating wounds, with 98% reepithelialization after five months.

Erosive pustular dermatosis of the scalp successfully treated with calcipotriol cream. Boffa MJ. *Br J Dermatol* 2003; 148: 593–5.

Topical calcipotriol twice daily was started in a patient with significant cutaneous atrophy. Calcipotriol was discontinued 2 months later, after complete resolution, and some hair regrowth was seen at 3 months and 9 months posttreatment.

Successful use of a fractional 2940-nm laser in treating chronic, severe erosive pustular dermatosis of the scalp. Grubbs HE, Robb CW. *JAAD Case Rep* 2019; 5(2): 188–90.

A patient had an excellent response to 19 treatments with fractional 2940-nm laser over 20 months, in combination with topical and oral dapsone and topical tacrolimus. She had previously failed treatment with topical corticosteroids, mycophenolate mofetil, and azathioprine.

Erythema annulare centrifugum

Bryan E. Anderson, Matthew F. Helm

Courtesy of Joslyn Kirby.

BACKGROUND

Erythema annulare centrifugum (EAC) is a gyrate erythema characterized by minimally pruritic, polycyclic, erythematous patches or plaques that may expand up to 2–3 mm/day and clear centrally. There are two forms: the far more common superficial form has a trailing scale at the inner borders of the erythema, whereas the deep form has erythematous induration with minimal to no scale. EAC has a mean duration of 2.8 years, and treatment is often difficult. EAC has been seen to persist for decades.

DIAGNOSIS/MANAGEMENT STRATEGY

EAC represents a hypersensitivity reaction to a myriad of conditions; therefore, a search for and treatment of an underlying disease is the primary management strategy. Most often an underlying cause is not found.

A concurrent skin infection is the most common underlying association. Fungal, bacterial, viral, mycobacterial, and parasitic pathogens have been reported. Typically, the infection is cutaneous and is at a distant location from the EAC eruption. Dermato-phytosis is implicated in up to 48%. Thus, the skin, especially the feet, groin, and nails, should be carefully examined for tinea. Anecdotal reports of other associated skin infections include molluscum contagiosum, herpesvirus infection, and *Pthirus pubis* infestation. Less commonly, the infection is internal with intestinal *Giardia* or *Candida*. Latent Epstein-Barr virus infection, human immunodeficiency virus (HIV) infection, chronic viral hepatitis, appendicitis, tonsillitis, secondary syphilis, urinary tract *Escherichia coli*, and nematode infestations have been anecdotally

reported. Although EAC is typically associated with an active infection, it has also been reported to occur after reactivation of herpes zoster virus in corresponding dermatomes.

Rarely, EAC may be associated with either benign or malignant hematologic and solid neoplasms. This paraneoplastic erythema annulare centrifugum eruption (PEACE) is thought to result from hypersensitivity to tumor proteins released by these neoplasms. However, in the absence of strong clinical suspicion, an extensive search for malignancy is not recommended. If neoplasia is identified, EAC activity correlates with tumor response to treatment.

Medications may be associated with EAC – anecdotal reports include acetazolamide, amitriptyline, ampicillin, azacitidine, boceprevir, chloroquine, cimetidine, cyclopenthi-azide, cotrimoxazole, etizolam, finasteride, gold, hydrochlorothiazide, hydroxy-chloroquine, ibuprofen, iron, Neutradonna (aluminum silicate and belladonna), oxprenolol, pegylated interferon- α_{2a} plus riba-virin, piroxicam, rituximab, salicylates, sorafenib, spironolactone, thioacetazone, and ustekinumab. Early reports of antimalarials as a cause of EAC may be debated: what was considered EAC in these reports may actually have been unrecognized forms of subacute cutaneous lupus erythematosus. Sipuleucel-T immunotherapy of autologous antigen presenting cells for prostate cancer has been associated with EAC. EAC may also be caused by hypersensitivity to other ingested agents, such as blue cheese *Penicillium*.

Other conditions associated with EAC include thyroid disease, liver disease, hypereosinophilic syndrome, sarcoidosis, surgical trauma, linear IgA dermatosis, and autoimmune disease such as relapsing polychondritis, rheumatoid arthritis, pemphigus vulgaris, hemolytic anemia, polyglandular autoimmune disease, autoimmune hepatitis, Budd-Chiari syndrome, and pregnancy. One form of EAC, described as *autoimmune progesterone dermatitis* (see [Chapter 20](#)), can be reproduced by intradermal and patch testing to progesterone and may involve Th1-type cytokines. Another form of EAC may occur annually and seasonally over 2–40 years and may be associated with hereditary lactate dehydrogenase deficiency. EAC may even be familial: there has been one report involving identical twins. Rarely, EAC may be a form of contact dermatitis: there is a single report of contact-induced EAC attributed to a hypersensitivity reaction from topical nickel and cobalt exposure.

Once the underlying condition is treated, EAC usually resolves spontaneously. Frequently, however, the cause is elusive, and treatment becomes empiric and temporizing. Spontaneous remission is also possible, making assessments of therapy difficult. *Topical steroids* may provide symptomatic relief and may improve its appearance. In one report of EAC with unknown etiology, all lesions cleared with *topical calcipotriol* treatment. *Topical tacrolimus* can be helpful as well. In another case, EAC remitted after the patient was treated with *oral metronidazole* given for rosacea. A trial of empiric antimicrobials may be helpful to eradicate an underlying, clinically undetected infection – a case series has shown significant improvement with *oral erythromycin* treatment. If these more conservative treatments fail, the patient's perceived need for treatment should be reassessed. Stronger treatments may be more harmful than the condition itself. Systemic glucocorticoids can usually suppress EAC, but it commonly recurs after the course is completed, and they cannot be routinely recommended. If EAC is very disabling to the patient, other *systemic immunomodulators* may need to be considered. One patient responded very well to *etanercept* therapy.

EAC should be distinguished from the following clinical mimickers: tinea corporis, granuloma annulare, sarcoidosis, mycosis fungoides, psoriasis, pityriasis rosea, tinea versicolor, cutaneous lupus, annular erythema of Sjögren syndrome, granuloma faciale, necrolytic migratory erythema, bullous pemphigoid, secondary

syphilis, Hansen disease, annular urticarial and fixed drug reactions, hypereosinophilic dermatitis, annular erythema of infancy, and other reactive erythemas such as erythema multiforme, erythema gyratum repens, erythema migrans, neutrophilic figurate erythema, palpable migratory arciform erythema, erythema marginatum, and even inflammatory metastatic breast carcinoma. Skin biopsy clarifies the diagnosis in these situations.

Specific Investigations

- Biopsy for histologic examination
 - Superficial type: focal spongiosis, superficial perivascular lymphocytic infiltrate
 - Deep type: superficial and deep perivascular lymphohistiocytic infiltrate
- Full skin examination for potential skin infections
- Potassium hydroxide (KOH) test or culture of suspected EAC lesion and any sites of potential dermatophyte infection
- Wood light examination
- Consider intradermal trichophyton or candidal skin injection and tuberculin test to test for underlying infection
- Review medication list
- Systemic workup: complete blood count (CBC), liver function tests (LFTs), urinalysis (UA), chest X-ray initial screen; if warranted, antinuclear antibodies (ANAs), thyroid-stimulating hormone (TSH), HIV, syphilis serology, malignancy workup including serum protein electrophoresis/urine protein electrophoresis (SPEP/UPEP) with immunofixation

Erythema annulare centrifugum and intestinal *Candida albicans* infection – coincidence or connection? Schmid MH, Wollenber A, Sander CA, et al. *Acta Derm Venereol* 1997; 77: 93–4.

Intradermal trichophyton and candidal skin injection tests may demonstrate a local cutaneous hypersensitivity. These tests may help confirm this reaction pattern and support a trial of empiric antifungals despite an inability to locate the site of a pathogen.

Erythema annulare centrifugum: a review of 24 cases with special reference to its association with underlying disease. Mahood JM. *Clin Exp Dermatol* 1983; 8: 383–7.

A basic workup for internal disease may include a CBC, LFTs, UA, and chest radiograph.

Erythema annulare centrifugum: results of a clinicopathologic study of 73 patients. Weyers W, Diaz-Cascajo C, Weyers I. *Am J Dermatopathol* 2003; 25: 451–62.

Clinicopathologic analysis of 66 cases of erythema annulare centrifugum. Kim KJ, Chang SE, Choi JH, et al. *J Dermatol* 2002; 29: 61–7.

Erythema annulare centrifugum in a HIV-positive patient. Gonzalez-Vela MC, Gonzalez-Lopez MA, Val-Bernal JF, et al. *Int J Dermatol* 2006; 45: 1423–5.

Unusual huge erythema annulare centrifugum presentation of second syphilis. Liu ZH, Chen JF. *QJM* 2014; 107: 231–2.

Erythema annulare centrifugum induced by generalized *Phthirus pubis* infestation. Bessis D, Chraïbi H, Guillot B, et al. *Br J Dermatol* 2003; 149: 1291.

Erythema annulare centrifugum. A case due to tuberculosis. Burkhart CG. *Int J Dermatol* 1982; 21: 538–9.

Erythema annulare centrifugum and *Escherichia coli* urinary infection. Borbujo J, de Miguel C, Lopez A, et al. *Lancet* 1996; 347: 897–8.

Erythema annulare centrifugum following herpes zoster infection: Wolf's isotopic response? Lee HW, Lee DK, Rhee DY, et al. *Br J Dermatol* 2005; 153: 1241–3.

Erythema annulare centrifugum revealing chronic lymphocytic leukemia. Stokkermans-Dubois J, Beylot-Barry M, Vergier B, et al. *Br J Dermatol* 2007; 157: 1045–7.

Erythema annulare centrifugum associated with mantle B-cell non-Hodgkin's lymphoma. Carlesimo M, Fidanza L, Mari E, et al. *Acta Derm Venereol* 2009; 89: 319–20.

Erythema annulare centrifugum: a rare skin finding of autoimmune hepatitis. Aygun C, Kocaman O, Gurbuz Y, et al. *Gastroenterol Res* 2010; 3: 96–8.

Pemphigus vulgaris presenting as erythema annulare centrifugum. Aguilar-Duran S, Deroide F, Mee J, et al. *Clin Exp Dermatol* 2015; 40: 466–7.

Erythema annulare centrifugum-like mycosis fungoides. Ceyhan AM, Akkaya VB, Chen W, et al. *Aust J Dermatol* 2010; 52: e11–3.

Erythema annulare centrifugum following pancreatobiliary surgery. Thami GP, Sachdeva A, Kaur S, et al. *J Dermatol* 2002; 29: 347–9.

Linear IgA dermatosis presenting with erythema annulare centrifugum lesions: report of three cases in adults. Dippel E, Orfanos CE, Zouboulis CHC. *J Eur Acad Dermatol Venereol* 2000; 15: 167–70.

Erythema annulare centrifugum in a patient with polyglandular autoimmune disease type 1. Garty B. *Cutis* 1998; 62: 231–2.

Pregnancy as a possible etiologic factor in erythema annulare centrifugum. Dogan G. *Am J Clin Dermatol* 2009; 10: 33–5.

Autoimmune progesterone dermatitis manifested as erythema annulare centrifugum: confirmation of progesterone sensitivity by in vitro interferon-gamma release. Halevy S, Cohen AD, Lunenfeld E, et al. *J Am Acad Dermatol* 2002; 47: 311–3.

Contact erythema annulare centrifugum. Sambucety PS, Agapito PG, Preto MAR. *Contact Dermatitis* 2006; 55: 309–10.

First-Line Therapies

• Treatment of underlying condition	E
• Discontinue potential causative medications	E
• Topical corticosteroids	E
• Ultraviolet light therapy	E
• Oral erythromycin	D
• Oral fluconazole	D
• Oral azithromycin	C

An observational study of the efficacy of azithromycin in erythema annulare centrifugum. Sardana K, Chugh S, Mahajan K. Clin Exp Dermatol 2018; 43: 296–9.

Clinical trial of 10 patients given oral azithromycin 250 mg once daily until clinical resolution and followed for relapse. Eight responded with no relapse during the monitoring period.

Erythromycin as a safe and effective treatment option for erythema annulare centrifugum. Chuang FC, Lin SH, Wu WM. Indian J Dermatol 2015; 60: 519.

Case series of eight subjects with EAC. Subjects were given erythromycin stearate 1000 mg per day for 2 weeks. All subjects showed reduction in lesion size and erythema at 2 weeks. Upon completion of the treatment course, three patients had recurrent disease. Retreatment with erythromycin was effective.

Pediatric erythema annulare centrifugum treated with oral fluconazole: a retrospective series. Kruse LL, Kenner-Bell BM, Mancini AJ. Pediatr Dermatol 2016; 33: 501–6.

Case series of five subjects with EAC. Patients were empirically treated with fluconazole 3–6 mg/kg/day (maximum dose of 200 mg/day) for 4–6 weeks. All showed improvement with three clearing entirely.

Erythema annulare centrifugum secondary to treatment with finasteride. Al Hammadi A, Asai Y, Patt MI, et al. J Drugs Dermatol 2007; 6: 460–3.

Erythema annulare centrifugum: an unusual case due to hydroxychloroquine sulfate. Hudson LD. Cutis 1985; 36: 129–30.

Erythema annulare centrifugum in the era of triple therapy with boceprevir plus pegylated interferon α -2b and ribavirin for hepatitis C virus infection. di Meo N, Stinco G, Fadel M, et al. J Cutan Med Surg 2015; 19: 203–4.

EAC has been associated with numerous medications. Elimination of the suspected agent may be curative.

Erythema annulare centrifugum and Hodgkin's disease: association with disease activity. Leimert JT, Corder MP, Skibba CA, et al. Arch Intern Med 1979; 139: 486–7.

Erythema annulare centrifugum responding to natural ultraviolet light. Coronel-Perez IM, Morillo-Andújar M. Actas Dermosifiliogr 2010; 101: 177–8.

Two patients, ages 22 and 27 years, each with more than 8 years of EAC, failed treatment with topical corticosteroids.

After years of sunlight avoidance, one patient cleared, and the other had significant improvement with summer sunlight exposure.

Second-Line Therapies

• Empiric antimicrobials	E
• Topical or systemic antipruritics	E
• Topical tacrolimus	E

Annular erythema responding to tacrolimus ointment. Rao NG, Pariser RJ. J Drugs Dermatol 2003; 2: 421–4.

Two patients with annular erythema of unclear etiology treated selected lesions with topical tacrolimus 0.1% ointment twice daily. Those lesions that were treated resolved within 2–6 weeks, whereas other untreated lesions did not respond until they, too, were treated with tacrolimus.

This suggests that tacrolimus, and not spontaneous remission, was responsible for the improvement.

Third-Line Therapies

• Systemic corticosteroids	E
• Immunomodulatory agents	E
• Topical calcipotriol	E
• Metronidazole	E

Erythema annulare centrifugum. Seidel DR, Burgdorf WHC. In: Demis DJ, et al., eds. Clinical Dermatology. Lippincott Williams & Wilkins, Philadelphia, 1999; Ch 7–5: 1–4.

Calcipotriol for erythema annulare centrifugum. Gniadecki R. Br J Dermatol 2002; 146: 317–9.

A 73-year-old woman had EAC of unknown cause that was resistant to topical and systemic steroids, antifungals, and psoralen and ultraviolet light (PUVA) treatment. It cleared completely after 3 months of topical, once-daily calcipotriol.

Erythema annulare centrifugum successfully treated with metronidazole. De Aloe G, Rubegni P, Risulo M, et al. Clin Exp Dermatol 2005; 30: 583–4.

A 38-year-old man with EAC failed oral antibiotics and antifungals, as well as topical calcipotriol. Only systemic steroids provided temporary improvement of his skin lesions. Because the patient had rosacea, oral metronidazole 400 mg daily was prescribed for 6 weeks, with resolution of EAC.

A novel therapeutic approach to erythema annulare centrifugum. Minni J, Sarro R. J Am Acad Dermatol 2006; 54: S134–5.

In a personal communication, one patient with extensive EAC was reported to clear with etanercept 25 mg twice-weekly injections. After 4 weeks of treatment the patient was 95% clear, and complete remission was achieved after continued therapy. After 6 months the treatment was discontinued and EAC recurred. The lesions responded again to a repeat treatment regimen.

Erythema dyschromicum perstans

Robert F. Duffy, Warren R. Heymann

Erythema dyschromicum perstans (EDP) is an acquired, generalized dermal hypermelanosis of unknown etiology. Clinically it presents as asymptomatic, ashen-gray-blue macules of varying sizes, most commonly on the trunk and proximal extremities. Variable components include erythema and papulation. It has been reported most frequently in dark-skinned Latin American people, although all racial groups can be affected. EDP has similarities to lichen planus pigmentosus and the 'ashy dermatosis' of Ramirez (which many consider to be synonymous with EDP), although the precise relationship of these conditions remains uncertain.

MANAGEMENT STRATEGY

Histology reveals vacuolar degeneration of the basal layer associated with pigmentary incontinence. Dermal vessels are surrounded with an infiltrate of lymphocytes and histiocytes, and many melanophages are present.

EDP may need to be differentiated from the late stage of pinta. Dark-field examination and serologic tests for syphilis should be carried out to exclude this treponematoses in suspected cases. Idiopathic eruptive macular pigmentation is a similar condition. Histology demonstrates that the pigment is located in the basal layer of the epidermis and the lichenoid inflammation characteristic of EDP is not present.

Although EDP may persist for many years, there have been reports of spontaneous resolution, making a conservative approach reasonable. Treatment is based on anecdotal evidence. Data suggests the use of *tacrolimus ointment*, either as monotherapy or in

combination with other treatment modalities (i.e., *topical steroids, light therapy, or laser*), as effective. Some systemic treatments (*steroids, isotretinoin, dapsone, and clofazimine*) have also shown efficacy.

Specific Investigation

- Biopsy

First-Line Therapies

• No therapy	D
• Topical corticosteroid	E
• Topical tacrolimus	E

Erythema dyschromicum perstans in children: a report of 14 cases. Torrelo A, Zaballos P, Colmenero I, et al. *J Eur Acad Dermatol Venereol* 2005; 19: 422–6.

No treatment was used. In six of these cases the eruption cleared or improved during follow-up ranging from 1 to 5 years.

Erythema dyschromicum perstans: identical to ashy dermatosis or not? Numata T, Harada K, Tsuboi R, et al. *Case Rep Dermatol* 2015; 7: 146–50.

The erythema responded to a topical steroid.

Second-Line Therapies

• Erbium-doped fractionated laser and topical tacrolimus	E
• Narrowband ultraviolet B (NB-UVB) therapy and topical steroids and tacrolimus	E

Improvement of erythema dyschromicum perstans using a combination of the 1,550-nm erbium-doped fractionated laser and topical tacrolimus ointment. Wolfshohl JA, Geddes ERC, Stout AB, et al. *Lasers Surg Med* 2017; 49: 60–2.

One patient had 75% improvement with five treatment sessions on 4–6-week intervals of erbium-doped fractionated laser with a 15 mm spot size, a fluence range between 5–9 mJ/microscopic treatment zone, a treatment level 5 corresponding to 14% coverage, and a total of eight passes with total energy ranging from 4.65–4.91 kJ. This was combined with concurrent daily then every other day application of tacrolimus.

Erythema dyschromicum perstans: a case report and systematic review of histologic presentation and treatment. Leung N, Oliveira M, Selim MA, et al. *Int J Women's Dermatol* 2018; 4: 216–22.

One patient experienced a significant decrease in hyperpigmentation following 2 months of NB-UVB starting at 300 mJ three-times weekly increased by 10–15% per session with continued use of clobetasol and tacrolimus.

Third-Line Therapies

• Isotretinoin	E
• Dapsone 100 mg/day for 3 months	E
• Clofazimine 100 mg/day for 3 months	D

Erythema dyschromicum perstans response to isotretinoin. Wang F, Zhao YK, Wang Z, et al. *JAMA Dermatol* 2016; 152: 841–2.

A 41-year-old man with EDP demonstrated 90% improvement within 4 months of isotretinoin (20 mg daily). Periodic recurrences responded to doses as low as 10 mg daily during 7 years of follow-up.

Erythema dyschromaticum perstans: response to dapsone therapy. Bahadir S, Cobanoglu U, Cimsit G, et al. *Int J Dermatol* 2004; 43(3): 220–2.

A 16-year-old boy with widespread EDP was treated with dapsone 100 mg daily for 3 months with lesion disappearance, pigmentation decrease, and cessation of new lesion formation.

Erythema dyschromaticum perstans in phototype II women: three unusual clinical cases studied with electron microscopy. Persechino S, Caperchi C, Cortesi G, et al. *Eur J Dermatol* 2011; 21: 261–2.

Three cases demonstrated marked decrease in pigmentation on treatment with dapsone 100 mg daily for 3 months.

Involvement of cell adhesion and activation molecules in the pathogenesis of erythema dyschromaticum perstans (ashy dermatitis). The effect of clofazimine therapy. Baranda L, Torres-Alvarez B, Cortes-Franco R, et al. *Arch Dermatol* 1997; 133: 325–9.

A prospective clinical and immunohistochemical study indicating that clofazimine reduces the inflammatory response in EDP. Four out of six patients treated with clofazimine 100 mg/day showed marked improvement after 3 months of treatment.

Erythema elevatum diutinum

Sidra S. Khan, Ian H. Coulson

Erythema elevatum diutinum (EED) is a rare neutrophilic dermatosis consisting of violaceous, brown or red papules, plaques, nodules, and occasionally vesicobullous lesions over the extensor surfaces of the joints and buttocks, genitalia, trunk, and face. Early lesions tend to be soft and erythematous. Advanced lesions tend to be nodular and firm, secondary to fibrosis. EED is thought to be a form of immune complex-mediated leukocytoclastic vasculitis, although its etiology remains unclear. Infections (including HIV and streptococcal), hematologic abnormalities, inflammatory bowel disease, celiac disease, verrucous carcinoma, systemic lupus erythematosus, primary Sjögren syndrome, ophthalmic disorders (peripheral keratitis), and pulmonary lymphoepithelioma-like carcinoma (possibly as part of a paraneoplastic syndrome) have been associated. Drug-induced EED may result from interferon- β , erythropoietin, antituberculosis chemotherapy, and cisplatin exposure.

Differential diagnoses of early lesions of EED include extrafacial granuloma faciale, Sweet syndrome, rheumatoid neutrophilic dermatitis or palisaded neutrophilic and granulomatous, dermatitis, and advanced lesions include rheumatoid nodules and multicentric reticulohistiocytosis.

MANAGEMENT STRATEGY

EED is a chronic disease that may persist for several years or decades and typically proves challenging to treat.

After management of any underlying disease, *dapsone* 100 mg daily remains the initial treatment of choice. The response may

be partial and dose dependent. Both intralesional and systemic corticosteroids (prednisolone 30–40 mg daily) have produced favorable responses.

Sulfonamides (sulfamethoxypyridazine 500 mg once daily and sulfapyridine 0.5–1 g three times daily), *nicotinamide/niacinamide* 100 mg three times daily, *colchicine* 0.5 mg twice daily with 0.5 mg three times daily for 3–4 days to abate minor disease flares, and *chloroquine* 300 mg daily have produced resolution of lesions.

Specific Investigations

- Full blood count
- Full metabolic panel
- Immunoglobulins and serum electrophoresis/immunofixation electrophoresis
- Antinuclear antibody (ANA)
- Antineutrophil cytoplasmic antibodies (ANCA)
- Anti-dsDNA antibody
- Antiphospholipid antibodies
- Celiac disease screen
- Hepatitis B and C serology
- HIV test
- Chest radiograph
- Urinalysis
- Histology
- Skin biopsy

Erythema elevatum diutinum: clinical, histopathologic, and immunohistochemical characteristics of six patients. Wahl CE, Bouldin MB, Gibson LE. *Am J Dermatopathol* 2005; 27: 397–400.

The vascular endothelium of EED stains positive for CD31, CD34, VEGF, and factor VIII, and negative for factor XIIIa, TGF β , and LANA. This pattern does not distinguish it from similar-appearing lesions. Therefore, the chronic and recurrent nature of EED is the primary means of distinguishing it from entities that are clinically and histologically similar.

Erythema elevatum diutinum and IgA paraproteinaemia: “a preclinical iceberg”. Chowdhury MMU, Inaloz HS, Motley RJ, et al. *Int J Dermatol* 2002; 41: 368–70.

The technique of immunofixation electrophoresis is more sensitive than immunoelectrophoresis. This uses a combination of zone electrophoresis and immunoprecipitation with specific antisera to detect monoclonal immunoglobulins or light chains at very low concentrations in serum and urine. This is useful in EED because patients may have associated paraproteinemias, which, in some cases, may undergo malignant transformation.

The authors note that in monoclonal disorders there is extensive asymptomatic tumor proliferation and possible malignant transformation in 20% of patients during long-term follow-up. It was recommended that there should be lengthy follow-up and monitoring for patients with both EED and IgA paraproteinemia because of the risk of progression to IgA myeloma.

Is IgA antineutrophil cytoplasmic antibody a marker for patients with erythema elevatum diutinum? A further three cases demonstrating this association. Crichlow SM, Alexandroff AB, Simpson RC, et al. *Br J Dermatol* 2011; 164: 675–7.

Two studies evaluating the prevalence of ANCAs in EED. IgA ANCAs were present in all patients with EED.

Erythema elevatum diutinum and HIV infection: a report of five cases. Muratori S, Carrera C, Gorani A, et al. *Br J Dermatol* 1999; 141: 335–8.

The largest case series of patients with EED and HIV infection. Streptococcal infection seemed to trigger exacerbations in four of five patients. EED can stimulate Kaposi sarcoma and bacillary angiomatosis, which can be challenging in the context of an HIV-seropositive patient. Histopathologic confirmation of the diagnosis is therefore advocated.

Erythema elevatum diutinum associated with peripheral ulcerative keratitis. Vaiyavatjamai P, Wattanakrai P. *J Eur Acad Dermatol Venereol* 2011; 25: 741–2.

Progressive keratolysis with pseudopterygium associated with erythema elevatum diutinum. Lekhanont K, Patarakittam T, Mantachote K, et al. *Ophthalmology* 2011; 118: 927–33.

Erythema elevatum diutinum with verrucous carcinoma: a rare association. Nair SR, Viswanath V, Sonavane AD, et al. *Indian J Dermatol Venereol Leprol* 2010; 76: 420–2.

Erythema elevatum diutinum as a paraneoplastic syndrome in a patient with pulmonary lymphoepithelioma-like carcinoma. Liu T-C, Chen I-S, Lin T-K, et al. *Lung Cancer* 2009; 63: 151–3.

Erythema elevatum diutinum presenting with a giant annular pattern. Di Giacomo TB, Marinho RT, Nico MMS. *Int J Dermatol* 2009; 48: 290–2.

Erythema elevatum diutinum associated with pyoderma gangrenosum in an HIV-positive patient. Maksimovic L, Duriez P, Lascaux-Cametz A-S, et al. *Ann Dermatol Venereol* 2010; 137: 386–90.

Erythema elevatum diutinum in systemic lupus erythematosus. Chan Y, Mok CC, Tang WYM. *Rheumatol Int* 2011; 31: 259–62.

These citations indicate the range of pathologies associated with EED.

First-Line Therapies

- Dapsone D
- Dapsone plus antiretrovirals in HIV-associated disease E
- Dapsone plus another agent (e.g., corticosteroids, antibiotics) D

Erythema elevatum diutinum: a case report and review of literature. Doktor V, Hadi A, Hadi A, et al. *Int J Dermatol* 2019; 58: 408–15.

This case report of EED also includes a thorough literature review and summary of 133 cases of EED between 1990 and 2014. Twenty-one cases were associated with HIV and 47 with paraproteinemias (IgA paraproteinemia making up 57.45%, thus making it the most common subtype). Of the 40 cases with associated autoimmune conditions, rheumatoid arthritis was the most common ($n = 10$). Treatment options vary from case to case and it is important to treat associated conditions. Within the review, 75 patients were treated with dapsone (50–100 mg once daily). Thirty-six achieved a complete treatment response, 24 achieved a partial response and seven achieved no response.

Other treatments included topical or systemic steroids and/or colchicine.

Alternative procedure to allow continuation of dapsone therapy despite serious adverse reaction in a case of dapsone-sensitive erythema elevatum diutinum. Seneschal J, Guillet S, Ezzedine K, et al. *Dermatology (Basel)* 2012; 224: 115–9.

This patient responded well to dapsone but developed drug reaction with eosinophilia and systemic symptoms (DRESS), confirmed in vitro by the presence of circulating dapsone-specific T cells. As treatment alternatives to dapsone are limited, it is recommended that dapsone hypersensitivity syndrome is confirmed using interferon assay and modified lymphocyte transformation tests. After confirmation, a dapsone tolerance induction protocol may be administered over a period of days in order to obtain tolerance, thus allowing continuation of dapsone.

Nodular lesions of erythema elevatum diutinum in patients infected with the human immunodeficiency virus. LeBoit PE, Cockerell CJ. *J Am Acad Dermatol* 1993; 28: 919–22.

A clinicopathologic study of four patients with HIV infection who had unusual nodular lesions of EED. None of the patients responded to treatment with oral dapsone, and the authors commented that this observed lack of response may reflect the preponderance of fibrosis rather than neutrophils in these advanced lesions.

Second-Line Therapies

- Sulfonamides D
- Colchicine D
- Oral steroids D
- Niacinamide and tetracycline E
- Chloroquine E
- Methotrexate E
- Dapsone with ciclosporin E

Erythema elevatum diutinum: a case successfully treated with colchicine. Henriksson R, Hofer PA, Hörnqvist R. *Clin Exp Dermatol* 1989; 14: 451–3.

A case report of a 68-year-old man with EED refractory to treatment with oral dapsone who responded well to treatment with colchicine 0.5 mg twice daily over 6 weeks. Minor flares were abated temporarily, increasing colchicine to 0.5 mg three times a day for 3–4 days, without provoking diarrhea.

Complete resolution of erythema elevatum diutinum using oral sulfasalazine. Chen ML, Chlopik A, Hoang MP. *Dermatol Online* 2017; 23(10):13030/qt8267v8v9.

A 35-year old female with EED initially responded very well to dapsone but stopped this after 7 months when she became pregnant (category C), whereupon her symptoms recurred. She was subsequently treated with oral sulfasalazine (category B) and reported completed resolution of symptoms. Although no difference in safety is explicitly proven between dapsone and sulfasalazine during pregnancy, some physicians and patients feel more comfortable with the latter.

Erythema elevatum diutinum treated with niacinamide and tetracycline. Kohler IK, Lorincz AL. *Arch Dermatol* 1980; 116: 693–5.

A 60-year-old woman with EED that cleared completely after 4 weeks of treatment with oral niacinamide 100 mg three times

daily and oral tetracycline hydrochloride 250 mg four times daily. After this, oral niacinamide alone was sufficient for disease suppression.

Successful combination therapy with dapsone and cyclosporine for erythema elevatum diutinum with unusual appearance. Takahashi H, Fukami Y, Honma M, et al. *J Dermatol* 2012; 39: 486–7.

In this case of EED with an unusual distribution on the soles, fingers, trunk, and feet accompanied with ulcerations, the patient initially failed to respond to oral dapsone 75 mg daily but improved with the addition of ciclosporin 4 mg/kg/day.

Third-Line Therapies	
• Topical dapsone 5%	E
• Localized surgical excision (nodular EED)	E
• Cyclophosphamide	E
• Plasma exchange ± thalidomide	E
• Reduction in cyclosporin dose	E
• Transdermal nicotine patches	E
• Methylprednisolone	E
• Colectomy	E
• Gluten-free diet	E
• Phenformin	E

Novel use of topical dapsone 5% gel for erythema elevatum diutinum: safer and effective. Frieling GW, William NL, Lim SJ. *J Drugs Dermatol* 2013; 12: 481–4.

This case report showed some improvement in erythema and flattening of lesions of EED using dapsone 5% gel for 1 week before start of oral dapsone therapy.

Other topical treatments, including topical corticosteroids and intralesional steroid injections, have shown variable results in a few case reports.

Successful surgical treatment of advanced erythema elevatum diutinum. Rinard JR, Mahabir RC, Greene JE, et al. *Can J Plast Surg* 2010; 18: 28–30.

In this case report, a patient with late-stage nodular EED, in whom medical treatment was contraindicated, was treated with continued surgical excisions of recurrent nodules with symptomatic relief.

Fibrotic nodules often respond poorly to dapsone; surgical excision may help.

Erythema elevatum diutinum in a patient with relapsing polycondritis. Bernard P, Bedane C, Delrous JL, et al. *J Am Acad Dermatol* 1992; 26: 312–5.

A 69-year-old man with a history of relapsing polycondritis developed EED, which responded to treatment with oral cyclophosphamide 100 mg daily and prednisolone 20 mg daily. Cyclophosphamide was discontinued after 2 months, and the prednisolone was subsequently tapered to 15 mg daily.

Erythema elevatum diutinum associated with IgA paraproteinemia successfully controlled with intermittent plasma exchange. Chow RK, Benny WB, Coupe RL, et al. *Arch Dermatol* 1996; 132: 1360–4.

Intermittent plasma exchange has been reported to successfully control EED associated with IgA paraproteinemia.

Case of erythema elevatum diutinum associated with IgA paraproteinemia successfully controlled with thalidomide and plasma exchange. Manni E, Cervadoro E, Papineschi F. *Ther Apher Dial* 2015; 19: 195.

An 83-year-old woman with EED treated with dapsone for a year was found to have an IgA kappa paraproteinemia consistent with monoclonal gammopathy of undetermined significance and commenced on treatment with plasma exchange, 3-weekly sessions down to 1-weekly sessions. Commenced thalidomide on week 13, with 200 mg/day and 100 mg/day alternatively and plasma exchange reduced to one exchange every 2 weeks. Thalidomide was then continued as monotherapy followed by a treatment regimen with periods of plasma exchange ± thalidomide, which led to improvement of skin lesions and stabilization of raised IgA values.

Erythema elevatum diutinum after liver transplantation: disappearance of the lesions associated with a reduction in cyclosporine dosage. Hernández-Cano N, De Lucas R, Lázaro TE, et al. *Pediatr Dermatol* 1998; 15: 411–2.

Lesions of EED resolved after a reduction in ciclosporin dosage in a 10-year-old patient who had previously received a cadaveric hepatic allograft because of Alagille disease.

Erythema elevatum diutinum manifesting as a penile ulcer. Yoshii N, Kanekura T, Higashi Y, et al. *Clin Exp Dermatol* 2007; 32: 211–3.

A 74-year-old man with EED lesions on his limbs responded well to the nicotine patches that released 6.25 mg nicotine applied every 24 hours. The penile lesions remained recalcitrant to the nicotine patches as well as dapsone, requiring treatment with methylprednisolone (40 mg/day).

Erythema elevatum diutinum: an unusual association with ulcerative colitis. Buahene K, Hudson M, Mowat A, et al. *Clin Exp Dermatol* 1991; 16: 204–6.

A 58-year-old woman developed EED during severe acute exacerbation of ulcerative colitis, which resolved after colectomy.

Erythema elevatum diutinum in association with coeliac disease. Tasanen K, Raudasoja R, Kallioinen M, et al. *Br J Dermatol* 1997; 136: 624–7.

A 47-year-old woman who presented with typical EED and previously undiagnosed celiac disease. Treatment with dapsone was partially effective, but complete healing of the EED lesions was achieved only after the introduction of a strict gluten-free diet. Maintenance treatment with a gluten-free diet only was required.

Erythema elevatum diutinum: cutaneous vasculitis, impaired clot lysis, and response to phenformin. Schumacher HR, Carroll E, Taylor F, et al. *J Rheumatol* 1977; 4: 103–12.

A variety of treatments were tried with no success in this case report, but phenformin 50 mg three times daily produced marked improvement for periods of 11 and 16 months on two occasions.

Phenformin is a biguanide antidiabetic drug that has been withdrawn in many countries due to high risk of lactic acidosis.

Erythema multiforme

Jean Revuz

Erythema multiforme (EM) is a distinct cutaneous reaction pattern to a variety of stimuli, predominantly herpes simplex virus (HSV) infection, occurring mostly in young adults. It usually runs a self-limiting course but has a tendency to recur. It is defined by the presence of 'typical' three-zone target lesions, with a usual acral distribution. The presence of mucosal involvement at more than one site distinguishes EM major from EM minor. A specific variant has mucosal lesions only, without skin involvement. EM major can be distinguished from Stevens–Johnson syndrome, which lacks typical targetoid lesions and an acral location, but rather presents with irregular macules or atypical targets and a truncal location; regardless, these two diseases are still frequently confused. EM is frequently misdiagnosed as other entities such as urticarial dermatoses and, more rarely, in cases of cutaneous lupus, vasculitis, erythema annulare, and drug eruptions. Paraneoplastic pemphigus may mimic EM major.

MANAGEMENT STRATEGY

In 30%–50% of cases the etiology of EM is unknown. The most commonly recognized precipitant is HSV infection; both types I and II HSV-specific DNA has been isolated from lesional tissue in 60%–70% of cases. HSV particles are found in the circulating precursors of epidermal Langerhans cells. A variety of other viral infections (orf, varicella zoster virus [VZV], Epstein–Barr virus [EBV], cytomegalovirus [CMV], human immunodeficiency virus [HIV], hepatitis B vaccination), bacterial infections (mainly *Mycoplasma pneumoniae* but also tularemia), and fungal infections (predominantly histoplasmosis) have been implicated. An extensive list of drugs has been reported to trigger EM, but most cases,

if not all, are the result of confusion with Stevens–Johnson syndrome. Rare cases may be attributed to contact allergy.

Acute episodes of EM need only *symptomatic treatment* in most cases. Recurrent EM, which may severely affect quality of life, has a well-recognized *preventive treatment* in case of HSV infection but may be highly recalcitrant when no cause is identified. A persistent continuous variety of EM has been reported with antidesmoplakin antibodies, which do not testify pemphigus.

There are no double-blind or open trials of treatments for acute episodes of EM. Most cases, particularly EM minor, run a self-limiting course. Symptomatic measures include *oral antihistamines* and *mild-to-moderate-potency* to reduce pruritus. Underlying conditions, mainly *Mycoplasma pneumoniae* infection, should be treated. Recurrent EM (>6 attacks per year) may respond to long-term *anti-HSV drugs*. In resistant cases a variety of other therapies can be helpful (see later).

Mucosal manifestations of EM major are a source of morbidity. The most common sites affected are the buccal mucosa and lips. Symptomatic measures include *mouthwashes*, a *soft diet*, *topical anesthetics*, and *topical corticosteroids* (e.g., 0.1% triamcinolone acetonide paste). Budesonide or beclomethasone inhalers (one puff three to four times daily) provide an alternative method of delivering local corticosteroid to the inflamed mucosal surfaces. Short courses of high-dose *oral prednisolone* may be needed for severe oral disease. Strict eye care to reduce secondary infection and scarring includes *saline washes* for removal of crusts, *local antibiotics*, and frequent *debridement of tarsal and bulbar conjunctival adhesions*.

Specific Investigation

- Histology/immunofluorescence

EM is a clinical diagnosis. Histology, with direct immunofluorescence, can be useful in atypical cases to exclude other bullous diseases that present with oral manifestations, such as pemphigus vulgaris or cicatricial pemphigoid.

Investigations directed at determining the underlying trigger factors include culture or serologic testing for HSV or other infections, especially *M. pneumoniae*, as indicated by clinical findings.

First-Line Therapies

• Antivirals (aciclovir, valaciclovir, ganciclovir)	A
• Macrolide antibiotics for <i>Mycoplasma pneumoniae</i> -induced EM major	C

Recurrent erythema multiforme: clinical features and treatment in a large series of patients. Schofield JK, Tatnall FM, Leigh IM. Br J Dermatol 1993; 128: 542–5.

A review of 65 patients with recurrent EM: 71% had episodes triggered by HSV infection. Treatment with standard doses of aciclovir for HSV was relatively disappointing; continuous aciclovir 400 mg twice daily for 6 months was more effective, with remission in some responders. Some patients responded to dapsone, antimalarials, azathioprine (10 of 11), and human immunoglobulin.

A double-blind, placebo-controlled trial of continuous aciclovir therapy in recurrent erythema multiforme. Tatnall FM, Schofield JK, et al. Br J Dermatol 1995; 132: 267–70.

Aciclovir 400 mg twice daily for 6 months suppressed EM in seven of 11 patients (including one with apparently idiopathic EM). Two patients went into complete remission.

A therapeutic trial of aciclovir is justified even when clinical evidence of HSV is lacking. Aciclovir 400 mg twice daily can be administered for 6 months to 2 years because it has a good long-term safety profile. It is ineffective in an acute episode once the herpetic lesion or EM eruption has developed. Recurrence is usual after stopping the drug.

Clinical and histologic features of *Mycoplasma pneumoniae*-related erythema multiforme: a single-center series of 33 cases compared with 100 cases induced by other causes. Amode R, Ingen-Housz-Oro S, Ortonne N, et al. J Am Acad Dermatol 2018; 79: 110–7.

MP-induced EM have more mucous membrane lesions, more atypical targets, and more respiratory tract sequelae; they have to be treated by macrolide antibiotics.

Recurrent erythema multiforme: clinical characteristics, etiologic associations, and treatment in a series of 48 patients at Mayo Clinic, 2000 to 2007. Wetter DA, Davis MD. J Am Acad Dermatol 2010; 62: 45–53.

Of 48 patients, HSV was responsible in 11 (23%); the cause remained unknown in 28 (58%). Systemic corticosteroids were used in most patients. Sixteen of 33 patients receiving continuous antiviral treatment had either partial or complete disease suppression. Mycophenolate mofetil provided partial or complete response in six of eight patients.

Second-Line Therapies

• Dapsone	C
• Azathioprine	C
• Thalidomide & lenalidomide	B
• Potassium iodide	C
Oral EM	
• Topical corticosteroid	B
• Levamisole	B
• Systemic corticosteroid	D

Characteristics of the oral lesions in patients with cutaneous recurrent erythema multiforme. Farthing PM, Maragou P, Coates M, et al. J Oral Pathol Med 1995; 24: 9–13.

In this series of 82 patients with typical cutaneous EM, 70% had oral mucosal involvement. Five patients with resistant disease were controlled with azathioprine 100–150 mg daily.

Azathioprine therapy in the management of persistent erythema multiforme. Jones RR. Br J Dermatol 1981; 105: 465–7.

Azathioprine 100–150 mg daily was effective in two patients and permitted reduction of the corticosteroid dosage.

Treatment by thalidomide of chronic multiforme erythema: its recurrent and continuous variants. A retrospective study of 26 patients. Cherouati K, Claudy A, Souteyrand P, et al. Ann Dermatol Venereol 1996; 123: 375–7 [in French].

Thalidomide reduces the duration of episodes of recurrent EM by 11 days on average; it is dramatically effective in the exceptional continuous variant. Remission can be maintained with low-dose (25–50 mg daily) thalidomide.

Lenalidomide as an alternative to thalidomide for treatment of recurrent erythema multiforme. Drahy F, Ingen-Housz-Oro S, Grootenboer-Mignot S, et al. JAMA Dermatol 2018; 154: 487–9.

Three patients were successfully treated with this analog of thalidomide with fewer side effects.

Potassium iodide in erythema nodosum and other erythematous dermatoses. Horio T, Danno K, Okamoto H, et al. J Am Acad Dermatol 1983; 9: 77–81.

Fourteen of 16 subjects with EM (six related to HSV infection) responded within 1 week to 300 mg potassium iodide three times daily. Gastrointestinal and cutaneous side effects can occur with this treatment.

Erythema multiforme – response to corticosteroid. Ting HC, Adam BA. Dermatologica 1984; 169: 175–8.

Thirteen patients with EM minor treated with systemic corticosteroids were compared with 12 patients who were treated without. Apart from a shorter duration of fever, the corticosteroid-treated group did not respond better than the non-corticosteroid-treated group.

There is no reason to treat EM minor with steroids. This drug may still be useful in EM major.

Open preliminary clinical trial of clobetasol propionate ointment in adhesive paste for treatment of chronic oral vesiculo-erosive diseases. Lozada-Nur F, Huang MZ, Zhou GA. Oral Surg Oral Med Oral Pathol 1991; 71: 283–7.

Clobetasol propionate 0.05% ointment mixed 1:1 with Orabase paste two to three times daily was helpful in four patients with chronic oral EM.

Erythema multiforme: diagnosis, clinical manifestations and treatment in a retrospective study of 22 patients. Sanchis JM, Bagán JV, Gavalda C, et al. J Oral Pathol Med 2010; 39: 747–52.

Systemic corticosteroids are effective in controlling the outbreaks; their use as maintenance therapy is not clearly indicated.

Recurrent oral erythema multiforme. Clinical experience with 11 patients. Bean SE, Quezada RK. JAMA 1983; 249: 2810–2.

In this retrospective study, patients with severe, recurrent oral EM involvement were treated with prednisolone 40–60 mg daily, subsequently tapered over 2–3 weeks. This reduced the time taken for oral erosions to heal but did not influence recurrences.

Some authorities, however, believe that use of corticosteroids in EM increases the frequency and chronicity of attacks.

Third-Line Therapies

• Antimalarials	D
• Human immunoglobulin	D
• Interferon- α	E
• Rituximab	D
• Tamoxifen	E
• Zinc sulfate	E
• Cimetidine	E
• Ciclosporin	E
• Pulsed methylprednisolone	E
• Apremilast	E
• Tofacitinib	E
• Anti-TNF drugs	E

Recurrent erythema multiforme: clinical features and treatment in a large series of patients. Schofield JK, Tatnall FM, Leigh IM. Br J Dermatol 1993; 128: 542–5.

The use of normal human immunoglobulins and antimalarials was reported in a few patients in this study. Intramuscular human immunoglobulin 750g once a month caused suppression of EM in 11 of 13 patients. One responder remained in remission after therapy was discontinued. There was a 50% success rate with antimalarials (both hydroxychloroquine and mepacrine) used in four patients.

Severe erythema multiforme responding to interferon alfa. Geraminejad P, Walling HW, Voigt MD, et al. J Am Acad Dermatol 2006; 54: S18–21.

A patient with recurrent EM associated with hepatitis C had been in complete remission for 6 years after treatment with IFN- α . A new recurrence was successfully treated with IFN- α in the absence of recurring hepatitis C virus infection.

Interferon may be a first-line treatment for patients with hepatitis C.

Rituximab, a new treatment for difficult to treat chronic erythema multiforme major. Five cases. Hirsch G, Ingen-Housz-Oro S, Fite C, et al. J Eur Acad Dermatol Venereol 2016; 30: 1140–3.

Chronic continuous or relapsing EM resistant to several drugs, including aciclovir corticosteroids, and thalidomide; four had complete remission.

Progesterone-induced erythema multiforme. Wojnarowska F, Greaves MW, Peachey RD, et al. J Roy Soc Med 1985; 78: 407–8.

EM linked to the luteal phase of the menstrual cycle was controlled with tamoxifen.

Topical treatment of recurrent herpes simplex and postherpetic erythema multiforme with low concentrations of zinc sulphate solution. Brody I. Br J Dermatol 1981; 104: 191–4.

Treatment of the skin at the site of the herpetic infection with zinc sulfate solution prevented relapse of postherpetic EM over a 2-year period of observation in one patient. For the oral mucous membrane, 0.01%–0.025% zinc sulfate solution was used.

Ciclosporin therapy for bullous erythema multiforme. Wilkel CS, McDonald CJ. Arch Dermatol 1990; 126: 397–8.

High-dose ciclosporin (5–10 mg/kg daily) suppressed an atypical bullous eruption with histologic features of EM.

Apremilast for treatment of recurrent erythema multiforme. Chen T, Levitt J, Geller L. Dermatol Online J. 2017; 15: 23(1): 13030/qt15s432gx.

Recalcitrant mucous membrane lesions of three patients were cleared by 30–60 mg daily.

Idiopathic erythema multiforme: evidence of underlying Janus kinase–signal transducer and activator of transcription activation and successful treatment with tofacitinib. Damsky W, King BA. JAAD Case Rep 2016; 2: 502–4.

Case report of success in a recalcitrant chronic EM.

Treatment of recurrent erythema multiforme with adalimumab as monotherapy. Baillis B, Maize JC Sr. JAAD Case Rep 2017; 3: 95–7.

A severe relapsing EM major associated with HSV was not controlled by aciclovir and systemic steroids. Adalimumab 40 mg every 2 weeks for 6 months cleared the disease but there was a flare at 6 months after the drug was no longer administered.

Erythema nodosum

Bridget E. Shields, Amy Forrestel, Misha Rosenbach

Erythema nodosum (EN) is an inflammatory septal panniculitis that presents as tender, erythematous nodules and plaques distributed symmetrically on the extensor surfaces of the lower extremities. EN is thought to be a delayed-type hypersensitivity reaction and may be isolated and idiopathic, or, more commonly, a sign of an underlying systemic disease (outlined later). Individual lesions frequently resolve within 2–6 weeks, but persistent lesions and intermittent disease recurrence may occur. EN is often accompanied by systemic symptoms such as fever, fatigue, arthritis, cough, and gastrointestinal complaints.

MANAGEMENT STRATEGIES

Management of EN first requires investigation for an underlying etiology, including a detailed history, review of systems, and targeted evaluation. Numerous etiologies have been implicated, including chronic inflammatory states, infections, reactions to medications or hormones, and malignancies. Even after extensive evaluation, many cases are classified as idiopathic.

Many infectious agents have been associated with EN. Bacterial and protozoan causes include: *Streptococcus* (most common), *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia trachomatis*, *Yersinia enterocolitica*, *Salmonella enteritidis*, *Giardia lamblia*, *Shigella*, *Klebsiella* spp., tuberculosis, brucellosis, psittacosis, cat scratch disease, chancroid, tularemia, rickettsiosis, leptospirosis, and *Campylobacter*. Viral causes include hepatitis B, hepatitis C, human immunodeficiency virus, and herpes simplex virus. Fungal triggers include blastomycosis, sporotrichosis, coccidioidomycosis, histoplasmosis, nocardiosis, and fungal kerions.

Chronic inflammatory conditions associated with EN include sarcoidosis (most common), inflammatory bowel disease (IBD), Behçet disease, Sweet syndrome, pyoderma faciale, and diverticulitis.

Medication-induced EN has been reported with use of oral contraceptives (most common) and other female hormone therapies, antibiotics (specifically penicillins and sulfonamides), iodides, bromides, quinolones, lidocaine injections, aromatase inhibitors, all-trans retinoic acid, propylthiouracil, granulocyte colony-stimulating factor, echinacea supplements, glatiramer acetate, valproate, non-steroidal antiinflammatory drugs (NSAIDs), thalidomide, and dapsone. Targeted chemotherapeutic agents such as BRAF and MEK inhibitors, and more recently the checkpoint inhibitor class of agents, have been described to cause an EN-like panniculitis. Multiple vaccines have been suggested as well, albeit in very small numbers – and the health benefits of vaccines outweigh the rare potential for this type of reaction.

Malignancies such as leukemias, lymphomas, myelodysplastic syndrome, and parathyroid carcinoma have rarely been implicated in triggering EN.

Skin biopsy is generally not necessary if the history and physical examination are suggestive of EN. Biopsies are typically performed in atypical cases, persistent or treatment-refractory cases, or cases where there is a broad differential diagnosis and a biopsy may help exclude alternative etiologies. Pathology classically demonstrates subcutaneous septal inflammation with limited extension into surrounding fat lobules. Inflammation may be acute or chronic, and can include histiocytes, foreign body giant cells, neutrophils, and eosinophils. Multinucleated giant cells ('Miescher granulomas') are occasionally seen. Other findings can include septal fibrosis and radial arrays of macrophages around blood vessels. If there is a concern for infectious panniculitis, tissue may be sent for culture and stains.

If identified, treatment or elimination of the underlying trigger will often lead to spontaneous remission of EN. This is the primary treatment strategy and should be emphasized in all cases; if there is an EN-triggering disease, it should be treated, and if there is an EN-associated medication, it should be discontinued. This may not be recommended in cases of molecular-targeted therapy.

Treatment of primary EN consists of bed rest, leg elevation, compression, NSAIDs, and potassium iodide. Naproxen and indomethacin have the most evidence in the treatment of EN, but aspirin, celecoxib, diclofenac, and ibuprofen have all been utilized. A reasonable starting dose of indomethacin is 50mg three times daily. Note that NSAIDs have also been reported as potential EN-inducing drugs, and in such cases treatment with NSAIDs is not advised. Potassium iodide is generally well tolerated, effective, and non-immunosuppressive but may not be widely available. Typical dosing is with a supersaturated solution of potassium iodide (SSKI) starting at 1–2 drops three times daily and gradually titrating up to 5 drops (often dissolved in orange juice to increase tolerability of taste) taken three times per day. One drop of SSKI contains approximately 50mg of iodide. SSKI tablets in 65mg and 130mg concentrations are also available. Side effects include hypothyroidism and hyperkalemia; rarely, concentrated iodide can induce a neutrophilic eruption (iododerma). SSKI should be used with caution in patients with dermatitis herpetiformis as it can flare the disease. Thyroid-stimulating hormone should be monitored monthly while on treatment.

In patients who fail these treatments, alternative therapies can be considered. *Prednisone* is highly effective and may be used in particularly refractory, widespread, or symptomatic patients to gain rapid control. Infection and malignancy should be ruled out before initiation. *Colchicine*, *hydroxychloroquine*, *dapsone*, and some immunomodulatory and immunosuppressive agents have anecdotal reports of efficacy.

Notably, while tumor necrosis factor (TNF)-alpha inhibitors have been efficacious in treating EN (especially in patients with underlying IBD), they have also been paradoxically associated with the development of EN.

Specific Investigations to Consider (not all are necessary in all patients)

- Complete blood count (with differential), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)
- Anti-streptolysin O (ASO) titer or anti-deoxyribonuclease B (anti-DNase B) titer, throat culture
- Urinalysis and urine pregnancy test
- Chest radiograph
- Purified protein derivative (PPD) standard tuberculosis skin test or interferon gamma release assay
- Skin biopsy

Erythema nodosum: a review. Soderstrom RM, Krull EA. *Cutis* 1978; 21: 806–10.

Streptococcal infection was the most common etiology, and sarcoidosis is the most common disease associated with EN.

All patients should have a chest radiograph, ASO titer, throat culture, and PPD/testing for latent tuberculosis.

Erythema nodosum: an evaluation of 100 cases. Mert A, Kumbasar H, Ozaras R, et al. *Clin Exp Rheumatol* 2007; 25: 563–70.

The results showed a 6:1 female predominance; 53% idiopathic and 11% streptococcal infections, 10% tuberculosis, 10% sarcoidosis, 6% Behçet, 5% drug reactions, 3% IBD, and 2% pregnancy.

First-Line Therapies

• NSAIDs	E
• Potassium iodide	B

Suppression of erythema nodosum by indomethacin. Ubogye Z, Persellin RH. *Acta Derm Venereol* 1982; 62: 265–7.

Three patients with EN secondary to streptococcal pharyngitis refractory to erythromycin, penicillin, and aspirin improved with indomethacin 100–150 mg for 2 weeks.

Chronic erythema nodosum treated with indomethacin. Barr WG, Robinson JA. *Ann Intern Med* 1981; 95: 659.

Idiopathic EN in a 32-year-old woman refractory to aspirin resolved with indomethacin 25 mg three times daily for 1 month.

Control of chronic erythema nodosum with naproxen. Lehman CW. *Cutis* 1980; 26: 66–7.

A 28-year-old woman with recurrent EN refractory to phenylbutazone and aspirin was treated with naproxen 250 mg orally twice daily for 1 month, with cessation of symptoms within 96 hours and clearing in 14 days. Relapsed with therapy cessation but recleared when naproxen restarted.

Potassium iodide in erythema nodosum and other erythematous dermatoses. Horio T, Danno K, Okamoto H, et al. *J Am Acad Dermatol* 1983; 9: 77–81.

Twelve of 16 patients treated with potassium iodide improved within a few days, with complete resolution in 10–14 days. Six had recurrent attacks, with resolution upon repeat dosing with

potassium iodide. Better outcomes were obtained with earlier treatment initiation.

Potassium iodide may be a reasonable choice for those patients who cannot tolerate NSAIDs or corticosteroids.

Treatment of erythema nodosum and nodular vasculitis with potassium iodide. Schultz EJ, Whiting DA. *Br J Dermatol* 1976; 94: 75–8.

Twenty-four of 28 patients with EN improved within 48 hours and resolved within 2 weeks with 300–900 mg daily of potassium iodide.

Potassium iodide in dermatology. A 19th century drug for the 21st century: uses, pharmacology, adverse effects, and contraindications. Sterling JB, Heymann WR. *J Am Acad Dermatol* 2000; 43: 691–7.

An excellent review article.

Second-Line Therapies

• Colchicine	D
• Hydroxychloroquine	E
• Prednisone	E

Traitement de l'érythème noueux par la colchicine. De Coninck P, Baclet JL, Di Bernardo C, et al. *Presse Med* 1984; 13: 680.

Five women were treated with colchicine (2 mg daily for 3 days, then 1 mg daily for 2–4 weeks) and improved within 72 hours. None recurred after treatment cessation.

Erythema nodosum treated with colchicine. Wallace S. *JAMA* 1967; 202: 144.

One patient with EN was successfully treated with colchicine.

A double-blind trial of colchicine in Behçet's syndrome. Yurdakul S, Mat C, Tüzün Y, et al. *Arthritis Rheum* 2001; 44: 2686–92.

Two-year randomized, double-blind, placebo-controlled study of 116 patients with Behçet syndrome. There were significantly fewer new attacks of EN among female patients on colchicine (1–2 mg/day) versus placebo. At trial end, 79% of female patients in the colchicine arm remained EN free compared with 39% of females in the placebo arm ($p=0.004$ by log-rank test). Additionally, the mean number of EN lesions was significantly less in the colchicine arm compared with placebo among the women (1.4 ± 3.9 versus 6.0 ± 14.9 , respectively; $p=0.002$).

Hydroxychloroquine in the treatment of chronic erythema nodosum. Alloway JA, Franks LK. *Br J Dermatol* 1995; 132: 661–70.

A 38-year-old woman with a 24-year history of EN with almost monthly flares refractory to aspirin and indomethacin was treated with hydroxychloroquine 200 mg orally twice daily. Within 3 months she had a dramatic reduction in lesions and remained stable for at least 6 months.

Hydroxychloroquine and chronic erythema nodosum. Jarrett P, Goodfield MJD. *Br J Dermatol* 1996; 134: 373.

A 52-year-old with idiopathic EN refractory to NSAIDs and prednisone improved with hydroxychloroquine 200 mg orally twice a day and prednisone 15 mg four times a day for 8 weeks. Prednisone was stopped, and 8 weeks later the

hydroxychloroquine dose was cut by half, but the patient experienced a flare, and the original dose was restarted. After 3 more months the hydroxychloroquine was stopped, although intermittent dosing was required.

Third-Line Therapies

• Dapsone	E
• Erythromycin	E
• Mycophenolate mofetil	E
• Etanercept	E
• Adalimumab	E
• Infliximab	E
• Prophylactic penicillin	E
• Vitamin B ₁₂ (if levels low)	E
• Tetracycline	E

Acne fulminans and erythema nodosum during isotretinoin therapy responding to dapsone. Tan B, Lear J, Smith A. Clin Exp Dermatol 1997; 22: 26–7.

Acne fulminans and EN that occurred in a patient 3 weeks after starting isotretinoin responded to dapsone without oral prednisone.

Dapsone for treatment of erythema nodosum. Song JS, Halim K, Vleugels RA, et al. Dermatol Online J 2016; 22.

Three patients with recurrent EN recalcitrant to standard therapies. Addition of dapsone resulted in resolution of EN in all three patients.

Extracorporeal monocyte granulocytapheresis was effective for a patient of erythema nodosum concomitant with ulcerative colitis. Fukunaga K, Sawada K, Fukuda Y, et al. Ther Apher Dial 2003; 7: 122–6.

A patient with ulcerative colitis and EN refractory to high-dose corticosteroids improved after monocyte granulocytapheresis once a week for 5 weeks. He was also on 5-aminosalicylic acid.

Severe erythema nodosum due to Behçet's disease responsive to erythromycin. Kaya TI, Tursen U, Baz K, et al. J Dermatol Treat 2003; 14: 124–7.

A patient with refractory Behçet disease and EN responded to coincidental treatment with erythromycin for erythrasma.

Use of mycophenolate mofetil in erythema nodosum. Boyd AS. J Am Acad Dermatol 2002; 47: 968–9.

A patient taking estrogen replacement with EN refractory to discontinuing hormone therapy and azathioprine cleared with mycophenolate mofetil 750 mg twice a day and remained clear after a slow taper.

Dermatologic manifestations of Crohn disease in children: response to infliximab. Kugathasan S, Miranda A, Nocton J, et al. J Pediatr Gastroenterol Nutr 2003; 37: 150–4.

One child with Crohn disease and resistant EN cleared with infliximab 5 mg/kg and was maintained on 6-mercaptopurine.

Treatment of chronic erythema nodosum with infliximab. Clayton TH, Walker BP, Stables GI. Clin Exp Dermatol 2006; 31: 823–4.

A 26-year-old woman with IBD and EN improved with infliximab.

Sweet's syndrome and erythema nodosum associated with Crohn's disease treated by infliximab. Vanbiervliet G, Anty R, Schneider S, et al. Gastroenterol Clin Biol 2002; 26: 295–7.

Patient with underlying Crohn disease who developed concurrent Sweet syndrome and EN, both of which resolved with infliximab.

Etanercept treatment of erythema nodosum. Boyd AS. Skinmed 2007; 6: 197–9.

One patient with a 5-year history of recalcitrant EN was treated with etanercept 25 mg subcutaneously twice. She was clear after 4 months. After 6 months the etanercept dose was reduced to 25 mg subcutaneously weekly.

Refractory chronic erythema nodosum successfully treated with adalimumab. Ortego-Centeno N, Callejas-Rubio JL, Sanchez-Cano D, et al. J Eur Acad Dermatol Venereol 2007; 21: 408–10.

A 79-year-old patient with chronic recalcitrant EN cleared with adalimumab 40 mg subcutaneously every 2 weeks and was clear after 7 months of follow-up.

Adalimumab for the treatment of Japanese patients with intestinal Behçet's disease. Tanida S, Inoue N, Kobayashi K, et al. Clin Gastroenterol Hepatol 2015; 13: 940–8. e3.

Twenty patients with active intestinal Behçet disease refractory to corticosteroids and/or immunomodulator therapies were given 160 mg adalimumab, 80 mg 2 weeks later, then 40 mg every other week for 52 weeks. Eighty-eight percent of the patients with EN cleared.

A case of fistulizing Crohn's disease and erythema nodosum managed with adalimumab. Quin A, Kane S, Ulitsky O. Nat Clin Pract Gastroenterol Hepatol 2008; 5: 278–81.

A 20-year-old female with EN and perianal fistula with sigmoid colitis with complete resolution following initiation of adalimumab 160 mg dose subcutaneously, followed by 80 mg at week 2, then 40 mg every other week.

Prophylaxis of recurrent erythema nodosum with penicillin. Bhalla M, Thami GP. Dermatology 2007; 215: 363–4.

Three patients with recurrent EN were cleared with monthly doses of intramuscular benzathine penicillin 2.4 million units. One patient had high ASO titers, and the other two had idiopathic biopsy-proven EN. All patients remained clear at 6 months.

The use of benzathine penicillin in streptococcal erythema nodosum: may it reduce recurrence? Aouam A, Hafsa M, Kooli K, et al. Presse Med 2019; 48: 1180–2.

Retrospective cohort study including 77 patients hospitalized with streptococcal EN. Patients with cutaneous nodules on the extensor lower legs consistent with EN who suffered preceding upper respiratory tract infection and elevated anti-streptolysin O antibody were enrolled. Following complete resolution of their acute EN, group A (24 patients) received antibiotic prophylaxis with intramuscular injection of benzathine penicillin G, 1.2 million IU (if <80 kg) and 2.4 million IU (if >80 kg) every 15 days. The comparison group B (53 patients) received no antibiotics. EN recurred in one patient in group A (4.1%) and in 16 patients in group B (30.2%). Rate of recurrence was significantly higher in the control group than the prophylactic group, $p=0.01$. Hazard ratio showed that prophylactic antibiotics with benzathine penicillin following an episode of streptococcal-induced EN reduced the risk of recurrence by 90% [HR 0.1, 95% CI 0.01–0.8].

Successful treatment of chronic erythema nodosum with vitamin B₁₂. Volkov I, Rudoy I, Press Y. J Am Board Fam Pract 2005; 18: 567–9.

One patient had EN resolve after being treated for a low serum B₁₂ level with twice-weekly injections of 1000 mcg of B₁₂.

Response of recalcitrant erythema nodosum to tetracyclines. Davis MD. J Am Acad Dermatol 2011; 64: 1211–2.

One patient with a renal transplant and recalcitrant EN resolved after 1 month of minocycline 100 mg twice daily. Minocycline was

discontinued because of hyperpigmentation. EN recurred within a week and resolved again with tetracycline 500 mg twice a day.

Role of tetracycline in recalcitrant erythema nodosum. Rohatgi S, Basavaraj KH, Ashwini PK, et al. Indian Dermatol Online J 2014; 5: 314–5.

A 40-year-old male with chronic recurrent EN cleared after 2 weeks of tetracycline 500 mg four times daily. The patient was switched to doxycycline and the EN recurred, so tetracycline was restarted with sustained complete regression for 6 months.

Erythrasma

Melissa C. Barkham, Brendan Khong

In its most typical form, erythrasma is characterized by well-defined, reddish-brown, flexural plaques that show fine scaling and no tendency to central clearing. It may also present with maceration of the toe webs.

The responsible organism, *Corynebacterium minutissimum*, is an inhabitant of normal human skin. Factors that predispose to clinically apparent infection include diabetes mellitus, obesity, human immunodeficiency virus (HIV), old age, and a humid environment.

MANAGEMENT STRATEGY

Erythrasma is often a trivial infection, but therapy may be requested because of the cosmetic appearance or because of pruritus. Coinfection with dermatophyte fungi or *Candida albicans* is common and may influence the choice of treatment.

Fusidic acid cream is the topical treatment of choice where no concomitant yeast or fungal infection is found. It is both effective and well tolerated. Despite the apparent efficacy of fusidic acid cream alone, a combination of oral and topical treatment for extensive or stubborn toe web infections might be more effective.

Topical imidazoles (miconazole, clotrimazole) are well tolerated and also effective against concomitant fungal or yeast infection.

There has been recent evidence for topical mupirocin 2% ointment as a treatment. However, more studies and comparison to placebo is required to evaluate its efficacy.

When the disease is extensive or when compliance with topical therapy is unlikely, oral antibiotics such as *single-dose clarithromycin* or *oral erythromycin* should be considered.

A combination of oral and topical treatment may be required for stubborn infections, particularly of the toe webs.

Specific Investigations

- Examination under Wood light
- Potassium hydroxide (KOH) preparation of skin scrapings

Rapid confirmation of the diagnosis is achieved by examination of the skin under Wood (long-wave ultraviolet) light. The characteristic coral-red fluorescence observed is due to the production of coproporphyrin III by the organism. Fluorescence may not be seen if the patient has bathed immediately before examination. Culture is unreliable because the organism does not always grow satisfactorily. Microscopy of skin scrapings is performed to seek evidence of concomitant infection, such as the presence of fungal hyphae or yeasts.

First-Line Therapies

• Fusidic acid cream	A
• Miconazole cream	C
• Clotrimazole cream	C
• Mupirocin 2% ointment	D
• Clindamycin lotion or solution	E

A comparison between the effectiveness of erythromycin, single dose clarithromycin and topical fusidic acid in the treatment of erythrasma. Avci O, Tanyildizi T, Kuskü E. *J Dermatolog Treatment* 2013; 24: 70–4.

Of the 151 patients included in this study, around two-thirds had toe web infections. A complete response (defined as no fluorescence) was observed in 30/31 patients treated with 2% fusidic acid cream twice daily for 14 days in this double-blind, placebo-controlled trial. The response was superior to oral clarithromycin (20/30), oral erythromycin (16/30), placebo cream (4/30), and placebo tablets (1/30). The authors acknowledged the limitations of the grading system of fluorescence used to assess response. They mention that the higher efficacy of fusidic acid cream over oral antibiotics might well be due to the removal of coproporphyrin III from the stratum corneum during topical applications.

A clinical double-blind trial of topical miconazole and clotrimazole against superficial fungal infections and erythrasma. Clayton YM, Knight AG. *Clin Exp Dermatol* 1976; 1: 225–32.

This was a comparison of the two preparations in dermatophyte infection, but 11 patients with erythrasma were also studied: six treated with miconazole, five with clotrimazole, both twice daily. All patients in both groups were free of infection at 4 weeks.

Topical treatment for erythrasma. Cochran RJ, Rosen T, Landers T. *Int J Dermatol* 1981; 20: 562–4.

Two cases cleared with two or three times' daily application of 2% aqueous clindamycin solution for 1 week. No recurrence was noted 6 weeks later.

Erythrasma: a report of nine men successfully managed with mupirocin 2% ointment monotherapy. Greywal T, Cohen PR. *Dermatol Online J* 2017; 23(5): 13030/qt9zh116s1.

A series of nine cases cleared with twice daily application of mupirocin 2% ointment within 2–4 weeks of therapy. There was no report of treatment-associated folliculitis. Mupirocin 2% ointment was not compared with placebo and clearance was measured by non-fluorescence under Wood lamp examination. No recurrence was noted during follow-up appointments. More studies are required.

Second-Line Therapies

• Single-dose clarithromycin	B
• Erythromycin	C

Erythrasma treated with single-dose clarithromycin. Wharton JR, Wilson PL, Kincannon JM. Arch Dermatol 1998; 134: 671–2.

Three patients treated with a single 1-g dose of clarithromycin showed no sign of residual disease at 2 weeks. Compliance is likely to be good with this regimen.

Interdigital Pedal Erythrasma treated with one-time dose of oral clarithromycin 1 g: Two case reports. Khan MJ. Clin Case Rep 2020; 8: 672–674.

Interdigital pedal erythrasma was successfully treated with a one-time dose of oral clarithromycin 1 g. This is ideal for patients who failed topical therapy or have mechanical or psychosocial

restrictions. Treatment provides better compliance, less gastric side effects, and lower treatment costs than oral alternatives.

Systemic or local treatment of erythrasma? A comparison between erythromycin tablets and Fucidin cream in general practice. Hamann K, Thorn P. Scand J Prim Health Care 1991; 9: 35–9.

This double-blind trial compared 14 days' treatment with erythromycin 500 mg twice daily, 2% fusidic acid cream twice daily, and placebo. Four weeks after treatment, 18 of 21 patients with erythromycin and 23 of 25 with fusidic acid cream were cured. Both were better than placebo.

Erythroderma

Arun C. Inamadar, Ragunatha Shivanna

Erythroderma (ED) is a skin reaction pattern presenting as an extreme state of anatomical and physiological dysfunction characterized by extensive erythema and scaling involving more than 90% of the body surface area.

Several skin disorders may evolve into erythroderma (Table 78.1): exacerbation of preexisting dermatoses (e.g., psoriasis, eczema, atopic dermatitis, pityriasis rubra pilaris, and pemphigus foliaceus), drug eruption, and cutaneous lymphomas (mycosis fungoides, Sézary syndrome, adult T-cell leukemia/lymphoma) are some of the common causes. Many cases remain idiopathic despite extensive search for the cause and in-depth laboratory investigations.

ED is associated with significant morbidity and mortality in addition to the variable prognosis inherent to underlying etiology.

MANAGEMENT STRATEGY

The precise diagnosis of erythroderma is essential for proper management and better therapeutic outcome. Erythroderma has a gradual and insidious onset except for drug-induced cases. Psoriasis is the most frequent cause of ED.

ED is a dermatological emergency necessitating immediate therapeutic intervention. The diagnosis of underlying cause of erythroderma and early recognition of consequences of erythroderma is crucial in reducing associated morbidity and mortality. The consequences of the erythroderma differ depending upon the etiology: vesiculobullous diseases like pemphigus foliaceus can end in acute skin failure and inflammatory disease (psoriasis, AD) and other disorders of keratinization (PRP) will culminate

in ED with a chronic course leading to chronic skin failure. The consequences of ED are due to failure of primary functions of the skin such as loss of an effective mechanical barrier, loss of thermoregulation from increased fluid loss via evaporation or exudation, and loss of protein due to the increased proliferative and metabolic activity with the risk of high-output cardiac failure. All these effects are greatest at the extremes of age.

The diagnostic clues can be uncovered by a detailed history, including comprehensive drug history comprising all over-the-counter and herbal remedies and thorough clinical examination. Table 78.2 lists the cutaneous examination clues for the diagnosis of diseases causing erythroderma. Drugs implicated in erythroderma described in the literature are anticonvulsants, antibiotics, non-steroidal antiinflammatory drugs, and even herbal medicines.

The clinicopathologic correlation is difficult because non-specific features of erythroderma may mask the specific features of an underlying dermatosis. Direct immunofluorescence studies may be of diagnostic utility in cases of erythroderma secondary to pemphigus foliaceus, bullous pemphigoid, graft-versus-host disease, and connective tissue disorders. Histopathology should be carried out as soon as possible and should be repeated in different areas and different stages of erythroderma. Immunohistochemistry techniques allow a better evaluation of the skin infiltrates, especially in cutaneous T-cell lymphoma (CTCL). Table 78.3 lists the investigations to be done and clinical parameters to be evaluated.

Initial management of all types of erythroderma is similar, even without an etiologic diagnosis. The main goal of management of erythroderma is restoring the functions of skin, and careful monitoring and prevention of infectious, metabolic, and systemic complications.

The first step is *discontinuation of any unnecessary medications* and appropriate workup. Bed rest and sedation should be advised when necessary. A sedative *antihistamine* such as *hydroxyzine hydrochloride* 25 mg twice daily is useful. *Regulating environmental temperature* is crucial since patients with this condition lose homeostatic body functions that prevent cooling or overheating. Ideally, room temperature must be kept at 30–32°C in order to slow catabolism and reduce the loss of calories through the skin. Skin barrier function can be improved with *colloid baths, wet compresses, along with emollient creams and low-potency topical corticosteroids*. Therapy must also include *nutrition*, preferably enteral nutrition, as it has also a protective effect on the intestinal mucosa and decreases bacterial colonization. Usually the number of calories required is 1500–2000 kcal/day. *Fluid balance* is a main focus in the management of ED. Once the percentage of the involved skin is established, *Ringer lactate (RL) infusion* of 1–2 mL/kg/% of involved skin must be started during the first 24 h.

A marked loss of exfoliated scales occurs that may reach 20–30 g/day. This contributes to the hypoalbuminemia commonly observed in ED. *Albumin* is recommended only if albumin serum level is <2.5 mg/dL. *Nutritional supplementation* is indicated if there is clinical evidence of pedal edema, or if biochemical values support for low serum protein, low serum proteins and reversal of albumin/globulin ratio are evident.

Wet wrap therapy (WWT) is an extremely effective treatment for acute erythrodermic eczema.

Bleach bath and antibiotics are advised if there is evidence of secondary infection. Routine use of antibiotics is contraindicated but there are specific indications for the use of antibiotics in ED, such as an increased number of bacteria cultured from the skin with selection of a single strain, sudden drop in temperature, deterioration in the patient's condition, and symptoms of infections pertaining to a particular system.

Table 78.1 Causes of erythroderma

1	Inflammation	• Psoriasis • Pityriasis rubra pilaris • Lichen planus • Eczemas
2	Infection and infestation	• Staphylococcal scalded skin syndrome • Toxic shock syndrome • Congenital cutaneous candidiasis • Dermatophytoses • Crusted scabies
3	Infiltration	• Sézary syndrome • Mycosis fungoides • Diffuse cutaneous mastocytosis • Internal malignancy
4	Ingestion	• Drugs • Alternative medicines • Systemic contact dermatitis
5	Inherited	• Ichthyosiform disorders • Primary immunodeficiency disorders • Metabolic disorders
6	Immunological	• Graft-versus-host disease • Dermatomyositis • Subacute cutaneous lupus erythematosus • Sarcoidosis
7	Idiopathic	No known etiological agent

From Inamadar AC, Rangunatha S. The rash that becomes an erythroderma. Clin Dermatol 2019;37(2):88–98, with permission from Elsevier.

The use of more specific pharmaceutical intervention requires careful consideration as directed by the etiology of the ED. Immunosuppressive drugs may be considered to be contraindicated if malignancy is suspected (particularly cutaneous lymphoma or paraneoplastic ED). When a firm diagnosis cannot be made, treatment may have to be directed at the most likely cause, based on the clinical and histologic features.

The rash that becomes an erythroderma. Inamadar AC, Rangunatha S. Clin Dermatol 2019; 37: 88–98.

A stepwise approach ensures completeness of clinical evaluation. The initial clinical presentation, cutaneous examination findings, and systemic clues reveal important information regarding the diagnosis, course, and prognosis of erythroderma. *The article is a very comprehensive account of rashes that progress to erythroderma.*

Acute skin failure: concept, causes, consequences and care. Inamadar AC, Palit A. Indian J Dermatol Venereol Leprol 2005; 71: 379–85.

The concept of skin failure is new to non-dermatologist clinicians and sketchy among many dermatologists. Here the pathomechanism of skin failure has been analyzed and a guideline for monitoring has been provided.

A practical approach to the diagnosis and treatment of adult erythroderma. Cuellar-Barboza A, Ocampo-Candiani J, Herz-Ruelas. Actas Dermosifiliogr 2018; 109: 777–90.

Table 78.2 Cutaneous examination clues for the diagnosis of diseases causing erythroderma

Sl no.	Cutaneous examination clues	Disease
1	Preexisting plaques, involvement of periumbilical area (infants), typical nail changes	Psoriasis
2	Preexisting eczematous/ lichenified flexural lesions, prurigo, sparing of diaper area (infants)	Atopic dermatitis
3	Black dots or follicular hyperkeratotic papules on proximal phalanx of fingers, islands of sparing of skin, 'orange' palmoplantar keratoderma	Pityriasis rubra pilaris
4	Annular and polycyclic erythematous plaques	Subacute cutaneous lupus erythematosus, dermatophytosis
5	Facial edema, purpuric rash on dependent areas	Drug reactions
6	Sparing of skin folds (deckchair sign) in elderly men	Papuloerythroderma of Ofuji
7	Macerated and malodorous intertriginous area, positive Nikolsky sign	Pemphigus foliaceus
8	Tenderness of skin, perioral radiating scale-crusts, positive Nikolsky sign	Staphylococcal scalded skin syndrome
9	Linear and swirled pattern of hyperkeratosis/ hyperpigmentation	Conradi–Hünemann–Happle syndrome
10	Scalp involvement with or without alopecia	Omenn syndrome
11	Erythema without scaling, Darier sign, doughy skin, flushing	Diffuse cutaneous mastocytosis
12	Marked periorificial eczematous lesions	Holocarboxylase synthetase deficiency
13	Multiple confetti-like normal skin	Reticulate ichthyosiform erythroderma (ichthyosis with confetti)
14	Leonine facies	Cutaneous T-cell lymphoma, chronic actinic dermatitis
15	Heliotrope rash, Gottron papules/sign, poikiloderma	Dermatomyositis

From Inamadar AC, Rangunatha S. The rash that becomes an erythroderma. Clin Dermatol 2019;37(2):88–98, with permission from Elsevier.

Table 78.3 Specific investigations

Baseline or routine investigations	Etiology directed/specific	Imaging studies	Clinical parameters
- Complete blood count - Liver function tests - Serial skin biopsies to histology - Total IgE - HIV serology - Potassium hydroxide preparation and fungal culture	- Blood culture - Screening for connective tissue disease - Immunodeficiency screen - Immunophenotyping of lymphocytes by flow cytometry - Sézary cell count in peripheral blood smear - T-cell receptor (TCR) gene rearrangement analysis by polymerase chain reaction (PCR) in the blood - High-throughput sequencing of T-cell receptor β gene - Lactate dehydrogenase - Protein electrophoresis - HTLV 1/2 serology - Skin biopsy to TCR gene rearrangement analysis - Lymph node excisional biopsy (if ≥ 1.5 cm or if abnormal characteristics are found, e.g., firm, irregular, clustered, or fixed) - Serum thymus and activation-regulated chemokines (TARC) levels	- Baseline chest X-ray (if acute respiratory distress syndrome [ARDS], later for comparison) - Computed tomography of thorax, abdomen, and pelvis (staging of CTCL, idiopathic erythroderma to search for internal malignancies)	- Pulse rate, respiratory rate - Temperature, level of consciousness - Urine output - Gastric emptying

The authors present a practical review of the etiology, diagnosis, and treatment of ED.

Diagnosing erythrodermic cutaneous T-cell lymphoma. Russell-Jones R. Br J Dermatol 2005; 153: 1–5.

A very useful review with an algorithm to help differentiate between erythroderma due to CTCL and ‘reactive’ causes of erythroderma. The author proposed three key procedures to determine the correct diagnosis for patients with chronic erythroderma of unknown etiology: biopsy of lesional skin; analysis of peripheral blood; and lymph node biopsy. Each sample should be analyzed for morphology, immunophenotype, and the presence of a T-cell clone.

Erythroderma with circulating atypical T-cells, likely Sézary syndrome. Ugonabo N, Kim R, Chen L, et al. Dermatol Online J 2019; 25: 10.

The authors present an erythrodermic patient with repeated biopsies demonstrating a spongiotic process that was found to have circulating, atypical T cells concerning for underlying erythrodermic T-cell leukemia, most closely related to Sézary syndrome. *The importance of serial biopsy is stressed.*

High-throughput sequencing of the T cell receptor β gene identifies aggressive early-stage mycosis fungoides. de Masson A, O’Malley JT, Elco CP, et al. Sci Transl Med 2018; 10(440).

Tumor clone frequency greater than 25% predicts aggressive course for CTCL. In patients with questionable histology, this test accurately diagnoses CTCL.

Ichthyosiform erythroderma revealing a severe combined immunodeficiency. [Article in French]. Ghariani Fetoui N,

Bousofara L, Hmida D, et al. Ann Dermatol Venereol 2020; 147: 131–4.

Neonatal erythroderma must be considered a warning sign of primary immunodeficiency requiring immediate immunological phenotyping as well as genetic testing for a definitive diagnosis.

Familial ‘benign’ pemphigus? Erythroderma and fatal outcome. Tansini PB, Boff AL, Weber MB, et al. An Bras Dermatol 2020; 95: 75–7.

The authors report an unusual case of generalized Hailey–Hailey disease with erythroderma and fatal outcome.

Erythroderma as first manifestation of squamous cell lung cancer: rare case report. Arandes-Marcocci J, Iglesias-Sancho M, Setó-Torrent N, et al. An Bras Dermatol 2020; 95: 67–70.

This case report demonstrates the need to search for a neoplasm in patients presenting with erythroderma, particularly in the presence of accompanying debilitating symptoms.

Drug induced exfoliative dermatitis: state of the art. Yacoub M-R, Berti A, Campochiaro C, et al. Clin Mol Allergy 2016; 14: 9

This is a very comprehensive review with in-depth discussion on prophylactic, supportive, and complications therapy of drug-induced exfoliative dermatitis (ED).

Lichenoid drug reaction due to anti-tubercular therapy presenting as erythroderma. Katara A, Arora P, Sardana K, et al. Dermatol Ther 2020; 33: e13169.

Lichenoid drug eruption (LDR) presenting as erythroderma is very rare. The authors report a case of exfoliative dermatitis secondary to LDR, which developed after 5 months of antitubercular therapy.

Norwegian scabies presenting as erythroderma in HIV: a case report. Paparizos V, Vasalou V, Velissariou E, et al. *Infez Med* 2019; 27: 332–5.

Crusted scabies is a rare and extreme manifestation of scabies that is observed mainly among immunosuppressed patients. Authors describe the case of a 55-year-old patient with a history of HIV infection and injection drug use. There should be a high degree of suspicion for this disease in patients with AIDS, even when the lesions do not have the classical appearance.

Paraneoplastic erythroderma: unusual presentation secondary to diffuse large B cell lymphoma. Lim PN, Fox CP, Pammi M, et al. *BMJ Case Rep* 2019; 12: e228412.

Paraneoplastic dermatoses can manifest as the first clinical sign of underlying malignancy, heralding a cancer diagnosis.

Bullous erythroderma: novel association of pityriasis rubra pilaris with bullous pemphigoid. Genovese G, Muratori S, Berti E, et al. *Clin Exp Dermatol* 2019; 44: 73–5.

Clinicians should be aware that concurrence of PRP and bullous erythroderma is a differential diagnosis to consider in patients with blistering erythroderma.

Erythroderma as a manifestation of leprosy. Baldissera RL, Shwetz GA, Fillus Neto J, et al. *An Bras Dermatol* 2019; 94: 89–92.

This report demonstrates that chronic multibacillary leprosy can manifest as erythroderma and thus should be included in the differential diagnosis.

Imatinib mesylate induced erythroderma. Lunge S, Bhise R. *J Assoc Physicians India* 2018; 66: 79–80.

Exfoliative dermatitis has been reported with imatinib in a 55-year-old female who initially presented with a maculopapular rash and developed erythroderma on continuation of the drug.

Pityriasis rubra pilaris-like erythroderma secondary to phosphoinositide 3-kinase inhibition. Dewan AK, Sowerby L, Jadeja S, et al. *Clin Exp Dermatol* 2018; 43: 890–4.

Phosphoinositide 3-kinase (PI3K) inhibitors are a class of small-molecule inhibitors approved for the treatment of certain leukemia and lymphomas.

Three patients on PI3K inhibitors for treatment of malignancy developed diffuse erythroderma and keratoderma. Clinical and histopathological findings were consistent with pityriasis rubra pilaris (PRP)-like reactions.

First-Line Therapies

• Bed rest	C
• Emollients	C
• Wet wrap technique (WWT)	D

Wet wrap dressings as a rescue therapy option for erythrodermic psoriasis. Navrotsky BRE, Nihi FM, Camilleri MJ, et al. *An Bras Dermatol* 2018; 93: 598–600.

Wet wrap dressings provide an ancillary treatment option for erythrodermic patients. Seven patients with erythrodermic psoriasis who responded promptly to WWT prior to the initiation of systemic treatment are reported.

Second-Line Therapies

• Topical steroids	C
• Psoralen and UVA therapy (PUVA)	C
• Oral corticosteroids/systemic steroids	C
• Reti-PUVA	E

Therapeutic options and prognosis of chronic idiopathic erythroderma in older adults. Ohga Y, Bolortuya B, Imafuku S. *Dermatol Ther* 2019; 32: e12977.

The authors have reported that chronic idiopathic erythroderma (CIE) that lasts for more than 3 months without specific cause occurs almost exclusively in older men. Twenty cases were identified, of which CIE was treated with oral corticosteroids, oral ciclosporin A (CsA), ultraviolet (UV) therapy, or a combination of these therapies. Low-dose oral CsA (50–100 mg/day) was the most effective treatment, which resulted in cures in four cases. UV therapy also effectively cured two subjects, and oral corticosteroids cured one patient. In patients that were treated with oral CsA or corticosteroids, the terminations of the treatments within 2–3 months resulted in relapses in multiple patients. Maintenance of the treatments for a certain period may be necessary in cases that involve treatments with these orally administered drugs.

Burns can be difficult to distinguish from erythroderma, making phototherapy problematic.

Third-Line Therapies

• Ciclosporin	B
• Other immunosuppressive drugs: methotrexate	B
• Systemic retinoids	E
• Biologics for psoriasis	B
• Topical lovastatin and cholesterol	E
• Topical simvastatin	E
• Apremilast	E

A systematic review of treatment strategies for erythrodermic psoriasis. Reynolds KA, Pithadia DJ, Lee EB, et al. *J Dermatol Treat* 2019 Nov 4 [Epub ahead of print].

This systematic review of the literature reveals a variety of immunomodulatory (ciclosporin, oral retinoids) and biologic therapies (secukinumab, ustekinumab, guselkumab, ixekizumab, and brodalumab) as effective molecules for treating erythrodermic psoriasis (EP).

Papuloerythroderma of Ofuji responding to treatment with ciclosporin. Sommer S, Henderson CA. *Clin Exp Dermatol* 2000; 25: 293–5.

A patient with papuloerythroderma of Ofuji responded to systemic steroids, but remission was not maintained on reduction of the dose. Ciclosporin was added, which led to rapid clearing of the skin, and remission was maintained after discontinuation of treatment.

Efficacy and safety of biologics in erythrodermic psoriasis: a multicenter, retrospective study. Viguier M, Pagés C, Aubin F, et al. *Br J Dermatol* 2012; 167: 417–23.

This study addresses the efficacy and safety of biologics (infliximab, adalimumab, etanercept, ustekinumab, and efalizumab) in 28 patients. Overall, 42% of patients with EP reached a 75% improvement of skin severity 10–14 weeks after starting biologics. Safety is mostly affected by infectious complications with skin origin.

Efficacy and safety of brodalumab in patients with generalized pustular psoriasis and psoriatic erythroderma: results from a 52-week, open-label study. Yamasaki K, Nakagawa H, Kubo Y, et al. *Br J Dermatol* 2017; 176: 741–51.

Improvement or remission was observed in 18 cases of psoriatic erythroderma over the course of this 52-week study.

Infliximab as sole or combined therapy, induces rapid clearing of erythrodermic psoriasis. Takahashi MDE, Castro LG, Romiti R. *Br J Dermatol* 2007; 157: 828–31.

This is an open-label, single-center study of seven patients with EP. One patient was treated with infliximab 5 mg/kg at weeks 0, 4, and 6 and methotrexate 15 mg/week. Four patients were treated with infliximab (same regimen as before) and acitretin 0.3–0.6 mg/kg. All five patients reported excellent outcome at week 6 after the third infusion.

Treatment of erythrodermic psoriasis with etanercept. Esposito M, Mazzotta A. *Br J Dermatol* 2006; 155: 156–9.

An open-label study of 10 patients with EP. Etanercept was administered as a 25-mg subcutaneous injection twice weekly; six achieved Psoriasis Area and Severity Index (PASI) 75 and two achieved PASI 50 at week 24. These improvements were noted as early as week 12 of the study.

Ustekinumab treatment of pityriasis rubra pilaris: a report of five cases. Napolitano M, Lembo L, Fania L, et al. *J Dermatol* 2018; 45: 202–6.

After three injections of ustekinumab, complete remission of skin lesions was achieved in four out of five cases and a significant clinical improvement was shown in one case. Ustekinumab may be a possible first-line treatment for PRP patients who are refractory to conventional therapies.

A case of erythrodermic psoriasis successfully treated with ixekizumab. Megna M, Gallo L, Balato N, et al. *Dermatol Ther* 2019; 32: e12825.

Ixekizumab, a fully human antiinterleukin (IL)-17A monoclonal antibody, is approved for moderate-to-severe plaque psoriasis, while its use in EP is off label. Authors report the case of a 66-year-old Caucasian female with EP successfully treated with ixekizumab.

Successful treatment of Netherton syndrome with ustekinumab in a 15-year-old girl. Volc S, Maier L, Gritsch A, et al. *Br J Dermatol* 2020 Jan 24 [Epub ahead of print].

Treatment of Netherton syndrome has always been challenging, but evidence is accumulating that an IL-17-dominant inflammatory response is found in orphan ichthyoses and that the inflammation may be targeted efficiently by ustekinumab, anti-TNF, and anti-IL-12/23 antibodies.

Secukinumab emerges as a rapidly effective therapy for pityriasis rubra pilaris. Bonomo L, Levitt JO. *Cutis* 2018; 101: 367–9.

The authors report two new cases of severe refractory PRP that responded rapidly to treatment with secukinumab, the IL-17A antagonist.

Complete resolution of erythrodermic psoriasis with first-line apremilast monotherapy. Krishnamoorthy G, Kotecha A, Pimentel J. *BMJ Case Rep* 2019; 12: e226959.

The authors report complete and longstanding resolution of EP with first-line apremilast monotherapy. Apremilast may be an effective option with comparatively minor side effects for EP.

Topical hypochlorite and skin acidification improves erythroderma of Omenn syndrome. Wat M, Olicker A, Meyerson H, et al. *Pediatrics* 2018; 141 (Suppl 5): S408–11.

This case reveals for the first time that dilute topical hypochlorite and skin pH restoration holds promise to control severe dermatitis associated with immunodeficiency and inflammatory syndromes with minimal side effects.

Extracorporeal photopheresis in Sézary syndrome: hematologic parameters as predictors of response. Evans AV, Wood BP, Scarisbrick JJ, et al. *Blood* 2001; 98: 1298–301.

Twenty-three patients with Sézary syndrome who received monthly (up to 1 year) extracorporeal photopheresis (ECP) as the sole therapy showed that 57% achieved a reduction in erythema of more than 25% from baseline.

Bexarotene therapy for mycosis fungoides and Sézary syndrome. Abbott RA, Whittaker SJ, Morris SL, et al. *Br J Dermatol* 2009; 160: 1299–307.

This retrospective study of 66 patients demonstrates that bexarotene is well tolerated in most patients and responses are well seen in almost half of patients with all disease stages. Two patients with erythroderma achieved complete response with bexarotene (one subsequently received reduced-intensity stem cell transplant and the other remains on bexarotene).

Non-endemic erythrodermic pemphigus foliaceus: a case with delayed diagnosis and response to rituximab. Patsatsi A, Kyriakou A, Douma S, et al. *J Dtsch Dermatol Ges* 2019; 17: 537–9.

Successful treatment of erythrodermic mycosis fungoides with mogamulizumab followed by etoposide monotherapy. Fujimura T, Tanita K, Sato Y, et al. *Case Rep Oncol* 2018; 11: 29–32.

In this report, the authors present a case of erythrodermic mycosis fungoides successfully treated with mogamulizumab followed by etoposide monotherapy.

CHILD syndrome: successful treatment of skin lesions with topical lovastatin and cholesterol lotion. Sandoval KR, Machado MCR, Oliveira ZNP, et al. *An Bras Dermatol* 2019; 94: 341–3.

The authors report a 2-month-old child treated with a topical solution containing cholesterol and lovastatin, with complete clearance of her CHILD nevus.

Erythrokeratodermas

Gabriele Richard

Courtesy of Dr Margarita Larralde, Buenos Aires, Argentina.

Erythrokeratodermas (EK) are a clinically and genetically heterogeneous group of rare inherited disorders of cornification characterized by two distinct morphologic features: localized hyperkeratosis and erythema. The best characterized form of EK is *erythrokeratoderma variabilis et progressiva* (EKVP). The hallmark of EKVP is the seemingly independent occurrence of transient, figurate erythematous patches and relatively fixed, sharply outlined hyperkeratotic plaques in a symmetrical distribution on the face and buttocks, and over extensor surfaces of the extremities. These hyperkeratotic plaques tend to increase in number and size before either stabilizing, regressing, or, rarely, disappearing later in life. Diffuse palmoplantar keratoderma (PPK) transgressing to the dorsal hands and feet is a common feature. EKVP is an autosomal dominant (ad) or, very rarely, autosomal recessive (ar) disorder caused by pathogenic sequence variants in one of the connexin genes, *GJB3* (connexin 31), *GJB4* (connexin 30.3), and *GJA1* (connexin 43) expressed in human epidermis, which result in disturbed gap junction intercellular communication or augmented hemichannel function.

Progressive symmetric erythrokeratoderma (PSEK) has been used to describe the presence of well-demarcated, localized-to-widespread hyperkeratotic plaques with underlying erythema in symmetrical distribution with diffuse PPK but without fleeting erythema. Nevertheless, genetic studies have revealed that 'PSEK' encompasses different forms of EK, each with distinct clinical features and molecular causes, and may be part of the EKVP spectrum. EK can be also a feature of other rare genetic syndromes, such as keratitis-ichthyosis-deafness syndrome;

loricrin keratoderma, mental retardation, enteropathy, deafness, peripheral neuropathy, ichthyosis, and keratoderma (MEDNIK) syndrome; severe dermatitis, multiple allergies, and metabolic wasting (SAM) syndrome; erythrokeratoderma-cardiomyopathy (EKC) syndrome; Chanarin-Dorfman syndrome; or *PNPLA1*-related autosomal recessive congenital ichthyosis.

Key features of *Olmsted syndrome* (ad/ar) are striking erythematous, sharply outlined, hyperkeratotic plaques with periorificial predilection on face, buttocks, groin, and abdomen; severe pruritus; and very painful, mutilating PPK impeding ambulation and reducing quality of life. Alopecia, nail dystrophy, propensity to cutaneous infections, follicular keratosis, and hyperhidrosis are less frequent features. The disorder can be caused by pathogenic gain-of-function variants in the *TRPV3* and *TRPM4* genes leading to constitutive activation of cation channels in the skin. Less common are variants in the *PERP* gene, encoding a component of desmosomes and other cell junctions, or in the X-linked *MBTPS2* gene, which produces a zinc metalloprotease essential for cholesterol homeostasis and endoplasmic reticulum stress response.

PSEK with or without thrombocytopenia (ar) results from defective acylceramide biosynthesis in the skin and bone marrow due to biallelic variants in the *KDSR* gene. The spectrum of severity is broad, including Harlequin or collodion presentation at birth and extensive erythrokeratoderma. Sharply demarcated, bright red, thick, verrucous or scaling plaques or streaks on the cheeks and chin, and in periorificial locations, as well as PPK, are characteristic. Half of reported individuals developed in infancy persistent and sometimes progressive thrombocytopenia, resulting in easy bruising or bleedings.

Erythrokeratoderma-spinocerebellar ataxia (type Giroux-Barbeau; SCA34) is a very rare form of ataxia (ad) originally described in a large French-Canadian family, which manifests during childhood with features of EKVP on hands, feet, and limbs. While skin findings disappear in the third decade of life, patients develop gait ataxia due to progressive cerebellar atrophy in the fourth and fifth decades. The causative genetic defects for SCA34 with or without EK involve the elongase gene *ELOVL4*, which encodes an enzyme for the elongation of very long-chain fatty acids and formation of complex lipids in the epidermis, retina, and central nervous system.

MANAGEMENT STRATEGY

Erythrokeratodermas (EK) are heritable, chronic disorders that often require lifelong treatment. Management depends on the location, severity, and extent of hyperkeratosis, which may vary over time and from patient to patient. The spectrum may range from fixed hyperkeratotic plaques over the knees and elbows to generalized hyperkeratosis with accentuated skin markings and peeling, or thickened plates with a spiny, hystrix-like appearance. Palmoplantar keratoderma (PPK) is a common feature and often debilitating due to pain from fissures, deep cracks, or digital ischemia when circular constriction bands form, and can limit ambulation and working with the hands.

The *topical management* of EK remains a therapeutic cornerstone, although it can be disappointing in some cases. Topical treatment of mild, localized hyperkeratosis is symptomatic and focuses on hydration, lubrication, and keratolysis. Whereas, in some patients, *emollients* such as petrolatum twice daily may suffice, most patients require topical treatment with *keratolytic agents*. Lactic acid (6%–12%) and urea applied once or twice daily in combination with emollients are effective, although their use may be limited, especially in children, because of irritation. Other α -hydroxy acids, salicylic acid (2%–6%), propylene glycol,

glycolic acid, vitamin D analogs (calcipotriol), or combinations of these are alternative treatment options. Topical treatment with *retinoids* and derivatives has been successful in some patients (especially with EKVP) but ineffective in others. Regimens with synthetic retinoids, such as short-contact topical tazarotene therapy combined with moisturizers, seem promising in EKVP. PPK may also benefit from soaking, mechanical removal, or surgical parings of excessive hyperkeratosis. In addition, avoidance of trauma to the skin, such as sudden temperature changes, friction, and mechanical irritation, may be beneficial.

Systemic retinoids are the treatment of choice in EK with extensive or generalized skin involvement. Although highly effective in EKVP, the therapeutic response in other EKs is less satisfactory and consistent, especially in Olmsted syndrome. The effects of acitretin or etretinate are superior to those of systemic isotretinoin. It seems advantageous to start at low doses of acitretin for 3–6 weeks and then to gradually increase the dose until the desired therapeutic effect is achieved. The minimal effective maintenance dose for EKVP is usually lower than for patients with other forms of EK or ichthyosis. Both morphologic components respond well to retinoid treatment, resulting in rapid, dramatic improvement or clearing of hyperkeratosis and significant moderation or resolution of erythema. Nevertheless, using retinoids should always be considered carefully, as chronic therapy is required for continuing results, and long-term side effects, especially in children, may ensue. Intermittent cycles of systemic retinoid treatment may be considered to balance between beneficial therapeutic and adverse effects.

In contrast to EKVP, topical and systemic treatment of Olmsted syndrome is challenging. Oral retinoids (acitretin, etretinate), corticosteroids, methotrexate, or surgical parings achieve only poor-to-moderate relief. Anecdotal *systemic rapamycin* (sirolimus), an mTOR pathway inhibitor, was effective in a few patients, reducing erythema, periorificial hyperkeratotic plaques, and pain, while PPK showed modest or no improvements. Pain medications (opioids, topical lidocaine, cold applications) were temporarily effective in managing chronic pain. One adult and two case series totaling seven children with Olmsted syndrome due to *TRPV3* mutations demonstrated rapid response and sustained improvement of debilitating PPK, flexural contractions, pruritus, pain, and other associated symptoms with oral *EGFR tyrosine kinase inhibitor erlotinib hydrochloride*. This treatment approach is based on a gain-of-function effect of pathogenic *TRPV3* variants, which in vitro and in transgenic mice leads to augmented activation of transient receptor potential cation channels in keratinocytes and may induce transactivation of EGFR with activation of the downstream mTOR pathway. No significant adverse effects have been reported; moderate hair loss and other minor side effects were tolerable or manageable with dose adjustments. Nevertheless, long-term treatment with EGFR inhibitors might be necessary in these patients, and requires careful monitoring and dose adjustments based on tolerability and side effects.

Anecdotally, *PUVA therapy* alone or combined with acitretin (Re-PUVA) has been beneficial in the treatment of PSEK, while narrowband UVB (NB-UVB) therapy has been effective for a patient with EKVP. Few patients have been reported with clearing of skin lesions under oral treatment with low-dose vitamin A or a polyaromatic retinoid (arotinoid ethylester).

The variable erythema in EKVP or residual periorificial lesions in Olmsted syndrome and KSDR-related PSEK often result in cosmetic concerns, which can be limited by masking uncovered skin with makeup and camouflage. Serious discomfort due to burning and pruritus at erythematous lesions can be therapeutically challenging. If systemic aromatic retinoid therapy alone fails to

reduce or suppress erythema and the associated burning and itching sensations, symptomatic relief has been achieved in anecdotal cases with systemic therapy using sedating *H₁-antihistamines*.

Specific Investigations

- Family history
- Histopathology

Erythrokeratoderma variabilis et progressiva. Ishida-Yamamoto A. *J Dermatol* 2016; 43: 280–5.

Review of clinical and histological features, treatment and underlying pathomechanisms of connexin-related EKVP. Connexin disorders of the skin. Richard G. *Clin Dermatol* 2005; 23: 23–32.

Summary of the clinical features and molecular genetics of EKVP due to causative variants in the connexin genes *GJB3* (Cx31) and *GJB4* (Cx30.3), as well as of other connexin disorders associated with *GJB2* (Cx26), *GJB6* (Cx30), and *GJA1* (Cx43).

The missense mutation G12D in connexin 30.3 can cause both erythrokeratoderma variabilis of Mendes da Costa and progressive symmetric erythrokeratoderma of Gottron. Van Steensel MAM, Oranje AP, van der Schroeff JG, et al. *Am J Med Genet Part A* 2008; 149A: 657–61.

Mutation analysis in five Dutch patients, two with PSEK and three with erythrokeratoderma variabilis (EKV), revealed the same G12D mutation in *GJB4* (Cx30.3) on the same ancestral haplotype, indicating that G12D is a Dutch founder mutation presenting with features of either EKV or PSEK. Systemic treatment of an adult male patient with PSEK with 20–40 mg etretinate during the wintertime reportedly resulted in satisfactory symptomatic relief. The name *erythrokeratoderma variabilis et progressiva* (EKVP) was introduced to indicate the clinical variability of this disorder.

Olmsted syndrome: clinical, molecular and therapeutic aspects. Duchatelet S, Hovnanian A. *Orphanet J Rare Dis* 2015; 10: 33. Thorough review of 73 published cases of Olmsted syndrome.

First-Line Therapies

• Emollients	D
• Topical keratolytics	D
• Topical retinoids	D
• Topical calcipotriol	E

Erythrokeratoderma variabilis successfully treated with topical tazarotene. Yoo S, Simzar S, Han K, et al. *Pediatr Dermatol* 2006; 23: 382–5.

Topical short-contact (15 min) treatment with tazarotene (0.05% gel) once a day followed by the topical corticosteroid (fluocinolone oil) application on moist skin and hydrophilic ointments resulted in complete remission of hyperkeratotic plaques and erythematous patches in a 16-month-old child with EKVP within 1 month. Emollients were continued during quiescent periods, and the aforementioned regimen during flares.

Tazarotene is a topical, receptor-selective retinoid.

Erythrokeratoderma variabilis. Report of 3 clinical cases and evaluation of the topical retinoic acid treatment. Lacerda

E, Costa MH, de Brito Caldeira J. *Med Cutan Ibero Lat Am* 1975; 3: 281–7.

Topical retinoic acid (0.1% cream) treatment of three EKVP patients substantially reduced hyperkeratosis. Discontinuation resulted in prompt relapse.

Progressive symmetrische erythrokeratoderme Darier-Gottron. Ott H, Lehmann S, Poblete-Guitierrez P, et al. *Hautarzt* 2004; 10: 994–6.

A 5-year-old boy with PSEK and severe PPK with flexural contractures on both hands was treated with topical steroids of various strength and urea without lasting improvement. Topical tretinoin 0.03% cream combined with hydrophilic ointments and physical therapy resulted in significant and lasting skin improvement and regression of contractures after a few weeks.

Progressive symmetric erythrokeratoderma: report of an Indian family. Gupta LK, Saini P, Khare AK, et al. *Int J Dermatol* 2014; 53: e317–9.

The proband of a multigenerational family with a clinical diagnosis of PSEK showed no appreciable improvement when treated with topical emollients, urea, and salicylic acid ointment, nor with acitretin 25 mg/day for 3 months.

Progressive symmetric erythrokeratoderma – response to topical calcipotriol. Bilgin I, Bozdağ KE, Uysal S, et al. *J Dermatol Case Rep* 2011; 5: 50–2.

A female with EK plaques in flexural regions and PPK was treated with 0.5 mg/kg/day isotretinoin for 2 months without improvement. Topical calcipotriol ointment applied twice daily yielded marked improvement of hyperkeratosis within 2 weeks.

Progressive symmetrical erythrokeratoderma on the face: a rare condition and successful treatment with calcipotriol. Tarkci N, Goencue K, Yueksel T, et al. *JAAD Case Rep* 2016; 2: 70–1.

A 7-year-old boy with sharply demarcated EK plaques on the face and elbows since 1 year of age showed complete resolution after twice daily topical application of calcipotriol ointment without adjuvant steroids or emollients for 1 month. Treatment was stopped without relapse in 4 months follow-up.

Second-Line Therapies

• Acitretin	C
• Isotretinoin	D
• EGFR inhibitors	D

Clinical and genetic heterogeneity of erythrokeratoderma variabilis. Common JEA, O'Toole EA, Leigh IM, et al. *J Invest Dermatol* 2005; 125: 920–7.

Four of six EKVP patients had a good-to-excellent response to 0.125–0.25 mg/kg/day oral acitretin. Two patients cleared completely, one on 20 mg acitretin daily. The remaining patients had residual hyperkeratosis, especially on the legs.

Erythrokeratoderma variabilis caused by a recessive mutation in GJB3. Fuchs-Telem D, Pessach Y, Mevorah B, et al. *Clin Exp Dermatol* 2011; 36: 406–11.

Third report of a consanguineous EKVP family due to biallelic mutations in *GJB3* (Cx31). A 14-year-old boy showed dramatic improvement followed by complete resolution of hyperkeratosis with low-dose treatment (25 mg four times a week)

with acitretin. The migratory erythematous patches, however, remained.

Both low-dose arotinoid ethylester and acitretin are effective in the treatment of familial erythrokeratoderma variabilis. Zhang L, Hong Y, Zheng S, et al. *Dermatol Ther* 2014; 27: 240–3.

Skin lesions in two siblings with EKVP cleared within 2 weeks/2 months with systemic therapy with either 0.03 mg/day arotinoid ethylester or 30 mg acitretin/day, respectively, and remained symptom free with reduced dosage for up to 6–12 months. Upon cessation of systemic treatment, relapse occurred after 3 or 6 months, respectively.

Case of erythrokeratoderma variabilis successfully treated with oral Vitamin A. Shizukawa H, Hiragun M, Hiragun T, et al. *J Dermatol* 2015; 42: 1124–5.

A 15-year-old Japanese female with EKVP was treated during childhood with topical vitamin D₃ analog and corticosteroids (unsuccessful), etretinate 0.4–0.6 mg/kg/day (marked improvement but discontinued due to side effects), and ciclosporin 2–3 mg/kg/day (discontinued due to side effects). At age 15, she was treated with oral vitamin A at 10,000 U/day, which was gradually increased by 10,000 U/day every 2 weeks. Improvements were noted at a dose of 30,000 U/day vitamin A, and showed a substantial benefit when the vitamin A dose was increased to 80,000 U/day without any adverse side effects. Halving the vitamin A dose exacerbated the skin lesions again.

Erythrokeratoderma variabilis with adult onset: report of a sporadic case unresponsive to systemic retinoids. Erbagci Z, Tuncel AA, Deniz H. *J Dermatol Treat* 2006; 17: 187–9.

Unusual case with onset of fixed EK at 23 years of age, without known molecular cause. Topical steroids, topical PUVA for 3 months, and keratolytics (10% salicylic acid) did not yield satisfactory results. Subsequent systemic isotretinoin (0.7 mg/kg/day) combined with topical ointments containing 20% urea showed no improvement after 3 months. Acitretin 0.5 mg/kg/day for 5 months was also unsuccessful. Sedating oral H₁-antihistamines were beneficial for relief of pruritus.

Late onset progressive symmetric erythrokeratoderma with pseudoainhum. Asha GS, Lakshmi DV, Shilpa K, et al. *Indian J Dermatol* 2016; 61(4): 448–50.

A 44-year-old male with history of PPK since 19 years of age and fixed EK plaques on the chest and lower abdomen for the past 3 years, which gradually spread to the back and extremities. Development of digital circular constriction bands led to autoamputation of two toes (pseudoainhum). The molecular cause and specific type of PSEK are unknown. Oral treatment with isotretinoin 20 mg/day showed marked improvement of EK on trunk within 6 weeks (unknown if pseudoainhum improved).

Mutations in KDSR cause recessive progressive symmetric erythrokeratoderma. Boyden LM, Vincent NG, Zhou J, et al. *Am J Human Genet* 2017; 100: 978–84.

Two patients with systemic isotretinoin therapy, of whom a 9-year-old child was treated with 1 mg/kg/day for 6 months, showed near complete resolution of skin lesions. The efficacy of retinoic acid derivatives was suggested to result from a retinoic acid-induced increase in sphingosine acetylation and sphingomyelinase upregulation, thus inducing alternate pathways for ceramide synthesis that can compensate in part for the defective ceramide de novo synthesis pathway in this condition.

Biallelic mutations in KDSR disrupt ceramide synthesis and result in a spectrum of keratinization disorders associated with thrombocytopenia. Takeichi T, Torrelo A, Lee JYW, et al. *J Invest Dermatol* 2017; 137: 2344–53.

In two males (15/19 years of age) with *KDSR*-related PSEK and isolated thrombocytopenia, oral acitretin at 0.5 mg/kg/day for several months showed no satisfying effect on skin features. In the younger patient, oral corticosteroids showed no optimal effect on thrombocytopenia. Splenectomy at 11 years of age improved thrombocyte count slightly, although recurrent nose bleeds persist. Another two patients had a more severe phenotype with premature birth and Harlequin ichthyosis presentation, necessitating neonatal intensive care in a humidified incubator. While the platelet count was normal at birth, it dropped drastically within the first weeks of life. One patient was treated with topical emollients, lubricating eye drops, and systemic acitretin, which yielded some reduction in the adherent scale, but he succumbed to pseudomonas septicemia. The other patient was not treated with systemic retinoids and the thickened scales gradually shed over 2 months, transitioning to generalized erythroderma and fine scaling, similar to *ABCA12*-associated Harlequin ichthyosis.

Epidermal growth factor receptor inhibition with erlotinib for palmoplantar keratoderma. Kenner-Bell BM, Paller AS, Lacouture ME. *J Am Acad Dermatol* 2010; 63(2): e58–9.

A 31-year-old female with Olmsted syndrome of unknown molecular cause has since childhood perioral keratoderma, alopecia, and painful, debilitating focal PPK with flexural contractions that render her unable to walk. Pain medications, twice-yearly surgical parings of hyperkeratotic masses on palms and soles, continuous oral retinoids, and keratolytics were not effective. Systemic treatment with the EGFR tyrosine kinase inhibitor *erlotinib* with 100 mg/day initially and 150 mg/day after several months rapidly cleared perioral lesions, improved PPK and range of motion considerably, and allowed walking without much discomfort. Albeit the drastic initial response could not be completely maintained, continuous treatment (over 2 years) in addition to oral retinoids showed no adverse effects.

Use of epidermal growth factor receptor inhibitor erlotinib to treat palmoplantar keratoderma in patients with Olmsted syndrome caused by *TRPV3* mutations. Greco C, Leclerc-Mercier S, Chaumon S, et al. *JAMA Dermatol* 2020; 156(2): 191–5.

Three teenage patients from two families with *TRPV3*-related Olmsted syndrome had massive, focal PPK, intolerable pain with erythromelalgia, severe growth delays, and variable neuropsychiatric symptoms. In one patient pain was resistant to opioids, and he showed temporary improvement of PPK and pain with oral steroids. All three patients were treated with the EGFR inhibitor *erlotinib* hydrochloride, with dosing around 2–2.5 mg/kg/day titrated to treatment effect, plasma levels, and tolerance for up to 12 months. A rapid improvement of pain and keratoderma with almost complete resolution was achieved within the first 3 months. Over time, pain medications could be discontinued, patients were able to wear shoes and walk unassisted, growth and weight parameters improved significantly, and depression, insomnia, and anorexia disappeared. Adverse side effects in all patients were mild acneiform eruptions and moderate diffuse alopecia. Nausea and abdominal pain observed in one patient resolved completely with dose adjustments to blood *erlotinib* concentrations under 500 ng/mL.

Targeted inhibition of the epidermal growth factor receptor and mammalian target of rapamycin signaling pathways in Olmsted syndrome. Zhan A, Duchatelet S, Lakdawala N, et al. *JAMA Dermatology* 2020; 156(2): 196–200.

Report of twins with *TRPV3*-related Olmsted syndrome, who developed after birth EK plaques on the scalp, periorbital and peroral skin, ears, neck, axillae, and genital area, and diffuse alopecia. Severe, painful PPK started around 6 months of age, and impeded normal ambulation. Initial treatment with the oral mTOR inhibitor sirolimus (rapamycin) 0.8 mg/m² twice daily, titrated to a trough concentration of 10–15 ng/mL, showed rapid improvements. After 5 months, erythema had resolved, periorificial hyperkeratotic plaques were substantially reduced, and pain and pruritus scores showed significant improvement. While no adverse effects were noted, PPK continued to progress. Sirolimus was discontinued after 9 months and subsequent treatment with the oral EGFR tyrosine kinase inhibitor *erlotinib* 2 mg/kg/day was started, yielding rapid improvement of PPK and pain scores, which was maintained over the 6-month treatment period. No short-term adverse effects were reported.

Two other male patients with a *TRPV3* missense variant and painful, diffuse PPK without periorificial erythrokeratoderma were initially treated with oral acitretin 10–15 mg daily for >4 years with limited improvement of PPK. Treatment with *erlotinib* 2 mg/kg/day yielded rapid improvement within days, which could be sustained, with almost complete resolution in one of the children.

Third-Line Therapies

• PUVA	E
• H ₁ -antihistamines	E
• mTOR inhibitors	E

Erythrokeratoderma variabilis: successful treatment with retinoid plus psoralen and ultraviolet A therapy. Yüksek J, Sezer E, Köseoglu D, et al. *Jpn Dermatol Assoc J* 2010; 725–7.

A female with EKV was first treated with 10 mg/day acitretin. After 1 week, PUVA therapy was added with 0.5 J/cm² UVA twice weekly, with incremental increases by 0.5 J/cm² UVA up to a cumulative dose of 129 J/cm². A significant improvement of hyperkeratosis and erythema was achieved after 3 months; then PUVA was stopped, and acitretin was continued for up to 9 months. Dry lips were the only side effect observed. Follow-up after discontinued Re-PUVA was not reported.

Case of erythrokeratoderma variabilis successfully treated with narrow band ultraviolet B. Okuda K, Nishida E, Tori K, et al. *J Dermatol* 2020; 47(1): e30–1.

Topical treatment of a 20-year-old female with EKVP due to a pathogenic *GJB3* variant with urea cream and steroid ointment was not effective. NB-UVB therapy with a starting dose of 0.3 J/cm² was increased by 20% each week to a maximum dose of 1.18 J/cm². At the 27th session, the EK plaques had regressed from 72% to 13% of involved surface on the lower extremities. A younger sibling with milder involvement was also treated with NB-UVB and hyperkeratotic lesions gradually resolved.

Erythromelalgia

Cato Mørk, Knut Kvernebo

Erythromelalgia (*erythros* – redness; *melos* – extremity; *algos* – pain) is an uncommon neurovascular disorder characterized by redness, increased skin temperature, and pain that usually occurs in the extremities. Pain is aggravated by warming and relieved by cooling. Symptoms and findings are usually intermittent and often missing during examination. Between attacks acrocyanosis, paresthesia, and Raynaud phenomenon may occur. Severity of symptoms varies from mild discomfort (most common) to disabling pain and gangrene. The diagnosis is often missed in cases with mild symptoms, whereas severe erythromelalgia is a rare condition.

Erythromelalgia can be a primary condition, or secondary to a primary microvascular event, or due to a primary autonomic nervous dysfunction. Regardless of etiology, the final common pathway of the pathogenesis includes maldistribution of skin perfusion with increased deep plexus thermoregulatory perfusion, and a relative lack of papillary nutritive perfusion with a corresponding degree of skin hypoxia.

A minority of erythromelalgia patients have a family history with genetic variants within the *SCN9A* gene encoding for the $Na_v1.7$, a voltage-gated sodium channel located on nerve endings. A gain-of-function mutation in this sodium channel may lead to aberrant sensory neuronal activity and extreme pain, particularly in response to heat. In our patient cohort of 35 patients with primary EM, 14.3% had potentially pathogenetic *SCN9A* variants.

MANAGEMENT STRATEGY

Before starting treatment, the patient's condition should be classified according to whether it is primary or secondary, the etiology

of secondary cases, and its severity. Erythromelalgia may be secondary to underlying diseases, such as myeloproliferative, connective tissue, cardiovascular, infectious, and neurologic diseases, diabetes mellitus, vasculitis, and neoplasia. If present, a primary condition should be optimally treated. There are many reports of remission after treatment of myeloproliferative disorders. Drug-induced erythromelalgia has been reported secondary to substances that may alter vasomotor tone, such as calcium channel blockers, bromocriptine, norepinephrine (noradrenaline), pergolide, ticlopidine, ciclosporin, iodine contrast, and mushroom and mercury poisoning.

All patients benefit from local *skin cooling* (applying cold towels or wet sand, walking on cold floors or even in the snow, air-conditioned rooms, or immersion in cooled water) and from elevation of the affected limb. Aggressive cooling may cause injury and worsen the erythromelalgia. Comfortable shoes to relieve pressure over the soles can help. Aggravating factors such as warmth, exercise, dependency of the extremity, tight shoes and gloves, and alcohol intake should be avoided.

No single medication or other treatment modality has been found to be universally helpful. Spontaneous remissions have occurred without treatment. There is a marked variation in therapeutic responses. Few controlled clinical trials have been published. The main reason may be the low prevalence, the heterogeneity of patients, and the lack of laboratory diagnostic methods.

Analgesics, including opiate analgesics, often have limited effect. Numerous drugs have been used with varying success. A few patients become free of symptoms with *acetylsalicylic acid*. Case reports or series of patients have shown beneficial effect with *vasodilators* (prostaglandin E_1 /prostacyclin or analogs, sodium nitroprusside, naftidrofuryl, calcium channel blockers). Other drugs that may be of benefit are *sodium channel blockers*, *antidepressants*, and *anticonvulsants*.

Numerous treatment alternatives based on case reports have been presented in the literature, such as topical *amitriptyline/ketamine*, *lidocaine*, *capsaicin*, *midodrine*, and *nitroglycerin*. Anecdotally, *ketanserin*, *methysergide*, *pizotifen*, β -blockers, *cycloheptadine* or other *antihistamines*, *carbamazepine*, *clonazepam*, *corticosteroids* or other *immunosuppressants*, *pentoxifylline*, *phenoxybenzamine*, *opiates*, *prazosin*, and *pregabalin* have been presented as effective. *Hyperbaric oxygen* treatment, *spinal cord stimulation*, *thalamic stimulation*, and *epidural blocks* have also been proposed. *Sympathectomy* has been beneficial in some patients and in other patients caused worsening of symptoms. Treatment modalities such as *hypnosis*, *biofeedback*, and learning to avoid triggers can be beneficial for coping with pain. A survey of members of The Erythromelalgia Association (TEA, erythromelalgia.org) shows that more than 50 therapeutic regimens have been tried out. TEA is a non-profit organization that may be helpful in providing information, awareness, and support.

Specific Investigations

- Full blood count with white cell differential count
- Serum chemistry, including blood sugar
- Antinuclear antibody and relevant rheumatologic tests
- Skin biopsy may be considered

Nonspecific capillary proliferation and vasculopathy indicate skin hypoxia in erythromelalgia. Kalgard OM, Clausen OP, Mellbye OJ, et al. Arch Dermatol 2011; 147: 309–14.

Platelet-mediated erythromelalgic, cerebral, ocular and coronary microvascular ischemic and thrombotic manifestations in patients with essential thrombocythemia and polycythemia vera: a distinct aspirin-responsive and Coumadin-resistant arterial thrombophilia. Michiels JJ, Berneman Z, Schroyens W, et al. Platelets 2006; 17: 528–44.

Erythromelalgia – a thrombotic complication in chronic myeloproliferative disorders. Tarach JS, Nowicka-Tarach BM, Matuszek B, et al. Med Sci Monit 2000; 6: 204–8.

Erythromelalgia is seen secondary to platelet aggregation and peripheral microvascular occlusion in myeloproliferative disorders and, untreated, may progress to painful acrocyanosis and even peripheral gangrene. Remission is observed after treatment of the myeloproliferative disorder.

Review of primary and secondary erythromelalgia. Mann N, King T, Murphy R. Clin Exp Dermatol 2019; 44: 477–82.

A brief, excellent overview of the diagnosis and management of primary and secondary forms of erythromelalgia.

First-Line Therapies	
• Treatment of underlying disease	C
• Aspirin	D
• Prostaglandins/prostacyclin or oral analogs	A

Treatment of secondary erythromelalgia addresses treatment of the primary diseases or conditions, and elimination of pharmacologic substances. A beneficial effect on the symptoms of erythromelalgia after successful treatment or elimination of the primary condition indicates a causal relationship.

Aspirin-responsive, migraine-like transient cerebral and ocular ischemic attacks and erythromelalgia in JAK2-positive essential thrombocythemia and polycythemia vera. Michiels JJ, Berneman Z, Gadisseur A, et al. Acta Hematol 2015; 133: 56–63.

Aspirin 250–500 mg daily or less may completely abolish the symptoms in erythromelalgia secondary to myeloproliferative conditions. The response is probably due to the antiplatelet effect. A reduction of platelet numbers by cytostatic treatment may also lead to relief.

The Erythromelalgia Association Survey 2003. www.erythromelalgia.org.

In a survey, 128 respondents had used aspirin (80–250 mg daily): 4 reported complete, 17 moderate, and 22 minimal relief; 78 had no improvement; and 6 reported worsening of their symptoms.

Aspirin is the first-line therapy if without contraindications to its use.

Erythromelalgia – A condition caused by microvascular arteriovenous shunting. Kvernebo K. Vasa 1998; 27: 3–39.

Based on the hypothesis of arteriovenous shunting, prostaglandin E₁ (PGE₁) and prostacyclin were tried as an intravenous infusion to enhance nutritive skin perfusion in severe erythromelalgia. In 9 of 10 patients, PGE₁ given as a continuous infusion for 3 days, starting with 6 ng/kg/min, then 10 ng/kg/min, and finally 12 ng/kg/min, induced remission from 3 months to 2 years. Two children were cured (observation time after treatment >25 years).

Prostacyclin reduces symptoms and sympathetic dysfunction in erythromelalgia in a double-blind randomized pilot

study. Kalgaard OM, Mørk C, Kvernebo K. Acta Derm Venereol 2003; 83: 442–4.

Significant reduction in symptoms and sympathetic dysfunction were demonstrated in eight patients treated with prostacyclin infusion compared with four patients with placebo infusion.

The prostaglandin E1 analog misoprostol reduces symptoms and microvascular arteriovenous shunting in erythromelalgia – a double-blind, crossover, placebo-compared study. Mørk C, Salerud EG, Asker CL, et al. J Invest Dermatol 2004; 122: 587–93.

Oral misoprostol (0.4–0.8 mg/day) reduced symptoms significantly more than placebo. Misoprostol is recommended as a first-line treatment, although many patients do not respond.

Second-Line Therapies	
• Topical: amitriptyline/ketamine, midodrine, capsaicin, lidocaine	C
• Sodium channel blockers (lidocaine, mexiletine, bupivacaine, XEN402)	C, D
• Pregabalin, gabapentin	D
• Antidepressants	D

Topical amitriptyline combined with ketamine for the treatment of erythromelalgia: a retrospective study of 36 patients at Mayo Clinic. Poterucha TJ, Weiss WT, Warndahl RA, et al. J Drugs Dermatol 2013; 12: 308–10.

The authors reported 75% improvement in pain with topical application of a compounded amitriptyline–ketamine formulation. The medication was well tolerated.

Topically applied midodrine, 0.2%, an α 1-agonist, for the treatment of erythromelalgia. Davies MD, Morr CS, Warndahl RA, et al. JAMA Dermatol 2015; 151: 1025–6.

Of 12 patients, 11 improved, with only two of the 12 having adverse reactions (one gastrointestinal discomfort, and the other displaying an increase in blood pressure).

The use of capsaicin cream in a case of erythromelalgia. Muhiddin KA, Gallen IW, Harries S, et al. Postgrad Med J 1994; 70: 841–3.

A 68-year-old woman with erythromelalgia responded to a twice-daily application of capsaicin cream 0.025% within 48 hours.

Lidocaine patch for pain of erythromelalgia: follow-up of 34 patients. Davis MD, Sandroni P. Arch Dermatol 2005; 141: 1320–1.

Anesthetic agents (lidocaine, bupivacaine, mexiletine) that non-selectively partially block the sodium channels may be used topically, intravenously, orally, epidurally, or intrathecally. A 90% reduction in pain was demonstrated with lidocaine IV infusion on a trial basis, but it has a narrow therapeutic window with significant cardiac, cognitive, and motor side effects. A 5% lidocaine patch for 12 hours/day was found helpful as first-line and adjunctive treatment of severely affected patients with erythromelalgia: 16 patients had no improvement, but 18 patients had a 5–90% improvement in pain score.

Treatment of Na_v1.7-mediated pain in inherited erythromelalgia using novel sodium channel blocker. Goldberg YP, Price N, Namdari R, et al. Pain 2012; 153: 80–5.

An exploratory, randomized, double-blind, two-period, crossover pilot study in four *SCN9A* mutation-proven inherited erythromelalgia patients using the orally administered $\text{Na}_v1.7$ antagonist XEN402 demonstrated alleviation of pain.

Pharmacological reversal of a pain phenotype in iPSC-derived sensory neurons and patients with inherited erythromelalgia. Cao L, McDonnell A, Nitzsche A, et al. *Sci Transl Med* 2016; 8: 335–56.

The results for selective sodium channel blockers are promising for patients with variants in the *SCN9A* gene. This is not yet a practical alternative because of limited availability of genetic testing and access to these agents in clinical practice.

Mexiletine as a treatment for primary erythromelalgia: normalization of biophysical properties of mutant L858F $\text{Na}_v1.7$ sodium channels. Gregg R, Cox JJ, Bennett DL, et al. *Br J Pharmacol* 2014; 171: 2255–63.

Mexiletine, an orally available form of lidocaine, has a normalizing effect on the pathologic gating properties of the L858F gain-of-function mutation in $\text{Na}_v1.7$; however, similar to lidocaine, there is variable clinical response

Response of primary erythromelalgia to pregabalin therapy. Kalava K, Roberts C, Adair JD, et al. *J Clin Rheumatol* 2013; 19: 284–5.

Using pregabalin at a dose of 100 mg three times a day, improvement was noted within 6 weeks in a 14-year-old girl.

Pediatric erythromelalgia: a retrospective review of 32 cases evaluated at Mayo Clinic over a 37-year period. Cook-Norris RH, Tollefson MM, Cruz-Inigo AD, et al. *J Am Acad Dermatol* 2012; 66: 416–23.

Earlier treatment with gabapentin (2/6) and antidepressants (4/10) was reported as very or somewhat helpful. Both medications are started at a low dose and titrated to effect.

Treatment of familial erythromelalgia with venlafaxine. Firmin D, Roduedas AM, Greco M, et al. *J Eur Acad Dermatol Venerol* 2007; 21: 836–7.

Venlafaxine helped the mother but not her two sons with erythromelalgia.

Third-Line Therapies

• Sodium nitroprusside	D
• Calcium channel blockers	C
• Magnesium	D

Erythromelalgia – a condition caused by microvascular arteriovenous shunting. Kvernebo K. *Vasa* 1998; 27: 3–39.

Sodium nitroprusside intravenously for 7 days in increasing doses (1, 3, and 5 mcg/kg/min) was successful in two patients with severe acute-onset erythromelalgia. The effect was accompanied by normalization of skin perfusion and transcutaneous oximetry.

Erythromelalgia: new theories and new therapies. Cohen JS. *J Am Acad Dermatol* 2000; 43: 841–7.

Various calcium channel blockers (amlodipine, nifedipine, diltiazem) may be helpful in approximately 25% of patients with erythromelalgia ($n=43$). As they can cause or exacerbate symptoms, they should be used with caution and with the use of short-acting drugs initially.

They are frequently used, but documentation for beneficial effect is sparse (6 of 14 patients). Their mechanism of action may be smooth muscle relaxation and reduced vascular responses elicited by β_2 -adrenoceptors.

High-dose oral magnesium treatment of chronic, intractable erythromelalgia. Cohen JS. *Ann Pharmacother* 2002; 36: 255–60.

Magnesium is a naturally occurring calcium channel blocker. Eight of 13 patients reported improvement, four no response, and one deterioration using magnesium in various doses and forms, starting at 350–400 mg/day and titrated to effect or limited by diarrhea as an adverse effect.

Erythropoietic protoporphyria

Maureen B. Poh-Fitzpatrick

In this metabolic disorder, a genetically determined ferrochelatase enzyme deficiency in bone marrow erythroid cells causes excessive protoporphyrin levels in erythrocytes, plasma, liver, bile, and feces. Protoporphyrin is a photoactive heme synthesis intermediary. In the skin, its exposure to long-wave ultraviolet (UV) or visible-light radiation can elicit oxygen-dependent acute cutaneous phototoxicity. Protoporphyrin undergoes hepatobiliary excretion, facilitating cholelithiasis. Protoporphyrin hepatotoxicity may progress to irreversible liver failure. Hypochromic microcytic anemia, when present, is typically mild and infrequently requires treatment. A rare, phenotypically similar disorder, X-linked dominant protoporphyria (XLP), caused by gain-of-function mutations in the erythroid-specific 5-aminolevulinic acid synthase gene, has a larger ratio of erythrocyte zinc-protoporphyrin to metal-free protoporphyrin than does erythropoietic protoporphyria (EPP). It is generally amenable to the same therapies.

MANAGEMENT STRATEGY

Protoporphyrin photosensitivity typically requires *sun avoidance* (lifestyle changes, protective clothing, physical barriers), which may lead to vitamin D deficiency. *Topical sunscreens* containing *titanium dioxide*, *zinc oxide*, *iron oxide*, or *dihydroxyacetone* block or filter long-wave ultraviolet (UV) and visible-light spectra but offer limited relief. Patients sensitive to light from computer, television, or phone screens or room lighting may benefit from eliminating or filtering offending devices (https://en.wikipedia.org/wiki/Erythropoietic_protoporphyria).

Epidermal melanization and hyperplasia achieved with *ultraviolet B (UVB) phototherapy*, or an *α-melanocyte-stimulating hormone analog (afamelanotide)*, can increase sunlight tolerance. Oral agents believed to photoprotect by quenching excited oxygen species include *β-carotene*, *cysteine*, *vitamin E*, and *vitamin C*. *Antihistamines*

may attenuate phototoxic flaring. Gallstones are managed *surgically*. Exacerbators of protoporphyrin-induced hepatotoxicity (alcohol, cholestatic drugs [including medicinal estrogens], dietary carbohydrate restriction) are best avoided. *Vaccination* against hepatitis A and B is recommended. Deteriorating liver function is only sporadically reversible by *enteric sorbents* (*cholestyramine*, *activated charcoal*) that interrupt enterohepatic porphyrin circulation, *bile acids* (to stimulate biliary protoporphyrin secretion), *blood transfusion or exchange*, *hematin infusion*, *glucose loading* (to retard endogenous porphyrinogenesis), *iron* (to increase protoporphyrin conversion to heme), or various combinations thereof. *Cimetidine* is postulated to inhibit porphyrinogenesis. End-stage liver disease warrants *liver transplantation*, aided by measures to reduce preoperative, intraoperative, and postoperative porphyrin levels (*exchange transfusion*, *hematin infusion*, *plasmapheresis*, *vitamin E*). Operating room lamps should be filtered to exclude wavelengths damaging to porphyrin-photosensitized skin and internal organs. *Hematopoietic cell transplantation* has been curative in highly selected cases and is optimal prevention for protoporphyrin hepatopathy in native or transplanted livers.

Specific Investigations

- Porphyrin analyses in erythrocytes (including metal-free: zinc-protoporphyrin ratio), serum or plasma, urine, feces
- Hematologic profile, iron studies if anemic
- Liver function profile, liver imaging, liver biopsy as clinically indicated
- Mutation analysis (for diagnostic confirmation and family counseling)
- Vitamin D assessment, bone density scan

Liver failure occurs in <5% of all cases. Because urine is typically free of excess porphyrins in uncomplicated protoporphyria, surveillance for coproporphyrinuria may discover patients with asymptomatic hepatic dysfunction.

Erythropoietic protoporphyria. Lecha M, Puy H, Deybach JC. Orphanet J Rare Dis 2009. doi: 10.1186/1750-1172-4-19.

Erythropoietic protoporphyria and X-linked protoporphyria: pathophysiology, genetics, clinical manifestations, and management. Balwani M. Mol Genet Metab 2019. doi: org/10.1016/j.ymgme.2019.01.020 [Epub ahead of print].

Protoporphyria overviews.

First-Line Therapies

• Avoidance of sunlight and harmful radiation from artificial light sources	
• Topical sunscreens, physical barriers or filters	C
• β-carotene	B
• Afamelanotide	A
• Vitamin D and calcium	D

Efficiency of opaque photoprotective agents in the visible light range. Kaye ET, Levin JA, Blank IH, et al. Arch Dermatol 1991; 127: 351–5.

Efficacy and cosmetic quality of sunscreens containing zinc oxide, titanium dioxide, and iron oxide.

Erythropoietic protoporphyria: IV. Protection from sunlight. Fusaro RM, Runge WJ. Br Med J 1970; 1: 730–1.

Seven patients had prolonged sunlight tolerance after applying a 3% dihydroxyacetone and 0.13% lawsone skin cream causing stratum corneum browning.

Beta-carotene therapy for erythropoietic protoporphyria and other photosensitivity diseases. Mathews-Roth MM, Pathak MA, Fitzpatrick TB, et al. Arch Dermatol 1977; 113: 1229–32.

Of 133 patients with EPP, 84% had a threefold increase in sunlight tolerance after ingesting pharmaceutical-grade β -carotene now available without prescription (Lumitene, Tishcon Corp.).

Doses producing serum levels of ≈ 800 mcg/dL (children: 30–120 mg/day, adults: 120–300 mg/day, in 2–3 mealtime doses) should be started 4–6 weeks before seasonal symptoms are anticipated. Efficacy varies and is often nil. Contraindicated in smokers due to increased lung cancer among heavy smokers treated with β -carotene in cancer prevention trials.

Long-term observational study of afamelanotide in 115 patients with erythropoietic protoporphyria. Biolcati G, Marchesini E, Sorge F, et al. Br J Dermatol 2015; 172: 1601–12.

Afamelanotide for erythropoietic protoporphyria. Langendonk JG, Balwani M, Anderson KE, et al. N Engl J Med 2015; 373: 48–59.

Afamelanotide increases skin melanization and may have other beneficial effects. Clinical trials of a subcutaneously implantable form have involved ≈ 300 protoporphyria patients worldwide. Approved for prevention of phototoxicity in adults with EPP by the European Medicines Agency (2014), and by the US Food and Drug Administration (2019).

Osteoporosis in patients with erythropoietic protoporphyria. Biewenga M, Matawlie RHS, Friesema ECF, et al. Br J Dermatol 2017; 177: 1693–8.

Among 44 EPP patients, 50% had low plasma vitamin D and 59% had low bone mineral density. Osteopenia/osteoporosis mitigation by following fracture-prevention measures including vitamin D and calcium supplementation and increased bone-strengthening physical activity is recommended.

Second-Line Therapy

- Phototherapy (narrowband UVB)

D

Narrow-band (TL-01) UVB phototherapy: an effective preventative treatment for the photodermatoses. Collins P, Ferguson J. Br J Dermatol 1995; 132: 956–63.

Six EPP patients had increased sunlight tolerance after serial narrowband UVB treatments.

Third-Line Therapies

• Cysteine	A
• Antihistamines (including cimetidine)	D, (E)
• Vitamin E	D
• Vitamin C	A
• Iron	D
• Cholestyramine, activated charcoal	D
• Blood transfusion or exchange	D
• Hematin infusion	D
• Plasmapheresis	D
• Bile acids	D
• Liver transplantation	B
• Hematopoietic cell transplantation	D

Long-term treatment of erythropoietic protoporphyria with cysteine. Mathews-Roth MM, Rosner B. Photodermatol Photoimmunol Photomed 2002; 18: 307–9.

Forty-seven patients received cysteine 500 mg twice daily in this phase III 3-year trial. Patient history and light exposure diaries were kept; some patients were phototested. Cysteine significantly increased light tolerance subjectively and objectively.

Inhibition of photosensitivity in erythropoietic protoporphyria with terfenadine. Farr PM, Diffey BL, Matthews JNS. Br J Dermatol 1990; 122: 809–15.

Terfenadine 60–120 mg twice daily for 48 days significantly reduced the flare surrounding, but not the erythema within, blue-light phototest sites on seven subjects, compared with pretreatment reactions.

Antihistamines have provided limited relief in clinical practice.

Cimetidine reduces erythrocyte protoporphyrin in erythropoietic protoporphyria. Yamamoto S, Hirano Y, Horie Y. Am J Gastroenterol 1993; 88: 1465–6.

This H_2 receptor antagonist (800 mg four times daily orally) was given to a patient with protoporphyric liver disease. Erythrocyte protoporphyrin fell from 16,000 to 11,000 mcg/dL during treatment. Inhibition of heme synthesis by cimetidine was postulated.

Only three porphyrin measurements were obtained: before and immediately after 2 weeks of cimetidine and 2 weeks after discontinuation.

Novel treatment using cimetidine for erythropoietic protoporphyria in children. Tu JH, Sheu SL, Teng JM. JAMA Dermatol 2016; 152: 1258–61.

Improved photosensitivity, erythrocyte protoporphyrins, and hepatic transaminases reported after cimetidine treatment of three children. Confirmatory studies needed.

A case of erythropoietic protoporphyria with liver cirrhosis suggesting a therapeutic value of supplementation with alpha-tocopherol. Komatsu H, Ishii K, Imamura K, et al. Hepatol Res 2000; 18: 298–309.

A patient with severe protoporphyric hepatopathy received intravenous vitamin E 500 IU/day. Erythrocyte protoporphyrins decreased; liver function improved. Sixteen weeks later, full clinical and biochemical recovery was noted.

Vitamin E has been used sporadically in protoporphyria, usually as adjunctive therapy.

A double-blind, placebo-controlled, crossover trial of oral vitamin C in erythropoietic protoporphyria. Boffa MJ, Ead RD, Reed P, et al. Photodermatol Photoimmunol Photomed 1996; 12: 27–30.

Vitamin C 1 g/day orally for 4 weeks was subjectively assessed by 9 of 12 patients to be associated with less photosensitivity than placebo, but the data did not reach significance.

Antioxidants such as vitamins C and E are postulated to quench porphyrin-generated oxyradicals in vivo.

Iron therapy for hepatic dysfunction in erythropoietic protoporphyria. Gordeuk VR, Brittenham GM, Hawkins CW, et al. Ann Intern Med 1986; 105: 27–31.

Carbonyl iron 400–4000 mg/day orally was given for 15 weeks to a patient with protoporphyria, iron-deficiency anemia, and liver dysfunction. Erythrocyte porphyrins fell, photosensitivity improved, and liver function normalized.

Oral ferrous sulfate 300 mg/day was given when liver function and porphyrin levels worsened again. Liver function again normalized and remained stable for several years.

Symptomatic response of erythropoietic protoporphyria to iron supplementation. Holme SA, Thomas CL, Whatley SD, Bentley AV, Badminton MN. *J Am Acad Dermatol* 2007; 56: 1070–2.

A patient reported greater sunlight tolerance while taking oral ferrous sulfate 200 mg twice daily.

Erythropoietic protoporphyria and iron therapy. McClements BM, Bingham A, Callendar ME, et al. *Br J Dermatol* 1990; 122: 423–4.

Oral ferrous fumarate 580 mg/day was followed by florid photosensitivity in a patient previously tolerant of iron supplements. Abnormal liver enzymes improved and erythrocyte protoporphyrin diminished after iron discontinuation.

In ferrochelatase-deficient protoporphyria patients, ALAS2 expression is enhanced and erythrocytic protoporphyrin concentration correlates with iron availability. Barman-Aksözen J, Minder EI, Schubiger C, et al. *Blood Cells Mol Dis* 2015; 54: 71–7.

It is postulated that iron deficiency may limit protoporphyrin excess in EPP and that iron should be repleted only when symptoms of iron deficiency are incapacitating.

Iron supplementation in EPP/XLP needs more study; some iron-treated protoporphyria patients improved while others worsened; some who improved may have had unrecognized XLP.

X-linked protoporphyria: iron supplementation improves protoporphyrin overload, liver damage and anaemia. Landefeld C, Kentouche K, Gruhn B, et al. *B J Haematol* 2016; 173: 482–4.

Fecal protoporphyrin excretion in erythropoietic protoporphyria: effect of cholestyramine and bile acid feeding. McCullough AJ, Barron D, Mullen KD, et al. *Gastroenterology* 1988; 94: 177–81.

Oral cholestyramine 12 g daily, but not bile acids 300–900 mg, increased fecal protoporphyrin excretion threefold in an EPP patient with hepatic dysfunction. Liver function and photosensitivity improved after 1 year of cholestyramine.

Bile acid ingestion was associated with improved liver function and erythrocyte porphyrin levels in another patient who eventually succumbed to liver failure. Efficacy remains uncertain, but bile acids in conjunction with an enteric sorbent are rational therapy in selected cases.

Liver failure in protoporphyria: long-term treatment with oral charcoal. Gorchein A, Foster GR. *Hepatology* 1999; 29: 995–6.

A patient with deteriorating hepatic function ingesting activated charcoal 10–12.5 g four times daily for 2 years exhibited improved liver function; blood porphyrin and photosensitivity diminished. Other treatments included blood transfusions, vitamin supplements, amiloride, ranitidine, and lactulose, so it is difficult to assess their relative merits.

Liver disease in erythropoietic protoporphyria: insights and implications for management. Anstey AV, Hift RJ. *Gut* 2007; 56: 1009–18.

A detailed review of protoporphyric hepatopathy with recommendations for monitoring and treatment.

Liver transplantation for erythropoietic protoporphyria liver disease. McGuire BM, Bonkovsky HL, Carithers RL, et al. *Liver Transpl* 2005; 11: 1590–6.

Experience with 20 patients receiving liver transplants in the United States from 1999 to 2004 is reviewed, including preoperative use of hematin, with or without plasmapheresis.

Liver transplantation for erythropoietic protoporphyria in Europe. Wahlin S, Stal P, Adam R, et al. *Liver Transpl* 2011; 17: 1021–6.

A European review of 35 liver transplants performed during 1983–2008. Hematopoietic stem cell transplantation was performed in three patients to prevent graft loss due to disease recurrence. Offering curative stem cell transplantation to patients at high risk for liver failure to forestall transplantation is suggested.

Perioperative measures during liver transplantation for erythropoietic protoporphyria. Meerman L, Verwer R, Sloof MJH, et al. *Transplantation* 1994; 57: 155–8.

Protection from phototoxic injury during surgery and endoscopy in erythropoietic protoporphyria. Wahlin S, Srikanthan N, Hamre B, et al. *Liver Transplantation* 2008; 14: 1340–6.

Recommendations for shielding operating room lamps for patients with protoporphyria.

The value of intravenous heme-albumin and plasmapheresis in reducing postoperative complications of orthotopic liver transplantation for erythropoietic protoporphyria. Reichheld JH, Katz E, Banner BF, et al. *Transplantation* 1999; 67: 922–8.

Three months of heme infusions (4 g daily to weekly), high-carbohydrate diet (300 mg/day), intravenous glucose, ursodeoxycholic acid (900 mg/day orally), and cholestyramine (10 g thrice daily orally) initially improved severe liver dysfunction in a patient who then deteriorated and required urgent transplantation. Intensive heme infusions (daily for 18 days), plasmapheresis (exchanges of 1–1.5 × total plasma volume performed 12 times over 19 days), and blood transfusions (14 units packed cells over 19 days) reduced blood porphyrins before successful transplantation was performed in an illumination-filtered environment to exclude 300–480 nm wavelengths.

A barrage of medical therapy is typical in protoporphyric crises, when it is rational to consider any treatments that might reverse deterioration or contribute to successful transplantation.

Treatment of recurrent allograft dysfunction with intravenous hematin after liver transplantation for erythropoietic protoporphyria. Dellon ES, Szczepiorkowski ZM, Dzik WH, et al. *Transplantation* 2002; 73: 911–5.

Hematin given intermittently for 2 years after protoporphyric hepatopathy recurred 700 days posttransplantation aided achievement and maintenance of disease remission in an allograft.

Management of patients with erythropoietic protoporphyria-related progressive liver disease. Ardalan ZS, Chandran S, Vasudevan A, et al. *Liver Transpl* 2019; 25: 1620–33.

An algorithm for monitoring early protoporphyria and managing progressive protoporphyric liver disease, and rationales for treatment decisions and timing in the extremely complex latter situation, including detailed considerations around liver transplantation and/or allogeneic stem cell transplantation, are presented. A review of relevant literature supports recommending treating iron deficiency in all XLP patients but only in severely anemic EPP patients.

Erythropoietic protoporphyria: altered phenotype after bone marrow transplantation for myelogenous leukemia in a patient heteroallelic for ferrochelatase gene

mutations. Poh-Fitzpatrick MB, Wang X, Anderson K, et al. *J Am Acad Dermatol* 2002; 46: 861–6.

A symptomatic woman harboring two ferrochelatase mutations developed leukemia. Bone marrow transplantation from a mildly affected sibling with only one mutation and minimally elevated blood protoporphyrin resulted in marked reduction of the recipient's protoporphyrins and photosensitivity, as well as leukemia remission.

Sequential liver and bone marrow transplantation for treatment of erythropoietic protoporphyria. Rand ER, Bunin ER, Cochran W, et al. *Pediatrics* 2006; 118: e1896–9.

Bone marrow transplanted 6 months after liver transplantation corrected the severe phenotype of a 14-year-old boy and halted further protoporphyrin-induced liver graft damage.

Curative bone marrow transplantation in erythropoietic protoporphyria after reversal of severe cholestasis. Wahlin S, Aschan J, Björnstedt M, et al. *J Hepatol* 2007; 46: 174–9.

Eighty days of medical management normalized liver biochemistry and improved histology in a man who then received a bone marrow transplant. Ten months later, liver and porphyrin tests were normal; no photosensitivity was reported.

Extramammary Paget disease

Caroline R. Morris, Eva A. Hurst

Extramammary Paget disease (EMPD) is a rare malignancy, first described by Crocker in 1889, who reported lesions on the scrotum and penis that were histologically similar to mammary Paget disease. EMPD most commonly occurs on apocrine rich skin of individuals between the ages of 50 and 80 years, with a peak incidence at age 65. It often presents as an erythematous plaque and is commonly misdiagnosed as an inflammatory condition resulting in treatment delays. Controversy exists over the pathogenesis of EMPD, but it is favored to arise as an intraepidermal neoplasm of glandular origin and is considered primary EMPD. More recently, it has been proposed that Toker cells, present in vulvar epidermis, are benign precursors of Paget cells. There may be a small subset called secondary EMPD, which represents intraepithelial spread of malignant adenocarcinoma cells from an underlying malignancy.

MANAGEMENT STRATEGY

Biopsy should be performed immediately upon suspicion of EMPD. Histologically, EMPD is characterized by intraepidermal proliferation of Paget cells (PCs), which have large vesicular nuclei and abundant pale cytoplasm. Extension into adnexal structures is common and may be misinterpreted as dermal invasion. In addition to hematoxylin and eosin, diagnosis is confirmed by utilizing a panel of immunoperoxidase studies including cytokeratin 7, carcinoembryonic antigen (CEA), epithelial membrane antibody, HER-2/neu, and gross cystic disease fluid protein-15. These can be used to differentiate EMPD from pagetoid variants of squamous cell carcinoma in situ and melanoma in situ. The expression of tissue-specific antigens within PCs appears to correlate with that of the underlying malignancy: prostatic antigen, uroplakins, and transcription factor CDX-2 in prostatic, urothelial, and intestinal adenocarcinomas, respectively. However, limitations to the use of tissue-specific markers necessitates careful clinicopathologic correlation.

Patients diagnosed with EMPD must be risk stratified. Ambiguity exists within the literature regarding risk for associated malignancies;

an associated underlying internal cancer has been reported in 7–40% of patients with EMPD. Most reported cases of internal malignancy are in close proximity to the cutaneous EMPD. Therefore, a directed internal malignancy evaluation is appropriate. Dependent on gender, appropriate studies to consider include mammography, Papanicolaou smear, pelvic ultrasonography, cystoscopy, colonoscopy, and computed tomography of the abdomen and pelvis.

The treatment of EMPD has long been *surgical excision* with adjuvant therapies in select cases. *Mohs micrographic surgery* (MMS) has emerged as a promising therapeutic option as it offers complete evaluation of tissue margin, maximal tissue preservation, and the lowest recurrence rates. However, it is limited by ill-defined clinical margins, microscopic extension of tumor cells, multifocal disease, and sometimes lesion size given the outpatient nature of MMS.

Close clinical follow-up of patients with EMPD is recommended due to recurrence risk. Biannual evaluation for at least 3 years, then annually for at least 10 years for non-invasive EMPD, has been suggested. In invasive EMPD or cases associated with a distant, underlying tumor, follow-up should be more frequent with a low threshold to biopsy any suspicious skin lesion. In general, patients with EMPD have a good prognosis with a 5-year overall survival of 75–95%. Dermal invasive EMPD is more frequently associated with regional lymph node metastasis and poor prognosis.

Specific Investigations

- Skin biopsy
- Full-body skin examination and lymph node evaluation
- Age-appropriate cancer screening and directed internal malignancy evaluation
- Sentinel lymph node biopsy in patients with dermal and/or lymphatic extension

Extramammary Paget's disease: a review of the literature – Part I: history, epidemiology, pathogenesis, presentation, histopathology, and diagnostic work-up. Morris C, Hurst E. *Dermatol Surg* 2020; 46: 151–8.

Systematic review of the literature. Patients with EMPD must be risk stratified and evaluated for an underlying internal malignancy. Sentinel lymph node biopsy is recommended in patients with invasive EMPD. The standard of treatment is surgery with new data suggesting that MMS may have superior clinical outcomes with lower recurrence rates.

Extramammary Paget's disease: treatment, prognostic factors and outcome in 76 patients. Hatta N, Yamada M, Hirano T, et al. *Br J Dermatol* 2008; 158: 313–8.

Retrospective review of 76 patients with EMPD. Sixty-six patients underwent curative surgical excision: five developed local recurrence. Surgical margin was not correlated with local recurrence. Thirteen patients developed systemic metastases; 10 died. Nodules in the primary tumor, clinical lymph node swelling, elevated CEA, depth of tumor invasion, and lymph node metastasis were significant prognostic factors. Depth of tumor invasion and CEA level were associated with reduced survival.

First-Line Therapies

• Wide local excision, with or without lymph node dissection	B
• Frozen section–guided wide local excision	B
• Mohs micrographic surgery	B

The role of sentinel lymph node biopsy in the management of invasive EMPD: multi-center, retrospective study of 151 patients. Fujisawa Y, Yoshino K, Kiyohara Y, et al. *J Dermatol Sci* 2015; 79: 38–42.

Retrospective review of 151 patients with invasive EMPD. The rate of lymph node (LN) metastasis was 80% in patients with lymphadenopathy compared to 15% without. Lymphadenopathy was associated with advanced primary tumor (nodule, thicker tumor, deeper invasion, presence of lymphovascular invasion). Survival was not affected by sentinel LN status even when an advanced primary tumor was present. SLNB with subsequent LN dissection may improve survival of patients with early stage lymphatic spread.

Indications for lymph node dissection in the treatment of EMPD. Tsutsumida A, Yamamoto Y, Minakawa H, et al. *Dermatol Surg* 2003; 29: 21–4.

Prospective study of 34 patients with genital or perineal EMPD treated with wide local excision. Patients with clinical or histologic evidence of metastatic disease underwent LN dissection. No patients with in-situ disease or microscopic papillary dermal invasion had LN metastasis and all had 100% 5-year survival. Tumor invasion into reticular dermis correlated with 33% 5-year survival. Tumor invasion into subcutaneous tissue correlated with 100% LN metastasis and 0% 5-year survival.

Possible effectiveness of lymph node dissection in patients with extramammary Paget's disease. Matsushita S, Hatanaka M, Katsue H, et al. *J Dermatol* 2013; 40: 574–5.

Retrospective review of 14 patients with advanced EMPD. Metastatic sentinel node (SN) was confirmed in five patients; one had a metastatic SN on bilateral sides. Their findings suggest that the incidence of distant metastasis is lower in patients with single metastatic SN and recommend LN dissection in patients with a single metastatic SN, thin primary tumor, and slight tumor burden in the metastatic SN.

A proposal for a TNM staging system for EMPD: retrospective analysis of 301 patients with invasive tumors. Ohara K, Fujisawa Y, Yoshino K, et al. *J Dermatol Sci* 2016; 83: 234–9.

Proposed TNM staging system for EMPD based on a retrospective review of 301 Japanese patients with invasive EMPD. Factors associated with survival included tumor thickness, lymphovascular invasion, number of LN metastases, and distant metastases. Patients were classified into five groups, with each showing a distinct survival curve, except stages II and IIIa demonstrated equivalent survival curves. Limitations include the retrospective nature, small number with tumor-related death, and inclusion of only Japanese patients. This classification system should be considered provisional pending further investigation.

Extramammary Paget's disease: a review of the literature – Part II: treatment and prognosis. Morris C, Hurst E. *Dermatol Surg* 2019. Epub.

Systematic review of the literature. Intraoperative pathological examination of frozen sections is often performed to determine margin status; however, this is limited by vertical processing, which limits margin analysis. Standard surgical approach often results in vast tissue loss necessitating extensive reconstruction, which can be associated with significant deformity and morbidity. More recent data suggests that MMS, which provides intraoperative microscopic evaluation of 100% of tissue margin, may have superior clinical outcomes with lower recurrence rates.

Nodal dissection is indicated if clinical or pathologic lymph node metastasis is present, although selective LN dissection is also strongly recommended in the case of invasion into the reticular dermis or subcutaneous tissue even in the absence of clinical or pathologic lymph node metastasis. However, there is no evidence that elective LN dissection, in the absence of palpable nodes, improves survival.

Second-Line Therapies

• Photodynamic therapy (PDT)	B
• Radiation therapy	B
• Topical imiquimod	B
• Systemic chemotherapy	B

Noninvasive extramammary Paget's disease treated with photodynamic therapy: case series from the Roswell Park Cancer Institute. Housel JP, Izikson L, Zeitouni NC. *Dermatol Surg* 2010; 36: 1718–24.

Retrospective case series of eight patients with 24 distinct EMPD lesions treated with photodynamic therapy (PDT). Of those treated with IV porfimer sodium, 78% had a complete response and a disease-free period of 12–96 months. Only 50% (8/16) of lesions treated with topical 5-aminolevulinic acid (ALA) showed complete response and just 38% were disease free at 9–88 months. PDT with IV porfimer sodium or topical ALA may present a useful, surgery-sparing therapeutic option in select patients.

Radiation therapy for extramammary Paget's disease: treatment outcomes and prognostic factors. Hata M, Koike I, Wada H, et al. *Ann Oncol* 2014; 25: 291–7.

Retrospective review of 41 patients with EMPD, including 15 with regional LN metastases, treated with radiation therapy. Total doses of 45–80.2 Gy (median = 60 Gy) were delivered with a median of 33 fractions. The 5-year local progression-free and disease-free rates were 82% and 46%, respectively. Five patients died due to tumor progression. Radiation therapy may be an effective and safe option for inoperable EMPD.

Effects of imiquimod on vulvar Paget's disease: a systematic review of literature. Machida H, Moenini A, Roman LD, et al. *Gynecol Oncol* 2015; 139: 165–71.

A systematic review including 63 cases of untreated or recurrent vulvar EMPD treated with topical imiquimod. The treatment regimens were highly variable, but the most common was topical application 3–4 times per week with a median treatment duration of 4 months. Complete response at 6 months was present in 35 patients. Of the complete responders, three had disease recurrence. Topical imiquimod therapy may be an effective therapeutic option for patients with recurrent or non-operable vulvar Paget disease.

Combination chemotherapy for metastatic EMPD. Oashi K, Tsutsumida A, Namikawa K, et al. *Br J Dermatol* 2014; 170: 1354–7.

Seven patients with metastatic EMPD were treated with combination chemotherapy (FECOM: epirubicin, mitomycin C, vincristine, carboplatin, 5-fluorouracil). Progression-free survival and overall survival (OS) was 6.6 months and 9.4 months, respectively, with a 1-year OS rate of 43%. All patients had at least a partial response or shrinkage in tumor size; none had complete response.

Usefulness of docetaxel as first-line chemotherapy for metastatic EMPD. Yoshino K, Fujisawa Y, Kiyohara Y, et al. *J Dermatol* 2016; 43: 633–7.

Retrospective multicenter analysis that demonstrated successful treatment of 18 metastatic EMPD with docetaxel (average number of treatment cycles = 9.1). Fifty-eight percent experienced partial response (PR), 25% stable disease (SD), and 17% progressive disease (PD) with a 1-year OS rate of 75%.

Docetaxel combined with cisplatin for metastatic EMPD. Cai H, Xu W, Yu B, et al. *Clin Genitourin Cancer* 2018;16: e899–901.

Prospective study of eight patients with metastatic EMPD treated with intermittent combination chemotherapy of docetaxel and cisplatin (average number of cycles = 9.4). In total, 50% experienced PR, 37.5% SD, and 12.5% PD with a 1-year OS rate of 87.5%.

Third-Line Therapies

• Androgen receptor antagonist	E
• Intralesional interferon- α_{2b}	E
• Combination topical imiquimod and PDT	E
• Trastuzumab	E

Androgen-deprivation regimen for multiple bone metastases of EMPD. Yoneyama K, Kamada N, Kinoshita K. *Br J Dermatol* 2005; 153: 853–5.

Case report of EMPD with multiple bone metastases successfully suppressed with bicalutamide (antiandrogen) and leuprorelin (LH-RH agonist). Tumor markers rose at day 70 and other antiandrogen therapies were trialed (flutamide and chlormadinone acetate) as bicalutamide resistance was suspected. The patient died 14 months after initiation of antiandrogen therapy. The authors hypothesize that the rapid development of treatment resistance implicates a mutation or amplification in the androgen receptor gene, which has been demonstrated in prostate cancer.

Intralesional interferon alfa-2b as neoadjuvant treatment for perianal EMPD. Panasiti V, Bottoni U, Devirgilis V, et al. *J Eur Acad Dermatol Venereol* 2008; 22: 522–3.

Case report of a patient with perianal EMPD treated with intralesional IFN- α_{2b} at a dose of 1 million IU three times per week for 3 weeks. Surgical resection was performed at 7 weeks after the tumor had shrunk. Patient had no clinical disease at 108 months follow-up.

EMPD of the scrotum with complete response to imiquimod and photodynamic therapy. Bauman TM, Rosman IS, Sheinbein DM. *BMJ Case Rep* 2018; doi: 10.1136/bcr-2017-221696.

Case report of EMPD treated with imiquimod 5% cream 5 days per week for 1 month and then 3 days per week for 2 months, followed by monthly 5-aminolevulinic acid PDT for 6 months (with continued application of imiquimod 3 days per week), with complete remission in over 5 years of follow-up.

Metastatic EMPD of scrotum responds completely to single agent trastuzumab in a hemodialysis patient: case report, molecular profiling and brief review of the literature. Barth P, Dulaimi Al-Saleem E, et al. *Case Rep Oncol Med* 2015; 895151.

Case report of metastatic EMPD with Her2/neu overexpression treated with trastuzumab as a single agent with complete response. The authors note that Her2/neu overexpression is seen in 30–40% of EMPD cases and this may present a therapeutic option in these cases.

EMPD: what do we know and how do we treat? Adashek J, Leonard A, Nealon S, et al. *Can J Urol* 2019; 26: 10012–21.

A systematic review of EMPD. Recent studies demonstrate expression of HER2 and androgen receptors, which may represent useful targets as future treatment strategies. CEA has shown potential as a possible biomarker for EMPD to aid in detection of metastatic disease and assessment of treatment response. There is growing support for the use of immunotherapy as a therapeutic modality for metastatic EMPD; however, no studies exist to date demonstrating the use of immunotherapy in the treatment of EMPD.

Fabry disease

Jaya Ganesh

Fabry disease (or Anderson–Fabry disease, OMIM 301500) is a progressive, X-linked lysosomal storage disorder caused by the deficiency or absence of the enzyme α -galactosidase A (GLA). This results in the accumulation of globotriaosylceramide (Gb3) and related glycosphingolipids within lysosomes. Systemic manifestations of Fabry disease include renal dysfunction, cardiomyopathy and arrhythmias, cerebrovascular complications, corneal and lenticular opacities, tinnitus and hearing loss, gastrointestinal disturbances, pulmonary disease, osteopenia, and depression. Causes of death include end-stage renal disease (ESRD), cardiac disease, or stroke. Males are more severely affected, but female carriers may exhibit symptoms depending on the pattern of X-chromosome inactivation (lyonization).

There are two major disease phenotypes: type 1 ‘classic’ and type 2 ‘later-onset’ forms. Males with type 1 disease have little or no functional α -Gal A enzymatic activity (<3% of normal mean activity) and develop symptoms in childhood or adolescence. Progressive deposition of Gb3 in the heart leads to arrhythmias, left ventricular hypertrophy, and hypertrophic cardiomyopathy (HCM). In the kidneys the disorder manifests as proteinuria, renal insufficiency, and, ultimately, ESRD, requiring dialysis and renal transplantation. Cerebrovascular disease, including transient ischemic attacks and strokes, may occur. Prior to enzyme replacement therapy (ERT), and without dialysis or renal transplantation, the average age of death of affected males with the type 1 classic phenotype was $\approx$ 40 years.

Type 2 ‘later-onset’ have higher residual α -Gal A activity, and do not show the early manifestations of type 1 males such as acroparesthesias, hypohidrosis, angiokeratomas, or corneal dystrophy. They present with renal and/or cardiac disease much later, typically in the third to seventh decades of life. Cutaneous features of Fabry disease include angiokeratoma, hypohidrosis (53% males

and 28% females), telangiectasia (23% males and 9% females), and lymphedema (16% males and 6% females).

Diffuse angiokeratomas are a characteristic cutaneous manifestation of Fabry disease and should alert the clinician to the possibility of the diagnosis. They typically cluster symmetrically around the umbilicus, hips, back, thighs, buttocks, penis, and scrotum (bathing trunk distribution); increase in number and size over time; and may correlate with the severity of the systemic manifestations of disease. Diffuse angiokeratomas may also be seen in other lysosomal storage diseases including fucosidosis, sialidosis, aspartylglucosaminuria, and β -galactosidase deficiency. Acroparesthesia produces episodic burning, severe pain, and tingling of the palms and soles. Pain crises are thought to result from glycolipid accumulation in the autonomic nervous system and vascular endothelium. A similar mechanism possibly underlies Fabry-associated hypohidrosis.

MANAGEMENT STRATEGY

Comprehensive medical therapy for Fabry disease requires a multidisciplinary approach that includes a combination of *targeted therapy to address the enzyme deficiency* and *medical treatment to address specific organ dysfunction*.

Angiokeratomas due to Fabry disease are typically asymptomatic; when indicated they can be treated with *surgical excision*, *electrocoagulation*, and *cryosurgery*. Various *lasers* have been utilized, including the CO₂, argon, copper vapor, and flashlamp-pumped dye lasers. Copper vapor lasers are superior to argon because of their wavelength specificity for hemoglobin. However, the flashlamp-pumped dye laser may produce less pain and bleeding and pigmentary change.

Neuropathic pain and acroparesthesias may benefit from avoidance of triggers, including physical exertion and temperature changes. *Diphenylhydantoin*, *carbamazepine*, *gabapentin*, *topiramate*, and *tricyclic antidepressants* are used for analgesia. Non-steroidal antiinflammatory drugs are generally ineffective and may worsen the renal disease, and narcotics should be avoided if possible.

Used in conjunction with ERT, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may reduce proteinuria and stabilize glomerular filtration rate (GFR). Peritoneal dialysis, hemodialysis, and renal transplantation are utilized for patients with renal failure. Careful monitoring and prompt intervention for cardiac arrhythmia and HCM are extremely important, and cardiac transplantation may be necessary.

Gastrointestinal complications, including delayed gastric emptying and dyspepsia, have been treated with *metoclopramide*, *pancrelipase*, *loperamide*, and *H₂ blockers*. *Hearing aids* assist in moderate hearing loss, whereas profound deafness requires cochlear implantation. *Aspirin* or *clopidogrel* is recommended for cardiovascular disease prophylaxis.

Two human enzyme products have been utilized in ERT: *agalsidase- β* (Fabrazyme, Sanofi-Genzyme Corporation) and *agalsidase- α* (Replagal, Shire Genetic Therapies). Both were approved by the European Agency for Evaluation of Medical Products in 2001, but only agalsidase- β is approved by the Food and Drug Administration for use in the United States. The enzymes are administered intravenously biweekly at a dose of 0.2 mg/kg for agalsidase- α and 1.0 mg/kg for agalsidase- β . No clear difference in clinical effect between the two preparations was demonstrated in a randomized, controlled, prospective study.

ERT stabilizes or slows progression of renal and cardiac disease, reduces neuropathic pain, stabilizes hearing loss, and improves sweat function and quality of life. Patients treated with ERT have a slowing of progression to ‘major’ clinical events (ESRD, myocardial infarction, stroke, or death). In a recent analysis of 969 male and 442 female patients enrolled in the longitudinal

Fabry Registry, patients with more advanced disease before initiating ERT were at a significantly higher risk of sustaining a severe Fabry-related clinical event compared with those who had milder disease and earlier institution of ERT. ERT has been associated with immunogenicity leading to antibody-mediated infusion reactions that may also reduce its efficacy.

Other therapeutic strategies involve small molecules called *active site-specific chaperones* that are useful with certain types of mutations in the *GLA* gene. In Fabry disease, some missense mutations that cause misfolding of the mutant *GLA* enzyme can result in the retention of the misfolded enzyme in the endoplasmic reticulum. The retained enzyme is then degraded rather than being trafficked to the appropriate location in the cell, i.e., the lysosome. Chaperones are orally active molecules that selectively bind to the misfolded enzyme, promote correct folding, and aid in delivery to lysosomes. Some mutant forms of the enzyme are more amenable to targeting and are responsive to *migalastat* (1-deoxygalactonojirimycin [Galafold, Amicus Therapeutics, NJ, USA]). Migalastat is an orally administered first-in-class molecular chaperone that has been approved for use in patients with amenable mutations in *GLA*. It is administered orally on alternate days. In a cohort of 67 patients, 75% had mutations deemed responsive to migalastat. In that group, improvements included the arrest of decline in GFR, left ventricular mass index, and gastrointestinal symptoms.

New, improved, and more effective treatment approaches are actively being studied. These include trials of gene therapy that are currently in progress.

Information on current clinical trials is posted at www.clinicaltrials.gov.

Fabry disease has now been added to the list of disorders screened for by newborn screening panels in some states in the United States.

Specific Investigations

1 Diagnostic workup

- Obtain family history
- Enzyme analysis (quantitation in plasma and white blood cells [WBCs], cultured cells, blood spot filter paper screening) (most definitive method in males, not reliable for females)
- *GLA* molecular DNA analysis (nearly 100% sensitivity in affected males; most reliable method for females)
- Preimplantation genetic diagnosis or prenatal diagnosis via amniocentesis or chorionic venous sampling (enzymatic and/or molecular assay)

2 Systemic workup (male and female)

- Renal function studies including urinalysis and assessment of 24-hour microalbuminuria and creatinine clearance
- Cardiac evaluation with electrocardiogram, echocardiography, 24-hour Holter monitoring, and cardiac magnetic resonance imaging (MRI) with gadolinium enhancement
- Dermatology evaluation
- Urine GB3, LysoGB3 (Fabry-associated lysosphingolipid) levels in blood
- Audiology
- Fundoscopy and slit-lamp examination
- Neurologic evaluation with surveillance MRI
- Pulmonary function studies
- Gastrointestinal examination with endoscopy as indicated

Angiokeratoma: decision making aid for the diagnosis of Fabry disease. Zampetti A, Orteu CH, Antuzzi D, et al., and the Interdisciplinary Study Group on Fabry Disease. *Br J Dermatol* 2012; 166: 712–20.

This article proposes an algorithm for the diagnosis of Fabry disease and reviews clinical and histologic features of angiokeratomas in detail. The algorithm uses personal and family history, the number and distribution of angiokeratomas, skin biopsy, dermoscopy (to detect more subtle lesions), electron microscopy, and genetic studies as sequential tools in the diagnostic process.

Treatment of Fabry disease: current and emerging strategies. Rozenfeld P, Neumann PM. *Curr Pharm Biotechnol* 2011; 12: 916–22.

This is an excellent overview of therapeutic options, including new treatments such as chaperone therapy.

Fabry disease and the skin: data from FOS, the Fabry Outcome Survey. Orteu CH, Jansen T, Lidove O, et al. *Br J Dermatol* 2007; 157: 331–7.

The Fabry Outcome Survey (FOS), a multicenter European database, was used to capture longitudinal multicenter data on patients with Fabry disease. This paper discusses the dermatologic manifestations present in that cohort.

A case of multiple angiomas without any angiokeratomas in a female heterozygote with Fabry disease. Mirceva V, Hein R, Ring J, et al. *Australas J Dermatol* 2010; 51: 36.

Case report wherein multiple angiomas were the only visible cutaneous manifestation of Fabry disease in an oligosymptomatic female.

Fabry disease. Germain DP. *Orphanet J Rare Dis* 2010; 5: 30.

This is a very comprehensive overview of the clinical characteristics of Fabry disease, current treatment modalities, and therapies on the horizon.

Fabry disease: a review of current management strategies. Mehta A, Beck M, Eyeskens F, et al. *Q J Med* 2010; 103: 641–59.

This review, written by a panel of experts with extensive clinical experience in Fabry disease, summarizes the recent literature and registry data to aid in providing therapy recommendations.

Human Gene Mutation Database: 2008 update. Stenson PD, Mort M, Ball EV, et al. *Genome Med* 2009; 1: 13. <http://www.hgmd.org>. The Institute of Medical Genetics, Cardiff, United Kingdom, 2011.

Over 800 mutations in the *GLA* gene have been identified, including missense and loss of function mutations. Mutation information is used for diagnosis, particularly in female heterozygotes, prenatal testing, and partial correlation with clinical phenotype. Mutation specificity also has major implications for pharmacogenomic management, for example, for the potential use of chaperone therapy in patients with missense mutations that cause protein misfolding.

Fabry disease. Mehta A, Hughes DA. In: Pagon RA, Adam MP, Ardinger HH, et al., eds. *GeneReviews*, Seattle: University of Washington.

This easily accessed, frequently updated database provides a comprehensive review of the clinical, biochemical, and molecular aspects of Fabry disease, with links to information about diagnostic testing and patient resources.

Fabry disease in infancy and early childhood: a systematic literature review. Laney DA, Peck DS, Atherton AM, et al. *Genet Med* 2015; 17: 323–30.

The authors performed a systematic retrospective analysis of 120 peer-reviewed publications and case reports about the pediatric Fabry population. Forty-one individual patients younger than 5 years of age were identified. Acroparesthesia was the most common clinical symptom, reported in nine patients. Other symptoms in very young children included heat sensitivity and gastrointestinal disease, especially recurrent abdominal pain and diarrhea. Importantly, renal damage, including foot process effacement, was noted to occur even before there was clinically evident proteinuria.

First-Line Therapies

• Enzyme replacement therapy	A
• Laser therapy	E
• Intense pulsed light	E
• Surgical excision	E
• Diphenylhydantoin	B
• Cryotherapy	E

Enzyme replacement therapy for Anderson–Fabry disease. El Dib RP, Pastores GM. *Cochrane Database Syst Rev* 2010; 5: CD006663.

This Cochrane review summarizes the available evidence with regard to five randomized-controlled clinical trials (representing 23 publications) involving agalsidase- α and agalsidase- β . The authors concluded that ERT can modify disease course in treated patients with Fabry disease, improving neuropathic pain, cardiac morphology, and renal function. There is also a positive influence on quality of life. Treatment is generally well tolerated, although neutralizing antibodies may affect clinical outcome. Longer-term effects on morbidity and mortality remain to be established.

Response of women with Fabry disease to enzyme-replacement therapy: comparison with men, using data from the FOS – the Fabry Outcome Survey. Hughes DA, Barba Romero MÁ, Hollak CE, et al. *Mol Genet Metab* 2011; 103: 207–14.

Data were obtained from the FOS of 78 affected women and 172 men. Clinical outcomes studied included cardiac structure and function, renal function, quality of life, pain, and a variety of other clinical features and quantifiable measures. Both sexes responded similarly to agalsidase- α . Anhidrosis improved, whereas angiokeratomas did not.

Agalsidase beta treatment is associated with improved quality of life in patients with Fabry disease: findings from the Fabry registry. Watt T, Burlina A, Cazzorla C, et al. *Genet Med* 2010; 12: 703–12.

Seventy-one men and 59 women treated with agalsidase- β had baseline and posttreatment quality of life measurements. Health-related quality of life improved in both sexes, although the effect was more pronounced in men.

Four-year prospective clinical trial of agalsidase alfa in children with Fabry disease. Schiffmann R, Martin RA, Reimschisel T, et al. *J Pediatr* 2010; 156: 832–7.

Of the 24 children who initially completed the 6-month open-label agalsidase- α study, 17 enrolled in this further 3.5-year extension study. Pain severity and Gb3 levels were reduced, and heart rate variability improved. Kidney function and left ventricular mass remained stable.

Risk factors for severe clinical events in male and female patients with Fabry disease treated with agalsidase beta enzyme replacement therapy: data from the Fabry Registry. Hopkin RJ, Cabrera G, Charrow J, et al. *Mol Genet Metab* 2016; 119: 151–9.

This article provides an in-depth review of risk factors for developing severe clinical events in a large cohort of patients treated with ERT, highlighting the need for multidisciplinary care and adjuvant therapies.

Angiokeratomas in Fabry's disease and Fordyce's disease: successful treatment with copper vapor laser. Lapins J, Emtestam L, Marcusson JA. *Acta Derm Venereol* 1993; 73: 133–5.

Angiokeratomas in two treated subjects were undetected at 3-month follow-up; treated skin was smooth, with minimal pigmentary alteration.

Successful treatment of angiokeratoma with potassium titanyl phosphate laser. Gorse SJ, James W, Murison MSC. *Br J Dermatol* 2004; 150: 620–1.

Excellent results using this laser were seen in two subjects with angiokeratomas.

Angiokeratomas of Fabry successfully treated with intense pulsed light. Morais P, Santos AL, Baudrier T, et al. *J Cosmet Laser Ther* 2008; 10: 218–22.

There was almost complete clearance of angiokeratomas in one severely affected subject without recurrence at 12-month follow-up.

Fabry disease: recognition and management of cutaneous manifestations. Möhrenschrager M, Braun-Falco M, Ring J, et al. *Am J Clin Dermatol* 2003; 4: 189–96.

Review article about current laser treatments for the angiokeratomas of Fabry disease, including variable pulse width 532-nm neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, 578-nm copper vapor laser, and flashlamp-pulsed dye laser.

Intravenous infusion of phenytoin relieves neuropathic pain: a randomized, double-blinded, placebo-controlled, crossover study. McClean GJ. *Anesth Analg* 1999; 89: 985–8.

This study evaluated 20 patients with acute flare-ups of neuropathic pain. Phenytoin reduced burning sensation, shooting pain, sensitivity, numbness, and overall pain.

Second-Line Therapies

• Gabapentin	D
• Carbamazepine	D

Use of gabapentin to reduce chronic neuropathic pain in Fabry disease. Ries M, Mengel E, Kutschke G, et al. *J Inher Metab Dis* 2003; 26: 413–4.

Six patients with Fabry disease experienced less pain than at baseline with few side effects after 4 weeks of treatment.

Carbamazepine in Fabry's disease: effective analgesia with dose-dependent exacerbation of autonomic dysfunction. Filling-Katz MR, Merrick HF, Fink JK, et al. *Neurology* 1989; 39: 598–600.

Five of seven patients had moderate to complete relief of pain based upon self-assessment. Complications included exacerbation of preexisting autonomic dysfunction, ileus, urinary retention, and gastrointestinal disturbance.

Third-Line and Future Therapies

• Site-specific molecular chaperone therapy (migalastat)	A
• Substrate reduction therapy (eliglustat tartrate, Genz 112638)	
• Gene replacement therapy	
• Renal transplantation/hemodialysis	C

Co-administration with the pharmacological chaperone AT1001 increases recombinant human α -galactosidase A tissue uptake and improves substrate reduction in Fabry mice. Benjamin ER, Khanna R, Schilling A, et al. *Mol Ther* 2012; 20: 717–26.

This study evaluated the efficacy of combined ERT and chaperone therapy. Coincubation of Fabry fibroblasts with recombinant human α -galactosidase A (rh α -Gal A) and AT1001 (1-deoxygalactonojirimycin, migalastat hydrochloride) resulted in up to fourfold higher levels of cellular α -Gal A and approximately 30% greater Gb3 reduction compared with ERT alone. In rats, AT1001 increased the circulating half-life of rh α -Gal A by >2.5-fold, and in GLA knockout mice resulted in up to fivefold higher α -Gal A levels and fourfold greater GL-3 reduction.

Treatment of Fabry's disease with the pharmacologic chaperone migalastat. Germain DP, Hughes DA, Nicholls K, et al. *New Engl J Med* 2016; 375: 545–55.

Sixty-seven patients with Fabry disease who had never received ERT or had not received ERT within 6 months before enrollment were randomized to 6 months of treatment with migalastat or placebo followed by an open-label migalastat for 6–12 months plus an additional year. All patients were genotyped, and 50 patients had mutant enzyme suitable for targeting by migalastat. Beneficial effects were observed in annualized rates of change in GFRs, reduction in left ventricular mass index (a significant predictor of adverse cardiac events), and improvement in gastrointestinal symptoms that are frequently debilitating. None of the migalastat-treated patients progressed to end-stage kidney disease, had strokes, or had cardiac-related mortality during the study.

Kidney transplant outcomes in patients with Fabry disease. Shah T, Gill J, Malhotra N, et al. *Transplantation* 2009; 87: 280–5.

This study evaluated 197 renal transplant recipients with Fabry disease and ESRD from 1987 to 2007. Rates of graft loss and death were compared with renal transplant recipients with other (non-Fabry) causes of ESRD, as well as a 10:1 matched cohort of transplant recipients with other causes of ESRD. Patients with Fabry disease had a superior graft survival and similar patient survival compared with other (non-Fabry) ESRD patients. However, they had a higher risk of death compared with a matched cohort.

Flushing

Jean S. McGee, Jonathan K. Wilkin

Flushing is defined as visible reddening of the skin over the face, neck, upper portion of the chest, and upper limbs, in association with the sensation of warmth.

MANAGEMENT STRATEGY

The initial step in the management of a patient with a flushing disorder is to make a specific diagnosis. The first algorithmic step is to distinguish between autonomic neurally-mediated flushing, in which eccrine sweating occurs at the time of the flushing ('wet flushing'), and direct vasodilator-mediated flushing, in which there is no accompanying eccrine sweating ('dry flushing'). The dry flushing reactions are further divided into those with prominent dysesthesia and those without.

The most common form of 'wet flushing' is thermoregulatory flushing resulting from exercise and/or exogenous heat. A simple measure such as ice chip therapy, as in holding an ice chip in the mouth, can quickly achieve control. Climacteric flushing in women is associated with inappropriate thermoregulation. Hormone replacement therapy is considered the mainstay of treatment. The second major form of 'wet flushing' is emotional flushing, which can be managed with oral β -blockers, such as nadolol 40 mg every morning or propranolol between 20 mg and 40 mg twice to three times daily.

The 'dry flushing' without dysesthesia is caused by either exogenous or endogenous circulating agents that directly work on the vascular smooth muscle to induce vasodilation. A high-dose nicotinic acid early in the course of therapy for hyperlipidemia can provoke dry flushing. These flushing events can be ameliorated

by simultaneous administration of aspirin. All calcium channel blockers can induce flushing as a side effect. An organic nitrate, such as nitroglycerin, can provoke flushing, followed by tolerance after the first week of therapy. Capsaicin in spicy foods, sodium nitrite in cured meats, and sulfites in salads and wines can provoke dry flushing. Alcohol-induced flushing in Asians can be prophylactically addressed with oral administration of aspirin 0.64 g or a combination of H_1 - and H_2 -antihistamines, 50 mg diphenhydramine and 300 mg cimetidine, respectively.

Endogenous circulating agents from underlying malignancies can induce flushing in association with other prominent features. Itching and urticaria should trigger a laboratory work-up for systemic mastocytosis. Flushing following hypertension, pallor, tachycardia, palpitations, and sweating should prompt an investigation for pheochromocytoma. Flushing with diarrhea should encourage a diagnostic test for carcinoid syndrome. Rare malignancies such as renal cell carcinoma, pancreatic cell carcinoma, and medullary thyroid carcinoma should always be on the differential diagnoses as well.

Specific Investigations

- Serum tryptase
- Urinary catecholamines and metanephrines
- Urinary 5-hydroxyindoleacetic acid and serotonin

First-Line Therapies

• Ice chips	B
• Hormone replacement	A
• Aspirin	A
• Topical brimonidine	A
• Topical oxymetazoline	B

Combined versus sequential hormone replacement therapy: a double-blind, placebo-controlled study on quality of life-related outcome measures. Bech P, Munk-Jensen N, Obel EB, et al. *Psychother Psychosom* 1998; 67: 259–65.

Continuous combined therapy of 2 mg oestradiol (E_2) and 1 mg norethisterone acetate (NETA) daily and sequential therapy of E_2 and NETA were both superior to placebo on the Kupperman scale of sweating, hot flushing, myalgia, and vertigo in 105 normal early postmenopausal women.

Even though hormone replacement therapy is the first-line therapy, contraindications can preclude use of this therapy in many women.

Randomized controlled trial of different aspirin regimens for reduction of niacin-induced flushing. Banka SS, Thachil R, Levine A, et al. *Am J Health Syst Pharm* 2017; 74: 898–903.

Simultaneous administration of aspirin and niacin reduced moderate-to-severe flushing events by a mean of 36.1% in a cohort of healthy adult volunteers.

Aspirin attenuation of alcohol-induced flushing and intoxication in Oriental and Occidental subjects. Truitt EB Jr, Gaynor CR, Mehl DL. *Alcohol Alcohol Suppl* 1987; 1: 595–9.

A group of 11 Oriental and Occidental subjects with histories of alcohol-induced flushing was compared to a similar ethnic group of non-flushing subjects. Prophylactic administration of oral aspirin 0.64 g 1-h prior significantly reduced facial flushing in the flushing group.

Brimonidine gel 0.33% rapidly improves patient-reported outcomes by controlling facial erythema of rosacea: a randomized, double-blind, vehicle-controlled study. Layton AM, Schaller M, Homey B, et al. *J Eur Acad Dermatol Venereol* 2015; 29: 2405–10.

The brimonidine group (once-daily application of brimonidine gel 0.33%) reported significant improvement in patient-reported outcomes on facial redness after 8 days, in comparison to the vehicle group.

Efficacy and safety of once-daily topical brimonidine tartrate gel 0.5% for the treatment of moderate to severe facial erythema of rosacea: results of two randomized, double-blind, and vehicle-controlled pivotal studies. Fowler J Jr, Jackson M, Moore A, et al. *J Drugs Dermatol* 2013; 12: 650–6.

Once-daily brimonidine tartrate application significantly improved severity of erythema based on Clinician's Erythema Assessment and patient's self-assessment, as compared with vehicle application.

Long-term safety and efficacy of once-daily topical brimonidine tartrate gel 0.5% for the treatment of moderate to severe facial erythema of rosacea: results of a 1-year open-label study. Moore A, Kempers S, Murakawa G, et al. *J Drugs Dermatol* 2014; 13: 56–61.

Once-daily brimonidine tartrate gel 0.5% for 1 year, equivalent to 345 subject years of exposure, demonstrated similar safety profile, as compared with vehicle. In addition, the durability of the therapeutic effects was maintained without tachyphylaxis in the brimonidine group.

Efficacy and safety of oxymetazoline cream 1.0% for treatment of persistent facial erythema associated with rosacea: findings from the 52-week open label REVEAL trial. Draeos ZD, Gold MH, Weiss RA, et al. *J Am Acad Dermatol* 2018; 78: 1156–63.

In an open-label study, 440 patients with rosacea applied oxymetazoline 1.0% cream once daily for 52 weeks. At the end of the study, 36.7% and 43.4% of patients achieved a 2-grade or greater composite improvement from baseline in both Clinician Erythema Assessment and Subject Self-Assessment.

Second-Line Therapies

• H ₁ and H ₂ antihistamines	C
• Selective serotonin reuptake inhibitors	A
• Serotonin-norepinephrine reuptake inhibitors	A
• Clonidine	A
• Gabapentin	A

Antihistamine blockade of alcohol-induced flushing in Orientals. Miller NS, Goodwin DW, Jones FC, et al. *J Stud Alcohol* 1988; 49: 16–20.

A combination of 50 mg diphenhydramine (H₁ receptor antagonist) and 300 mg cimetidine (H₂ receptor antagonist) prior to administration of alcohol in Oriental subjects demonstrated a significant reduction in the skin flushing, as compared to placebo.

Scombroid poisoning: prompt resolution of symptoms with cimetidine. Blakesley ML. *Ann Emerg Med* 1983; 12: 104–6.

Four cases of toxic erythema and histamine overload of scombroid poisoning from ingestion of tainted tuna fish promptly resolved with intravenous administration of cimetidine 300 mg.

Paroxetine is an effective treatment for hot flashes: results from a prospective randomized clinical trial. Stearns V, Slack R, Greep N, et al. *J Clin Oncol* 2005; 23: 6919–30.

In an open-label trial, 151 women were randomly assigned to 4 weeks of paroxetine 10 mg or 20 mg followed by placebo for 4 weeks or placebo for 4 weeks followed by paroxetine 10 mg or 20 mg for 4 weeks. Paroxetine 10 mg was associated with a significant improvement in hot flash frequency with no added benefit of increasing the dose to 20 mg.

Venlafaxine for the control of hot flashes: results of a longitudinal continuation study. Barton D, La Vasseur B, Loprinzi C, et al. *Oncol Nurs Forum* 2002; 29: 33–40.

In 102 postmenopausal women, venlafaxine 37.5–150 mg daily for 8 weeks reduced severity and frequency of hot flashes.

Oral clonidine in postmenopausal patients with breast cancer experiencing tamoxifen-induced hot flashes: a University of Rochester Cancer Center Community Clinical Oncology Program study. Pandya KJ, Raubertas RF, Flynn PJ, et al. *Ann Intern Med* 2000; 132: 788–93.

In 194 postmenopausal women with breast cancer on adjuvant tamoxifen therapy, oral clonidine 0.1 mg daily was effective against tamoxifen-induced hot flashes.

However, several randomized, double-blind, placebo-controlled clinical trials demonstrate conflicting therapeutic effects of oral clonidine in postmenopausal women with climacteric flushing.

Clonidine and facial flushing in rosacea. Cunliffe WJ, Dodman B, Binner JG. *Br Med J* 1977; 1: 105.

A group of 17 patients with rosacea flushing were given either clonidine 0.05 mg twice daily or matched placebo with crossover after 3 months. Only five patients reported an improvement in the frequency and severity of their facial flushing attacks.

Gabapentin's effects on hot flashes in postmenopausal women: a randomized controlled trial. Guttuso T Jr, Kurlan R, McDermott MP, et al. *Obstet Gynecol* 2003; 101: 337–45.

After 12 weeks of treatment, gabapentin 900 mg per day was associated with a 45% reduction in hot flash frequency from baseline, as compared with placebo with a 29% reduction in 59 postmenopausal women with seven or more hot flashes per day.

Third-Line Therapies

• Ibuprofen gel	B
• β-blockers	D
• Pulsed dye laser	D
• Intense pulsed light	D
• Botulinum toxin	A
• Thoracic sympathectomy	B
• Somatostatin analogs	B

Topical ibuprofen inhibits blushing during embarrassment and facial flushing during aerobic exercise in people with a fear of blushing. Drummond PD, Minosora K, Little G, et al. *Eur Neuropsychopharmacol* 2013; 23: 1747–53.

A group of 30 participants topically applied ibuprofen 5% over a 1-cm diameter patch on the cheek. The treatment inhibited prostaglandin-mediated blood flow to the cheek during emotional arousal and aerobic exercise.

Symptomatic treatment of idiopathic and rosacea-associated cutaneous flushing with propranolol. Craige H, Cohen JB. *J Am Acad Dermatol* 2005; 53: 881–4.

Eight of the nine patients with histories of facial erythema or blushing reported fewer flushing episodes and diminished symptoms with propranolol therapy between 20 mg and 40 mg twice daily to three times daily.

Particularly, β -blockers suppressed flushing reactions in patients with associated anxiety.

Carvedilol for the treatment of refractory facial flushing and persistent erythema of rosacea. Hsu CC, Lee JY. *Arch Dermatol* 2011; 147: 1258–60.

In a 48-year-old woman with facial flushing and persistent erythema and edema, carvedilol 6.25 mg one to three times daily maintained therapeutic response for 16 months.

Pulsed dye laser treatment of rosacea improves erythema, symptomatology, and quality of life. Tan SR, Tope WD. *J Am Acad Dermatol* 2004; 51: 592–9.

A group of 16 patients with erythematotelangiectatic rosacea were treated with pulsed dye laser at purpuragenic fluences for a total of two treatments at 8-week intervals. A statistically significant improvement was observed in symptoms, which included flushing, burning, itching, dryness, swelling, and skin sensitivity.

Intense pulsed light for the treatment of rosacea and telangiectasias. Kassir R, Kolluru A, Kassir M. *J Cosmet Laser Ther* 2011; 13: 216–22.

In a prospective study, 102 patients with mild-to-severe rosacea received intense pulsed light treatments at 1–3-week intervals with an average of 7.2 treatments. In this cohort, 78% of patients reported reduced flushing and improved skin texture.

A pilot, double-blind, placebo-controlled study to assess the efficacy and safety of incobotulinumtoxinA injections in the treatment of rosacea. Dayan SH, Ashourian N, Cho K. *J Drugs Dermatol* 2017; 16: 549–54.

Nine subjects with rosacea were randomized into either 20 U of incobotulinumtoxinA injections into both cheeks or equal volumes of saline solution injections. IncobotulinumtoxinA injections demonstrated reduction in rosacea features within 4 weeks and increased patient satisfaction, as compared with saline injections.

Effectiveness and safety of endoscopic thoracic sympathectomy for excessive sweating and facial blushing: a systematic review. Malmivaara A, Kuukasjärvi P, Autti-Ramo I, et al. *Int J Technol Assess Health Care* 2007; 23: 54–62.

A review of 15 prospective studies with a follow-up of shorter than 2 years demonstrated that endoscopic thoracic sympathectomy decreased excessive sweating and facial blushing. However, immediate complications related to the procedure occurred in up to 10% of patients. In addition, compensatory sweating below breast level occurred in up to 90% of the patients.

Treatment of the carcinoid syndrome with the longacting somatostatin analogue lanreotide: a prospective study in 39 patients. Ruzniewski P, Ducreux M, Chayvialle JA, et al. *Gut* 1996; 39: 279–83.

In a prospective multicenter study, 39 patients with carcinoid syndrome received lanreotide 30 mg intramuscularly every 14 days for 6 months. After 1 month of treatment, flushing episodes decreased significantly and completely resolved in 39% of the patients.

Follicular mucinosis

Jing Mia Gao, Malcolm Rustin

Follicular mucinosis is characterized histologically by mucinous degeneration of the follicular outer root sheaths and sebaceous glands with an inflammatory infiltrate composed of lymphocytes, histiocytes, and eosinophils. Clinically it presents as erythematous, scaly, and infiltrated plaques with follicular prominence, acneiform lesions, or focal alopecia (alopecia mucinosa). The disorder may be considered as primary follicular mucinosis, an uncommon, benign, idiopathic form of the disease affecting younger patients with fewer lesions, usually situated on the head and neck. Secondary follicular mucinosis occurs in older patients with more generalized lesions and a chronic course associated with other disorders, particularly cutaneous T-cell lymphoma (15%–30% of cases) and folliculotropic mycosis fungoides. No single clinical or histologic feature predicts a benign course, although an isolated patch in the head and neck region is more likely to be primary follicular mucinosis. Follicular mucinosis associated with hematological malignancies tends (not invariably) to be associated with age over 30 years, a wider distribution of lesions, and systemic features such as night sweats, weight loss, or lymphadenopathy. There are also increasing reports of drug-induced follicular mucinosis.

MANAGEMENT STRATEGY

There is no standard therapy, and because spontaneous resolution occurs in the benign forms, *observation* alone is certainly justified, particularly in the younger patient with limited disease. However, the need for *follow-up and evaluation to exclude lymphoma* must be emphasized. Follicular mucinosis associated with

mycosis fungoides, medications, or other neoplastic or inflammatory disorders is managed by treating the underlying associated condition.

Specific Investigations

- Skin biopsy
- Immunohistochemistry and T-cell gene receptor analysis may be helpful adjuncts
- Consider investigations to rule out lymphoma or other underlying disorders, depending on the presenting clinical features (general examination, plain radiology, and computed tomography scans)

The cutaneous mucinoses. Truhan AP, Roenigk HH. *J Am Acad Dermatol* 1986; 14: 1–18.

Follicular mucinosis: a clinicopathologic, histochemical, immunohistochemical and molecular study comparing the primary benign form and the mycosis fungoides-associated follicular mucinosis. Rongioletti F, De Lucchi D, Meyes D, et al. *J Cutan Pathol* 2010; 37: 15–9.

Two excellent reviews of the follicular mucinosis literature, including histopathology and investigation.

Pediatric follicular mucinosis: presentation, histopathology, molecular genetics, treatment and outcomes over an 11-year period at the Mayo Clinic. Alikhan A, Griffin J, Nguyen N, et al. *Pediatr Dermatol* 2013; 30: 192–8.

A review of the clinical and histopathologic findings as well as the treatment and clinical outcomes in children with follicular mucinosis with and without mycosis fungoides.

Follicular mucinosis in patients with hematologic malignancies other than mycosis fungoides: a clinicopathologic study. Geller S, Gomez CJ, Myskowski PL, et al. *J Am Acad Dermatol* 2019; 80: 1704–11.

A review of the clinicopathological characteristics of follicular mucinosis associated with systemic hematologic malignancies versus those that are cutaneous lymphoma-associated.

First-Line Therapies

• Topical and intralesional corticosteroids	D
• Dapsone	E
• Mepacrine	E
• Tetracycline	E

Follicular mucinosis: a study of 47 patients. Emmerson RW. *Br J Dermatol* 1969; 81: 395–413.

Topical or intralesional corticosteroids improved surface eczematous change in eight of 22 patients with benign disease whose lesions resolved spontaneously, independently of treatment, within 2 years. Six of 10 patients with benign chronic disease of more than 2 years' duration showed slight improvement with topical or intralesional corticosteroids.

Neonatal follicular mucinosis. Dalle S, Marrou K, Balme B, et al. *Br J Dermatol* 2007; 157: 609–10.

A solitary plaque on the scalp of a 21-day-old newborn responded to mild-potency topical corticosteroid with resolution within 2 months.

Urticaria-like follicular mucinosis responding to dapsone. Al Harthi F, Kudwah A, Ajlan A, et al. *Acta Derm Venereol* 2003; 83: 389–90.

Itchy, urticaria-like papules on the face, chest, and back of a 25-year-old man for 2 years responded to dapsone 100 mg daily long term after previously failing to respond to oral prednisolone. Attempts to reduce the dosage resulted in recurrence.

Atypical follicular mucinosis controlled with mepacrine. Sonnex TS, Ryan T, Dawber RPR. *Br J Dermatol* 1981; 105: 83–4.

Facial lesions in a 39-year-old man responded to mepacrine 100 mg twice daily. Lesions redeveloped on cessation of therapy.

A case of follicular mucinosis treated successfully with minocycline. Yotsumoto S, Uchimiya H, Kanzaki T. *Br J Dermatol* 2000; 142: 841–2.

A 36-year-old man with follicular mucinosis failed indomethacin treatment. Minocycline 100 mg daily for 6 weeks induced complete remission.

Follicular mucinosis: clinical, histologic and molecular remission with minocycline. Parker S, Murad M. *J Am Acad Dermatol* 2010; 62: 139–41.

A 28-year-old man with follicular mucinosis and a clonal rearrangement of the T-cell receptor gamma chain gene treated with minocycline 100 mg twice daily for 1 year had clinical, histologic, and molecular remission.

Second-Line Therapies

• Isotretinoin	E
• Psoralen and UVA (PUVA)	E
• UVA1	E
• Indomethacin	E
• Interferon	E
• Systemic corticosteroids	E
• Superficial radiotherapy	D
• Photodynamic therapy	E
• Hydroxychloroquine	D
• Topical tacrolimus	E
• Topical pimecrolimus	E
• Topical bexarotene	E
• Topical imiquimod 5%	E

Follicular mucinosis presenting as an acneiform eruption: report of four cases. Wittenberg GP, Gibson LE, Pittelkow MR, et al. *J Am Acad Dermatol* 1998; 38: 849–51.

Two women under 40 years of age had acneiform facial lesions. One had reduced numbers and size of lesions after tretinoin gel 0.01% daily and oral pentoxifylline 400 mg three times daily, followed 2 years later by isotretinoin 40 mg daily. The second significantly improved after isotretinoin 40 mg daily and intermittent clobetasol cream.

Follicular mucinosis treated with PUVA. Kenicer KJA, Lakshminipathi T. *Br J Dermatol* 1982; 107: 48–9.

A 79-year-old woman with facial, truncal, and limb papules with no evidence of systemic disease failed to respond to topical corticosteroids and localized radiotherapy (100 Gy over 5 days). After 98 sessions of psoralen and ultraviolet A (PUVA) over 5 months (total dose 45.4 J/cm²), she remained disease free.

Treatment of idiopathic mucinosis follicularis with UVA1 cold light phototherapy. Von Kobyletzki G, Kreuter JA, Nordmeier R, et al. *Dermatology* 2000; 201: 76–7.

A 26-year-old Caucasian woman with itchy follicular papules on the trunk for 7 months was diagnosed histologically and started on potent corticosteroids with no success. Ultraviolet A1 (UVA1) cold light source (340–530 nm) was used five times a week for 3 weeks, which induced remission, sustained at 3 months.

Follicular mucinosis: response to indomethacin. Kodama H, Umemura S, Nohara N. *J Dermatol* 1988; 15: 72–5.

Plaques and papules on the face and back of a 48-year-old man with no signs of cutaneous lymphoma were unresponsive to topical corticosteroids, UVA, or dapsone. Topical indomethacin 1% in white petrolatum was applied until the lesions disappeared. Oral indomethacin 75 mg daily reduced untreated lesions but was not tolerated. The patient was lesion free 5 years later.

Successful treatment of recalcitrant primary follicular mucinosis with indomethacin and low-dose intralesional interferon alpha. Kim KR, Lee JY, Kim MK, Yoon TY. *Ann Dermatol* 2009; 21: 285–7.

A 52-year-old woman with plaques on both cheeks failed to respond to minocycline, dapsone, topical steroids, and methotrexate. A remarkable improvement was achieved with indomethacin 25 mg twice daily and intralesional corticosteroid administration after 3 months. Intralesional steroids were discontinued, and half-dose indomethacin maintained remission for a further 4 months until lack of availability led to its discontinuation. A rebound flare was controlled with intralesional interferon- α_{2a} 3×10^6 biweekly for 5 weeks with subsequent increase in the injection interval to four times a week. Complete remission was achieved after 6 months with no recurrence 4 months later.

Acneiform follicular mucinosis. Passaro EMC, Silveira MT, Valente NYS. *Clin Exp Dermatol* 2004; 29: 396–8.

A 36-year-old man presented with a 1-year history of acneiform follicular mucinosis and was commenced on 40 mg prednisolone for 20 days. His symptoms improved quickly, and the prednisolone was weaned off by day 48. He had been clear for 7 months at the time of writing.

Alopecia mucinosa: a follow-up study. Coskey RJ, Mehregan AH. *Arch Dermatol* 1970; 102: 193–4.

Patients with one or two facial lesions were given superficial X-ray therapy in a weekly dose of 7.5 Gy for 4 weeks (three cases) or a combination of X-ray therapy and topical corticosteroid cream (six cases). In all cases lesions resolved.

Primary follicular mucinosis: excellent response to treatment with photodynamic therapy. Fernandez-Guarino M, Harto Castano A, Cariilo R. *J Eur Acad Dermatol Venereol* 2008; 22: 393–404.

A 74-year-old woman with a 4-year history of recalcitrant facial plaques cleared with one session of photodynamic therapy (topical methyl-aminolevulinic acid, red light source, 630 nm, 37 J/cm², 7.5 min). She had previously been recalcitrant to topical corticosteroids, narrowband ultraviolet B (UVB), and sulfone. She remained clinically clear 9 months posttreatment.

Treatment of so-called idiopathic follicular mucinosis with hydroxychloroquine. Schneider SW, Metze D, Bonsmann G. *Br J Dermatol* 2010; 163: 420–3.

Six patients were treated with hydroxychloroquine 200 mg three times daily for 10 days with subsequent adjustment for weight, usually to 200 mg twice daily. All patients demonstrated clinical improvement within 6 weeks and complete remission within 2–5 months with full hair regrowth. Individual patients were observed for 3–23 years, and no relapses were seen.

Follicular mucinosis treated with topical 0.1% tacrolimus ointment. Kluk J, Krassilnik N, McBride S. Clin Exp Dermatol 2014; 39: 227–8.

A 36-year-old man treated with topical 0.1% tacrolimus ointment twice daily for lesions affecting the face and neck. Dramatic improvement was observed at 10 days. Topical 0.1% tacrolimus ointment was then tapered over 4 weeks, and remission has been maintained at 1 year.

A case of follicular mucinosis treated successfully with pimecrolimus. Gorpelioglu C, Sarifakioglu E, Bayrak R. Clin Exp Dermatol 2008; 34: 86–7.

A 24-year-old man applied topical 1% pimecrolimus twice daily to a plaque on his chin after lack of response to local corticosteroids. Complete remission was achieved within 1 month, and treatment was discontinued. He remained clear at 7 months' follow-up.

A case of idiopathic follicular mucinosis treated with bexarotene gel. Heyl J, Mehregan D, Kado J, et al. Int J Dermatol 2014; 53: 838–41.

A 34-year-old man applied topical bexarotene gel twice daily to affected areas on the shins for 6 weeks and then reduced to once daily due to local erythema (known side effect of bexarotene). Complete hair regrowth on shins at 26 weeks.

Treatment of primary follicular mucinosis with imiquimod 5% cream. Alonso de Celada R, Feito Rodriguez F, Noguero Morel L, et al. Pediatr Dermatol 2014; 31: 406–8.

A 10-year-old child who had treatment failure with clobetasol propionate applied topical imiquimod 5% daily for 8 weeks, achieving full resolution. Complete remission persists after 3 years.

Folliculitis

Ellen H. de Moll, Robert G. Phelps

Folliculitis is defined as inflammation of the pilosebaceous unit, which can occur superficially, presenting as tender, red papules and pustules, or within the dermal portion of the follicle manifesting as abscesses and furuncles. The etiology of folliculitis can stem from both infectious and non-infectious causes. Among infectious etiologies, bacteria are common, including Gram-positive *Streptococcus* and *Staphylococcus aureus*, as well as Gram-negative *Pseudomonas* infections. Viral etiologies include herpes and molluscum, and fungi and yeast folliculitis can be caused by dermatophytes and *Pityrosporum*, respectively. Less commonly, parasitic folliculitis may be caused by agents such as *Demodex*, scabies, and larva migrans.

Non-infectious folliculitis can be caused by mechanical factors such as friction, occlusion, and trauma, including epilation and sunshine. Irritant folliculitis is associated with cutting oils and coal tar, while a history of significant sun exposure can trigger actinic folliculitis. Perforating folliculitis is commonly associated with diabetes mellitus and chronic renal failure. Eosinophilic pustular folliculitis can be seen in infants, immunocompromised or HIV patients, or the rarer Ofuji's subtype. Many other inflammatory diseases are associated with sterile folliculitis, including Behçet disease, reactive arthritis, systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue disease, inflammatory bowel disease, lymphoproliferative disease, and pregnancy. There is a growing list of medications that can cause folliculitis including lithium, halogens, corticosteroids (both topically and systemically), androgens, ACTH, isoniazid, phenytoin, and sirolimus. Immune-targeted therapy is a category of medications that cause folliculitis as a side effect, including epidermal growth factor receptor (EGFR) inhibitors, tumor necrosis factor- α (TNF- α) inhibitors, trastuzumab, sorafenib, vemurafenib, and dabrafenib.

A thorough history and physical examination are crucial to highlight the most likely etiology in each case. Prolonged antibiotic use in acne patients, particularly tetracycline use, is associated with the development of Gram-negative folliculitis, caused by *Pseudomonas* and other similar bacteria. Exposure to contaminated pools or Jacuzzis are frequent sources of *Pseudomonas* folliculitis. Pityrosporum folliculitis is seen commonly in young adults as pruritic perifollicular papules on the upper trunk, often in warm climates or seasons.

MANAGEMENT STRATEGY

Once the etiology of the folliculitis is ascertained, infectious folliculitis is best managed with a *pathogen-direct antimicrobial regimen*. Therapeutic options include antiseptics and topical or systemic antibiotics for bacterial folliculitis. Coverage for methicillin-resistant *Staphylococcus aureus* (MRSA) should be considered in high-risk patients, pending culture sensitivities. For viral, fungal, yeast, and parasitic folliculitis, *targeted therapy as appropriate* is suitable. Mechanically induced folliculitis often improves with removal of the precipitant. Eosinophilic folliculitis is responsive to phototherapy, and folliculitis related to underlying inflammatory conditions often improves with treatment of primary disease.

Specific Investigations

- Physical examination and past medical history with particular focus on medication usage, concurrent diseases, sun exposure, and family history
- Bacterial, fungal, or viral culture and polymerase chain reaction (PCR) methods with drug sensitivity testing
- Gram stain, Tzanck smear, potassium hydroxide (KOH) preparation
- Tissue biopsy for histologic examination with microorganism stains
- Complete blood count, workup for immunodeficiencies, blood chemistries, renal function test, HIV status
- Nasal culture in chronic or recurrent bacterial cases

First-Line Therapies

Topical therapy

• Mupirocin, clindamycin, and retapamulin for <i>S. aureus</i>	A
• Mupirocin for decolonization of <i>S. aureus</i> of the nares	A
• Daily chlorhexidine or tea tree oil soap body wash for recurrent <i>Staphylococcus</i> spp.	B
• Selenium sulfide shampoo or propylene glycol for <i>Pityrosporum</i> spp.	C
• Permethrin or metronidazole for <i>Demodex</i> spp.	A
• Topical adapalene as prophylaxis for actinic folliculitis	D
• Corticosteroid or tacrolimus for eosinophilic pustular folliculitis	C, D

Oral therapy

• Dicloxacillin or cephalexin for β -hemolytic streptococci or methicillin-sensitive <i>S. aureus</i> (MSSA)	B
• Trimethoprim/sulfamethoxazole, clindamycin, doxycycline, or linezolid for MRSA	B
• Ciprofloxacin for <i>Pseudomonas</i>	C
• Ampicillin, trimethoprim/sulfamethoxazole, or ciprofloxacin for Gram-negative bacteria	B
• Itraconazole or fluconazole for <i>Pityrosporum</i> spp.	A
• Aciclovir, valaciclovir, or famciclovir for herpes	A
• Ivermectin and metronidazole (combination therapy) for <i>Demodex</i> spp.	A, B
• Ivermectin for <i>Demodex</i> spp.	D
• Indomethacin or ciclosporin for eosinophilic pustular folliculitis	C
• Tetracycline for EGFR inhibitor-induced folliculitis	B

Facial bacterial infections: folliculitis. Laureano AC, Schwartz RA, Cohen PJ. Clin Dermatol 2014; 32: 711–4.

Dicloxacillin (250–500 mg four times per day) or cephalexin (250–500 mg four times per day) for 7–10 days is usually sufficient in eradicating conventional facial folliculitis.

Topical retapamulin ointment, 1%, versus sodium fusidate ointment, 2%, for impetigo: a randomized, observer-blinded, noninferiority study. Oranje AP, Chosidow O, Sacchidanand S, et al. Dermatology 2007; 215: 331–40.

Retapamulin was equally efficacious with sodium fusidate in the topical treatment of superficial skin infections.

Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. Stevens DL, Bisno AL, Chambers HF, et al. Clin Infect Dis July 15, 2014; 59: e10–52.

The expert panel's recommendations include a decolonization regimen of 5 days of topical mupirocin and daily chlorhexidine body washes plus daily decontamination of personal items to prevent recurrences.

How resistant is *Staphylococcus aureus* to the topical antibiotic mupirocin? Rakshit, T, Suchitra S. Journal of Global Antimicrobial Resistance 2017; 8: 102–3.

Authors express concern for low- and high-level mupirocin resistance in MRSA but, in a prospective study of 405 cases of MRSA, found no evidence of resistance at a tertiary care hospital in India.

Treatment of MRSA soft tissue infections: an overview. Morgan M. Injury 2011; 42: S11–7.

Suggested antimicrobials for folliculitis include cotrimoxazole, clindamycin, doxycycline, linezolid, rifampicin, and fusidic acid.

Community-acquired methicillin-resistant *Staphylococcus aureus* skin infections: implications for patients and practitioners. Cohen PR. Am J Clin Dermatol 2007; 8: 259–70.

A 10- to 14-day course of oral trimethoprim/sulfamethoxazole (1–2 tablets twice daily), clindamycin (300–450 mg four times per day), or doxycycline (100 mg twice daily) is most useful.

Folliculitis: recognition and management. Luelmo-Aguilar J, Santandreu MS. Am J Clin Dermatol 2004; 5: 301–10.

Pseudomonas folliculitis can resolve within 7–10 days with good skin hygiene and avoidance of contaminated water. Oral ciprofloxacin (250–750 mg twice daily) can be used for severe cases or immunocompromised patients.

Demodex mites: facts and controversies. Elston DM. Clin Dermatol 2010; 28: 502–4.

Topical permethrin 5% cream, oral ivermectin, and oral metronidazole are reasonable treatments.

Recalcitrant papulopustular rosacea in an immunocompetent patient responding to combination therapy with oral ivermectin and topical permethrin. Kallen KJ, Davis CL, Billings SD, et al. Cutis 2007; 80: 149–51.

Resolution of the folliculitis was noted with a treatment combination of 5% permethrin and ivermectin.

First reported case of actinic folliculitis treated successfully with topical retinoid. Rahman S, Powell J, Al-Ismaïl D. Clinical and Experimental Dermatology Jan 2020; E-pub.

Topical adapalene was used as prophylaxis for recurrent actinic folliculitis with success.

Successful treatment of eosinophilic pustular folliculitis with topical tacrolimus 0.1% ointment. Ng SS, Tay YK. Dermatol Online J 2012; 18: 10.

Folliculitis in a patient showed improvement with twice-daily application of 0.1% tacrolimus ointment for 2 weeks. Complete resolution was noted after 1 month.

Short-term treatment of pityrosporum folliculitis: a double blind placebo-controlled study. Parsad D, Saini R, Negi KS. J Eur Acad Dermatol Venereol 1998; 11: 188–90.

A randomized trial showed remarkable response to itraconazole (200 mg/day for 7 days) compared with placebo in 26 patients after 5 weeks.

Evidence-based Danish guidelines for the treatment of *Malassezia*-related skin diseases. Hald M, Arendrup MC, Svejgaard EL, et al. Acta Derm Venereol 2015; 95: 12–9.

Despite the greater evidence for efficacy of itraconazole, oral fluconazole is still used more due to its more favorable side-effect profile and lower risk for drug interactions.

Evaluation of the efficacy of oral ivermectin in comparison with ivermectin-metronidazole combined therapy in the treatment of ocular and skin lesions of *Demodex folliculorum*. Salem DA, El-Shazly A, Nabih N, et al. Int J Infect Dis 2013; 17: e343.

In this trial of 120 patients with skin lesions and blepharitis, combination therapy with oral ivermectin and oral metronidazole was more effective for reducing mite counts than oral ivermectin monotherapy.

Therapeutic effectiveness of various treatments for eosinophilic pustular folliculitis. Fukamachi S, Kabashima K, Sugita K, et al. Acta Derm Venereol 2009; 89: 155–9.

Oral ciclosporin was highly effective, as was indomethacin, in alleviating the folliculitis of 11 patients.

Doxycycline for prevention of erlotinib-induced rash in patients with non-small-cell lung cancer (NSCLC) after failure of first-line chemotherapy: a randomized, open-label trial. Deplanque G, Gervais R, Alain Vergnenegre A, et al. JAAD 2016; 74(6): 1077–85.

An open-label, randomized, prospective phase II trial of 147 patients demonstrated that doxycycline reduced the severity, but not the incidence, of EGFR-inhibitor-associated folliculitis.

Second-Line Therapies

Antimicrobial therapies

- Topical fusidic acid for *S. aureus* **A**
- Topical benzoyl peroxide washes and bleach baths for recurrent *Staphylococcus* **B**
- Oral tigecycline and vancomycin for MRSA **A**
- Benzoyl benzoate 10% or crotamiton 10% for *Demodex* spp. **B**

Other treatment modalities

- Intramuscular immunoglobulin **B**
- Photodynamic therapy **D**

High usage of topical fusidic acid and rapid clonal expansion of fusidic acid-resistant *Staphylococcus aureus*: a cautionary tale. Williamson DA, Monecke S, Heffernan H, et al. Clin Infect Dis 2014; 59: 1451.

Topical fusidic acid was once a first-line treatment option but increasing resistance of *S. aureus* to fusidic acid has been observed, and the drug is not as readily available in the United States.

***Demodex folliculorum* and topical treatment: acaricidal action evaluated by standardized skin surface biopsy.** Forton F, Seys B, Marchal JL, et al. Br J Dermatol 1978; 138: 461–6.

Benzyl benzoate 10% and crotamiton 10% as well as 6.4% sublimed sulfur led to a substantial decrease in *Demodex* mites, in an open-label study of randomized patients.

Efficacy and safety of tigecycline compared with vancomycin or linezolid for treatment of serious infections with methicillin-resistant *Staphylococcus aureus* or vancomycin-resistant *Enterococci*: a Phase 3, multicenter, double-blind,

randomized study. Florescu I, Beuran M, Dimov R, et al. J Antimicrob Chemother 2008; 62(Suppl 1): i17–28.

Tigecycline and vancomycin showed similar clinical cure rates in patients with skin and skin structure infections caused by MRSA.

Intramuscular immunoglobulin for recalcitrant suppurative diseases of the skin: a retrospective review of 63 cases. Goo B, Chung HJ, Chung WG, et al. Br J Dermatol 2007; 157: 563–8.

Intramuscular human immunoglobulin injections reduced the severity and the appearance of new lesions in patients with intractable suppurative skin diseases, including folliculitis.

Topical methyl aminolevulinate photodynamic therapy for the treatment of folliculitis. Horn M, Wolf P. Photodermatol Photoimmunol Photomed 2007; 23: 145–7.

Six of seven patients with recalcitrant folliculitis had significant reduction in inflammation with one session of methyl aminolevulinate photodynamic therapy.

Folliculitis decalvans

Nekma Meah, Matthew Harries

Folliculitis decalvans (FD) is a rare, neutrophilic, inflammatory scalp condition presenting as single or multiple areas of alopecia, characterized by pustule formation, erythema, and increased scale with 'tufted' hair follicles evident at the edge of the scarring hair loss patch. FD can involve any areas of the scalp, although the vertex and occiput are most affected; non-scalp involvement is uncommon. FD tends to run a chronic, progressive course. Multivariate analysis from one large retrospective case series suggests that onset at <25 years of age and presence of pustules are independently associated with severe disease.

The condition can occur in either sex but has a predilection for adult men. Frequent isolation of *Staphylococcus aureus* from lesional skin and observed improvement with antistaphylococcal therapy has implicated this bacterium in disease development. An abnormal host response in genetically susceptible individuals may also be contributory. However, recent identification of a persistent, abnormal subepidermal microbiota and non-staphylococcal bacterial biofilms deeper in lesional hair follicles may suggest alternative microbial factors contributing to disease activity.

MANAGEMENT STRATEGY

The goal of therapy in FD is to arrest the inflammatory process and prevent extension of irreversible alopecia. Initial investigations should exclude other conditions known to mimic FD (e.g., tinea capitis) and the rare complication of squamous cell carcinoma. A confirmatory scalp biopsy is often performed, and a bacteriology swab should be taken from lesional skin to determine culture and sensitivity (as bacterial resistance is common). Nasal staphylococcal eradication should also be considered in confirmed carriers.

To date, there are no reported randomized controlled trials for treatment in FD. Efficacy data are available from case reports, case series, and small studies only. *Systemic antibiotics* (tetracyclines, flucloxacillin, macrolides, and third generation cephalosporins) remain the mainstay of initial therapy, although relapses are common on stopping treatment. The combination of oral rifampicin and clindamycin administered as a 10-week course has been shown to reduce activity and induce sustained remission, and thus is considered the most effective treatment for FD. Occasionally, repeat

courses may be required. Rifampicin monotherapy is not advised due to the risk of developing drug resistance.

Second-line treatment options include isotretinoin, corticosteroids, dapsone, and oral zinc sulfate. Isotretinoin is reported to have lower relapse rates than antibiotics with treatment cessation, while corticosteroids (topical, intralesional, and oral) are recognized adjunctive therapies. Dapsone (75–100 mg) may also produce a satisfactory outcome but often requires low-dose maintenance therapy to sustain remission. Oral zinc sulfate, as monotherapy or combined with fusidic acid, may also be efficacious.

Third-line treatment options include a range of topical, physical, biological, and cellular therapy. Topical tacrolimus ointment, medical (manuka) honey, photodynamic therapy, and human immunoglobulin therapy may be effective. More recently, biological therapy (adalimumab/biosimilar, infliximab, and secukinumab) have been successful in treating severe recalcitrant disease.

In those unresponsive to medical therapy surgical interventions, such as scalp excision, laser epilation or superficial radiotherapy may be considered to permanently epilate the scalp, thereby removing the inflammatory focus of the condition.

Specific Investigations

- Scalp skin swab for bacteriology
- Nasal swab for bacteriology
- Scrapings and plucked hairs for mycology
- Scalp biopsy
- Consider immunodeficiency screen

How not to get scar(r)ed: a guide to diagnosis in primary cicatricial alopecias. Harries MJ, Trueb R, Messenger A, et al. Br J Dermatol 2009; 160: 482–501.

A systematic approach is presented to accurately diagnose scarring alopecias, including FD.

Tinea capitis mimicking folliculitis decalvans. Tangjaturonruamee C, Piraccini BM, Vincenzi C, et al. Mycoses 2011; 54: 87–98.

A case of tinea capitis caused by *Microsporum canis* mimicking FD.

Folliculitis decalvans and cellular immunity – 2 brothers with oral candidiasis. Shitara A, Igareshi R, Morohashi M. Jpn J Dermatol 1974; 28: 133.

Severe FD in two siblings who also had chronic oral candidiasis; defective cell-mediated immunity was demonstrated.

Updates in therapeutics for folliculitis decalvans: a systematic review with evidence-based analysis. Rambhia PH, Conic RR, Murad A, et al. J Am Acad Dermatol 2019; 80: 794–801.

A systematic review of current treatments for FD and treatment outcomes.

First-Line Therapies

Topical antibiotics

- Fusidic acid, clindamycin, erythromycin, mupirocin **E**

Systemic antibiotics

- Rifampicin and clindamycin **C**
- Tetracycline antibiotics, flucloxacillin, fluoroquinolones, and third generation cephalosporins **C**
- Azithromycin **D**

Folliculitis decalvans: a multicenter review of 82 patients. Vañó-Galván S, Molina-Ruiz AM, Fernández-Crehuet P, et al. *J Eur Acad Dermatol Venereol* 2015; 29: 1750–7.

A retrospective review of 82 patients with FD. Between 90% and 100% of patients on either oral doxycycline 100 mg daily, azithromycin 500 mg three times a week, or combination of clindamycin and rifampicin demonstrated improvement.

Effective treatment of folliculitis decalvans using selected antimicrobial agents. Sillani C, Bin Z, Ying Z, et al. *Int J Trichology* 2010; 2: 20–3.

Thirteen patients with mild-to-moderate FD. Minocycline 100 mg twice daily as monotherapy was effective in six patients, with a further three patients responding to minocycline and rifampicin in combination.

Folliculitis decalvans including tufted folliculitis: clinical, histological and therapeutic findings. Powell JJ, Dawber RPR, Gatter K. *Br J Dermatol* 1999; 140: 328–33.

Eighteen patients with folliculitis decalvans were treated with oral rifampicin 300 mg twice daily and oral clindamycin 300 mg twice daily combination for 10 weeks. All patients reported improvement during treatment, with 10 patients achieving a lasting remission.

Second-Line Therapies

• Isotretinoin	C
• Systemic/intralesional corticosteroids	D
• Fusidic acid and oral zinc sulfate	E
• Dapsone	E

Oral isotretinoin as the most effective treatment in folliculitis decalvans: a retrospective comparison of different treatment regimens in 28 patients. Tietze JK, Heppt MV, von Preußen A, et al. *J Eur Acad Dermatol Venereol* 2015; 29: 1816–21.

Nine of 10 patients receiving oral isotretinoin (0.2–0.5 mg/kg daily for 5–7 months followed by 10 mg daily two to three times a week) achieved complete remission. Three patients required low-dose isotretinoin long term.

Isotretinoin treatment for folliculitis decalvans: a retrospective case-series study. Aksoy B, Hapa A, Mutlu E. *Int J Dermatol* 2018; 57: 250–3.

Thirty-nine male patients with FD treated with isotretinoin monotherapy 0.1–1.02 mg/kg/day (median duration of therapy of 2.5 months): 82% (32) achieved complete response, 84.6% (22) had hair regrowth, and 44% (16) achieved durable remission. Of note, 66% of patients on higher dose of treatment and longer duration of therapy (≥ 0.4 mg/kg for ≥ 3 months) did not experience disease relapse.

Retrospective review of folliculitis decalvans in 23 patients with course and treatment analysis of long-standing cases. Bunagan MJ, Banka N, Shapiro J. *J Cutan Med Surg* 2015; 19: 45–9.

The combination of oral tetracycline, intralesional triamcinolone every 4–6 weeks, and clobetasol lotion resulted in remission in seven out of 10 patients on this regimen.

Folliculitis decalvans. Long-lasting response to combined therapy with fusidic acid and zinc. Abeck D, Korting HC, Braun-Falco O. *Acta Derm Venereol* 1992; 72: 143–5.

Three patients responded to oral fusidic acid (500 mg three times a day) and topical fusidic acid cream for 3 weeks combined with oral zinc sulfate 200 mg twice a day for 6 months and once a day thereafter. Disease relapse coincided with stopping zinc sulfate.

Dapsone treatment of folliculitis decalvans. Paquet P, Pierard GE. *Ann Dermatol Venereol* 2004; 131: 195–7.

Two patients treated with dapsone 75–100 mg daily showed clinical response 1–2 months into treatment. A maintenance dose of 25 mg daily resulted in sustained remission.

Third-Line Therapies

• Topical photodynamic therapy	C
• Systemic photodynamic therapy	E
• Tacrolimus 0.1% ointment	E
• Keratolytics and tar shampoo	E
• Medical honey	E
• Oral L-tyrosine	E
• Surgical excision	E
• Shaving of scalp	E
• Laser epilation	E
• Superficial radiotherapy	E
• Anti-TNF therapy	E
• Secukinumab	E
• Immunoglobulin therapy	E
• Autologous fat transplantation	E

Treatment of folliculitis decalvans with photodynamic therapy: results in 10 patients. Miguel-Gomez L, Vañó-Galván S, Perez-Garcia B, et al. *J Am Acad Dermatol* 2015; 72: 1085–7.

A prospective study of topical photodynamic therapy delivered every 4 weeks. Nine patients (90%) achieved clinical improvement at 16 weeks.

Systemic photodynamic therapy in folliculitis decalvans. Collier NJ, Allan D, Diaz Pesantes F, et al. *Clin Exp Dermatol* 2018; 43: 46–9.

A case of recalcitrant FD demonstrating clinical and histological response to systemic photodynamic therapy (PDT) (ultraviolet light (100–140 J/cm²) with the photosensitizer porfimer sodium (1 mg/kg)). Four treatments were administered over several months. Adverse effects were mild photosensitivity.

Treatment of folliculitis decalvans with tacrolimus ointment. Bastida J, Valeron-Almazan P, Santana-Molina N, et al. *Int J Dermatol* 2012; 51: 216–20.

Tacrolimus 0.1% ointment applied twice daily in four patients with recalcitrant disease. A favorable outcome was achieved in all four cases.

Resolution of folliculitis decalvans with medical honey. Yeh J, Hartman R, Xu J. *Dermatol Online J* 2019; 25: 14.

Nightly applications of manuka honey combined with oral cephalixin in one patient resulted in resolution of pustules allowing the antibiotic to be discontinued.

Tufted hair folliculitis. Tong AK, Baden HP. *J Am Acad Dermatol* 1989; 21: 1096–9.

Tufted folliculitis successfully treated by surgical excision.

Nd:YAG laser treatment of recalcitrant folliculitis decalvans. Parlette EC, Kroeger N, Ross EV. *Dermatol Surg* 2004; 30: 1152–4.

Remission achieved with laser epilation in a patient with Fitzpatrick skin type VI.

Treatment of folliculitis decalvans using intensity-modulated radiation via tomotherapy. Elsayad K, Kriz J, Haverkamp U, et al. *Strahlenther Onkol* 2015; 191: 883–8.

A case of recalcitrant FD responding to 11 Gy delivered in two radiation series.

Therapy-resistant folliculitis decalvans and lichen planopilaris successfully treated with adalimumab. Kreutzer K, Effendy I. *J Dtsch Dermatol Ges* 2014; 12: 74–6.

Two patients with FD responded well to adalimumab 40 mg administered fortnightly. Marked improvement was noted after 8–12 weeks.

A case of isotretinoin therapy-refractory folliculitis decalvans treated successfully with biosimilar adalimumab (Exemptia). Shireen F, Sudhakar A. *Int J Trichology* 2018; 10: 240–1.

A 23-year-old male with refractory FD is effectively treated with biosimilar adalimumab (Exemptia). The treatment regimen included 80 mg subcutaneously (SC) weekly for 2 weeks; 40 mg SC weekly in weeks 3, 4, 6, 8, 10, 12, 14, and 16; and then

monthly thereafter. The patient remained in remission on maintenance therapy.

Successful treatment of refractory folliculitis decalvans with secukinumab. Ismail FF, Sinclair R. *Aus J Dermatol* 2020; 61(2): 165–166.

A 30-year-old female with recalcitrant FD was treated with secukinumab (300 mg SC in weeks 0, 1, 2, 3 and 4, followed by 300 mg SC every 4 weeks thereafter). Significant improvement was reported 4 months after initiation of therapy.

Intramuscular immunoglobulin for recalcitrant suppurative diseases of the skin: a retrospective review of 63 cases. Goo B, Chung HJ, Chung WG, et al. *Br J Dermatol* 2007; 157: 563–8.

Three patients with FD were rated to have a 'good response' after intramuscular human immunoglobulin administered once a month.

Adipose tissue transplant in recurrent folliculitis decalvans. Tedesco M. *Int J Immunopathol Pharmacol* 2018; 32: 2058738418814688.

Two sessions of autologous fat transplantation were successful in controlling active FD in a 41-year-old female. Twenty milliliters of fat were aspirated from the median knee and administered into the inflamed scalp per session. Presumably the adipose tissue is functioning as a source of stem cells.

Fox–Fordyce disease

Ian H. Coulson

Obliteration of the follicular infundibulum with keratin in the apocrine gland-bearing skin is the cause of this rare, paroxysmally intensely itchy condition. Apocrine sweat retention and rupture of the gland duct under periods of apocrine sudomotor stimulation, particularly emotional stress, result in the development of an itchy, spongiotic intraepidermal vesicle. It mainly affects women between the ages of 13 and 35 years but has rarely been reported before puberty, after menopause, and in men. Itchy, dome-shaped, flesh-colored or keratotic papules that develop peripubertally in the apocrine areas of the axillae, pubic, periumbilical, and periareolar skin characterize this condition. Sparsity of axillary hair and hypohidrosis are usual, although rarely the disease can be exacerbated by hyperhidrosis. Improvement observed in pregnancy and during the administration of oral contraceptives has led to speculation regarding an endocrine etiology, although this has been unsubstantiated by blood sex hormone investigations. Very few reports in twins and within families suggest a possible genetic component. Fox–Fordyce disease (FFD) can occur after laser hair removal and has been reported in Turner syndrome.

MANAGEMENT STRATEGY

There are no controlled trials of any agents in FFD.

Topical and intralesional corticosteroids are frequently tried and may be of limited benefit, but atrophy in the axillary area will limit their potency and duration of use. Topical *tretinoin* and *adapalene* have been reported to reduce itch, but alternation with a mild corticosteroid may be needed to reduce retinoid irritancy.

Clindamycin lotion may be of help. The oral contraceptive pill (OCP) may bring relief to some women. Oral *isotretinoin* may give temporary relief. *Electrocautery* and *excision* of the periareolar skin may offer permanent solutions. A recent report advocates an ingenious method of removal of the apocrine glands using a micro-liposuction cannula. There is a single report of axillary disease responding to intralesional botulinum toxin injection. Physical modalities such as *microwave devices* and CO₂ and erbium glass lasers have their advocates.

Specific Investigation

- Biopsy

Fox–Fordyce disease: diagnosis by transverse histologic sections. Stashower ME, Krivda SJ, Turiansky GW. *J Am Acad Dermatol* 2000; 42: 89–91.

Transverse sectioning demonstrates the follicular plugging and infundibular spongiosis more readily than conventional sections.

Dilation of apocrine glands. A forgotten but helpful histopathological clue to the diagnosis of axillary Fox–Fordyce disease. Macarenco RS, Garces S JC. *Am J Dermatopathol* 2009; 31: 393–7.

Apocrine gland dilation may be used as a low-power magnification clue, which should be followed by a search for further histologic changes to confirm or rule out the diagnosis.

Clinicopathological study of Fox–Fordyce disease. Kao PH, Hsu CK, Lee JY. *J Dermatol* 2009; 36: 485–90.

Focal spongiosis in the upper infundibulum with perifollicular fibrosis and lymphohistiocytic infiltrate were consistent features in their case series.

Fox–Fordyce-like disease following laser hair removal appearing on all treated areas. Helou J, Maatouk I, Moutran R, et al. *Lasers Med Sci* 2013; 28: 1205–7.

The most recent of reports highlighting that laser epilation in several anatomic sites may induce FFD.

Perifollicular xanthomatosis as a key histologic finding in Fox–Fordyce disease. Mataix J, Silvestre JE, Niveiro M, et al. *Actas Dermosifiliogr* 2008; 99: 145–8.

There are occasional conditions to consider in the differential diagnosis! There is even controversy as to whether perifollicular xanthomatosis is part of the spectrum of this disorder.

First-Line Therapies

• Topical and intralesional corticosteroids	D
• Topical clindamycin	E
• Oral contraceptive pill	D
• Topical retinoids	D
• Ultraviolet B (UVB)	D
• Topical pimecrolimus and tacrolimus	D
• Topical calcipotriol betamethasone	E

A new treatment of Fox–Fordyce disease. Helfman RJ. *South Med J* 1962; 55: 681–4.

A single report of successful symptom relief of axillary lesions with 10 mg/mL triamcinolone diluted with an equal volume of 1% lidocaine to four sites on nine occasions over 3 months.

Fox-Fordyce disease: a report of 2 cases responding to topical clindamycin. George A, Bhatia A, Thomas E. *Int J Dermatol* 2013; 52: 1571–2.

Some authors speculate that the keratolytic effect of propylene glycol may have been responsible for the therapeutic effect.

Fox-Fordyce disease. Treatment with an oral contraceptive. Kronthal HI, Pomeranz JR, Sitomer G. *Arch Dermatol* 1965; 91: 243–5.

Two female patients responded to a high-estrogen dose combined OCP (norethynodrel and mestranol).

Fox-Fordyce disease: response to adapalene 0.1%. Kassuga LE, Medrado MM, Chevrant NS, et al. *An Bras Dermatol* 2012; 87: 329–31.

The authors report that 0.1% adapalene cream produced satisfactory improvement of the signs and symptoms of a single patient with FFD. In acne, this product is less irritating than tretinoin, so it may be a more tolerable topical retinoid option.

Topical tretinoin use is reported but likely to be more irritant.

Treatment of Fox-Fordyce disease. Pinkus H. *JAMA* 1973; 223: 924.

Erythemogenic doses of UVB (once weekly for 4–6 weeks) produced long-lasting relief to several patients.

Pimecrolimus is effective in Fox-Fordyce disease. Pock L, Svrcková M, Machácková R. *Int J Dermatol* 2006; 45: 1134–5.

A series of three patients who benefited from topical pimecrolimus.

Clinical effects of topical tacrolimus on Fox-Fordyce disease. Kaya Erdoğan H, Bulur I, Kaya Z. *Case Rep Dermatol Med* 2015: 205418.

Two case reports, one with a successful response in terms of itch, from twice-daily 0.1% tacrolimus ointment applied for 3 months.

Rapid remission with calcipotriol betamethasone in refractory Fox-Fordyce disease. Yang L, Zhang S, Wang T, et al. *Dermatol Ther* 2020; 33: e13223. doi: 10.1111/dth.13223.

A case report of a 26-year-old woman with recalcitrant FFD who responded to calcipotriol betamethasone within 2 weeks, with no recurrence at 3 months.

Second-Line Therapies

• Oral isotretinoin	E
• Electrocautery	D
• Excision	D
• Apocrine gland removal using microliposuction	E
• Botulinum toxin	E
• Microwave and lasers	E

Fox-Fordyce disease in a male patient – response to oral retinoid treatment. Effendy I, Ossowski B, Happle R. *Clin Exp Dermatol* 1994; 19: 67–9.

Oral treatment with isotretinoin (30 mg daily for 8 weeks and then 15 mg daily for 2 months) resulted in temporary relief. Relapse occurred 3 months after discontinuation.

Fox-Fordyce disease in the postmenopausal period treated successfully with electrocoagulation. Pasricha JS, Nayyar KC. *Dermatologica* 1973; 147: 271–3.

Electrocoagulation to a level of 3–4 mm under local anesthetic produced a permanent resolution of symptoms in the axillae of two patients.

Surgical treatment of areolar hidradenitis suppurativa and Fox-Fordyce disease. Chavoin J-P, Charasson T, Barnard J-D. *Ann Chir Plast Esthet* 1994; 39: 233–8.

A simple technique involving dermal detachment of the areola, excision of the underlying apocrine glands, and reattachment of the areola with good cosmetic results.

This treatment has not proved beneficial long term.

Axillary Fox-Fordyce disease treated with liposuction-assisted curettage. Chae KM, Marshall MA, Marshall SE. *Arch Dermatol* 2002; 138: 452–4.

A novel technique of curettage removal of the apocrine glands using a small liposuction cannula with symptom relief, great cosmesis, and a follow-up at publication of 8 months. A liposuction cannula was introduced through a stab incision in the axilla and, with the aperture of the cannula turned up toward the underside of the dermis, the deeper dermis was curetted to create inflammation and subsequent fibrosis. The same technique can be used to treat axillary hyperhidrosis.

Successful treatment of refractory pruritic Fox-Fordyce disease with botulinum toxin type A. González-Ramos J, Alonso-Pacheco ML, Goiburú-Chenú B, et al. *Br J Dermatol* 2016; 174: 458–9.

A single case report of a woman receiving 100 U of Botox to each axilla; itching completely abated and papules partially regressed, and the response was sustained over 8 months of follow-up after a single treatment.

Successful treatment of areolar Fox-Fordyce disease with surgical excision and 1550-nm fractionated erbium glass laser. Han HH, Lee JY, Rhie JW. *Int Wound J* 2016; 13: 1016–9.

Fox-Fordyce disease treatment with fractional CO₂ laser. Ahmed Al-Qarqaz F, Al-Shannag R. *Int J Dermatol* 2013; 52: 1571–2. Single reports regarding different laser modalities.

A novel modality using microwave technology for the treatment of Fox-Fordyce disease. Taylor D, Au J, Boen M, et al. *JAAD Case Rep* 2015; 2(1): 1–3.

A single report of utilizing the MiraDry microwave system for axillary disease. Two treatments were required.

Furunculosis

Charles A. Gropper, Karthik Krishnamurthy

Furunculosis, commonly referred to as *boils*, is a deep infection of the pilosebaceous unit. Lesions may occur on any hair-bearing surface, including the nares. Coalescing multiple lesions (carbuncles) are usually very tender and may have multiple draining sites.

MANAGEMENT STRATEGY

The infectious agent most commonly implicated is *Staphylococcus aureus*; methicillin-resistant strains of *S. aureus* (MRSA) are now recognized as the dominant isolate overall. In recent years, the designations of community-acquired MRSA (CA-MRSA) versus hospital-acquired MRSA (HA-MRSA) have become blurred due to a convergence in both antibiotic susceptibility profiles and risk of sequelae. There are rare reports of dissemination causing epidural abscess, bacterial endocarditis, and pulmonary infection.

Group A beta-hemolytic *Streptococcus*, Gram-negative bacteria, and yeast-forms should remain in the differential diagnosis. In addition, *Mycobacterium* spp., especially *M. fortuitum*, have been implicated in furunculosis in patients using footbaths in beauty salons.

Nasal, pharyngeal, axillary, perineal, and rectal pathogen carriage is implicated in recurrent disease. In rare cases, patients with impaired neutrophil function and immunodeficiency syndromes, such as common variable immunodeficiency and hyper-IgE syndrome, also present with recurrent 'cold abscess' furunculosis.

Isolated lesions should be *incised and drained*. Multiple, mostly observational, studies indicate high postsurgical cure rates (85%–90%) whether or not an active antibiotic is used. Therefore, according to the Centers for Disease Control (2006) and Infectious Diseases Society of America (2011), empiric antibiotics should be reserved for those with:

- Severe or extensive disease (e.g., involving multiple sites of infection)

- Rapid progression in presence of associated cellulitis
- Signs and symptoms of systemic illness
- Associated comorbidities/immunosuppression (diabetes mellitus, human immunodeficiency virus, neoplasm)
- Extremes of age
- Abscess in area difficult to drain completely (e.g., face, hand, and genitalia)
- Associated septic phlebitis
- Lack of response to incision and drainage alone

Swabs of any purulent discharge should be collected for bacterial culture; antibiotic therapy may be redirected based on sensitivities and clinical scenario. Acid-fast staining and culture may be warranted if a temporal relationship to a pedicure is noted. Currently, antibiotics carrying a Food and Drug Administration (FDA) indication for use against MRSA include *linezolid*, *ceftaroline* ('advanced'-generation cephalosporin), *telavancin* (similar to vancomycin), *tigecycline* (derivative of minocycline), and *teicoplanin*. Other antibiotics with anti-MRSA activity include *trimethoprim-sulfamethoxazole* (TMP-SMX), *daptomycin*, *vancomycin*, *doxycycline*, *minocycline*, *clindamycin*, *rifampin*, and *quinupristin-dalfopristin*. Evidence of nasal carriage of staphylococci should be sought in those with recurrent disease and eradicated with either *oral rifampicin* (not as monotherapy) or *nasal mupirocin* or *fusidic acid*.

Specific Investigations

- Culture and sensitivity of purulent drainage
- Acid-fast stain and culture (if indicated)
- Moistened nasal swab for culture (if recurrent)
- Neutrophil count and immunoglobulin levels (if relevant and/or recurrent)

First-Line Therapy

- Surgery: incision and drainage

A

Randomized, double-blind, placebo-controlled trial of cephalexin for treatment of uncomplicated skin abscesses in a population at risk for community-acquired methicillin-resistant *Staphylococcus aureus* infection. Rajendran PM, Young D, Maurer T, et al. Antimicrob Agents Chemother 2007; 51: 4044–8.

Randomized, double-blind trial of 166 outpatient subjects comparing placebo to cephalexin at 500 mg orally four times daily for 7 days after incision and drainage of skin and soft tissue abscesses. The primary outcome was clinical cure or failure 7 days after incision and drainage. Of the isolates tested 87.8% were MRSA. Clinical cure rates (90.5% in the 84 placebo recipients and 84.1% in the 82 cephalexin recipients) provides strong evidence that antibiotics may be unnecessary after surgical drainage of uncomplicated skin and soft tissue abscesses caused by community strains of MRSA.

Second-Line Therapies

- Doxycycline or minocycline
- Trimethoprim/sulfamethoxazole
- Clindamycin
- Linezolid

B
B
B
B

Adjunctive for patients meeting criteria are listed in Management Strategy earlier.

Clinical practice guidelines by the Infectious Diseases Society of America for the treatment of methicillin-resistant *Staphylococcus aureus* infections in adults and children: executive summary. Liu C, Bayer A, Cosgrove SE, et al. Clin Infect Dis 2011; 52: 285–92.

Oral antibiotics that may be used as empiric therapy for CA-MRSA include TMP-SMX, doxycycline (or minocycline), clindamycin, and linezolid. Several observational studies and one small, randomized trial suggest that TMP-SMX, doxycycline, and minocycline are effective for such infections. Clindamycin is effective in children with CA-MRSA skin and soft tissue infection (SSTI). Linezolid is FDA-approved for SSTI but is not superior to less expensive alternatives.

Tetracyclines as an oral treatment option for patients with community onset skin and soft tissue infections caused by methicillin-resistant *Staphylococcus aureus*. Ruhe JJ, Menon A. Antimicrob Agents Chemother 2007; 51: 3298–303.

Retrospective study of 276 outpatients. The median percentage of patients infected with MRSA strains that were susceptible to tetracycline was 95%. A total of 225 patients (80%) underwent incision and drainage. Doxycycline or minocycline was administered in 90 episodes (32%); the other 192 SSTIs were treated with β -lactams. Receipt of β -lactam antibiotics was associated with treatment failure.

Prevalence, severity, and treatment of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) skin and soft tissue infections in 10 medical clinics in Texas: a South Texas Ambulatory Research Network (STARNet) study. Forcade NA, Parchman ML, Jorgensen JH, et al. J Am Board Fam Med 2011; 24: 543–50.

A community-based study. Overall, 73 of 119 (61%) patients presenting with SSTIs meeting eligibility requirements had CA-MRSA. Most received incision and drainage plus an antibiotic (64%). Antibiotic monotherapy was frequently prescribed: TMP-SMX (78%), clindamycin (4%), doxycycline (2%), and mupirocin (2%). The rest received TMP-SMX in combination with other antibiotics. Isolates were 93% susceptible to clindamycin and 100% susceptible to TMP-SMX, doxycycline, vancomycin, and linezolid.

Trimethoprim-sulfamethoxazole or clindamycin for treatment of community-acquired methicillin-resistant *Staphylococcus aureus* skin and soft tissue infections. Hyun DY, Mason EO, Forbes A, et al. Pediatr Infect Dis J 2009; 28: 57–9.

A retrospective study of 508 patients who had MRSA isolated either from surgically obtained drainage or from spontaneous drainage of the infection site; 215 patients were prescribed oral TMP-SMX therapy, and 200 were prescribed oral clindamycin. No significant differences were observed in the percentage who returned because of worsening or incomplete resolution. Most of the patients had incision and drainage (94% of TMP-SMX patients, 86% of clindamycin patients), so results may reflect improvement from incision and drainage than antibiotic choice.

Third-Line Therapies/Prevention

• Topical nadifloxacin	B
• Nasal mupirocin	B
• Bleach bath	E
• Colonization with less pathogenic staphylococci	E
• Retapamulin	E
• Fusidic acid	B

Efficacy and safety of nadifloxacin for bacterial skin infections: results from clinical and postmarketing studies. Narayanan V, Motlekar S, Kadhe G, et al. Dermatol Ther 2014; 4: 233–48.

A total of 272 subjects were enrolled in the study, and subjects were randomly assigned to one of the three treatment groups: 92 in the nadifloxacin group, 90 in the mupirocin group, and 90 in the framycetin group. A significant reduction in the mean scores for bacterial infection symptoms in the nadifloxacin groups was observed compared with the mupirocin, framycetin, and fusidic acid groups. No adverse events (AEs) were reported in the clinical studies.

Randomized controlled trial of chlorhexidine gluconate for washing, intranasal mupirocin, and rifampin and doxycycline versus no treatment for the eradication of methicillin-resistant *Staphylococcus aureus* colonization. Simor AE, Phillips E, McGeer A, et al. Clin Infect Dis 2007; 44: 178–85.

Treatment with this regimen for 7 days was safe and effective in eradicating MRSA colonization in hospitalized patients for at least 3 months.

Hypochlorite killing of community-associated methicillin-resistant *Staphylococcus aureus*. Fisher RG, Chain RL, Hair PS. Pediatr Infect Dis J 2008; 27: 934–5.

In vitro study of hypochlorite (bleach) against CA-MRSA. Maximal killing was found after 5 minutes in 2.5 μ L/mL bleach. A 2.5- μ L/mL bleach solution is approximately equivalent to one-half cup of bleach in one-quarter tub of water. In vivo studies will be required to show clinical effectiveness.

Recurrent staphylococcal infection in families. Steele R. Arch Dermatol 1980; 116: 189–90.

Fifteen of 17 families inoculated with less pathogenic strains of *S. aureus* remained disease free at 6 months, whereas only four of the 15 control families had no recurrences.

In vitro activity of retapamulin against *Staphylococcus aureus* isolates resistant to fusidic acid and mupirocin. Woodford N, Afzal-Shah M, Warner M, et al. J Antimicrob Chemother 2008; 766–8.

Retapamulin inhibited 99.9% of all *S. aureus* isolates. Further in vivo studies are indicated to assess efficacy in the treatment of furunculosis.

Treatment and prevention of recurrent staphylococcal furunculosis: clinical and bacteriologic follow-up. Hedström SA. Scand J Infect Dis 1985; 17: 55–8.

Sodium fusidate ointment was used twice daily for a month as prophylaxis for nasal furunculosis with cessation of furuncles in 10 of 20 cases. Controls took antibiotics systemically, and three of 20 had no furuncles. After a year, those who used topical therapy had fewer recurrent lesions.

Geographic tongue

Jessica Shiu, Jennifer K. Chen, Janellen Smith

Geographic tongue is a reactive mucosal inflammatory condition characterized by arcuate or annular alternating hypertrophic or atrophic filiform papillae producing a geographic pattern. Synonyms include *benign migratory glossitis* and *glossitis areata migrans*. Geographic tongue may be an asymptomatic incidental finding. Similar changes may occur in oral sites other than the tongue (geographic stomatitis or benign migratory stomatitis).

MANAGEMENT STRATEGY

Geographic tongue is a common glossitis that affects 2% of the population. If asymptomatic, no treatment is necessary other than reassurance that the condition is benign and usually not a sign of systemic illness. Geographic tongue will remit spontaneously but may persist for years. Occasionally, patients may complain of a burning discomfort, particularly in atrophic areas. Effective therapy can be challenging.

Geographic tongue has been associated with psoriasis (especially pustular psoriasis); the two diseases share a strong association with human leukocyte antigen (HLA)-Cw6. It has also been associated with reactive arthritis; pityriasis rubra pilaris; atopic diathesis; Down syndrome; nutritional deficiency; diabetes; hormonal changes; and medications including lithium, oral contraceptives, and vascular endothelial growth factor or multikinase inhibitors such as bevacizumab, sunitinib, and sorafenib. The clinician should also consider acute or chronic atrophic candidiasis as a differential diagnosis.

For symptomatic patients, measures that may be considered include the avoidance of hot, spicy, or acidic foods;

gentle brushing of the tongue; avoidance of harsh antibacterial mouthwashes, chewing gum, and breath mints; and soothing rinses with saline solutions. Occasionally, the topical application of *fluorinated corticosteroids* or *diphenhydramine elixir* after meals and at bedtime may be recommended. *Topical anesthetic rinses or gels* provide temporary relief. *Antiyeast treatments* may be palliative.

Specific Investigations

- Culture for candidiasis
- If symptomatic, consider complete blood cell count, iron panel, vitamin B₆, vitamin B₁₂, vitamin D, folate, and zinc levels; glucose; and hemoglobin A_{1c}
- No investigation necessary in asymptomatic patients

Geographic tongue. Shareef S, Etefagh L. [Updated 2020 Feb 17]. In: StatPearls [Internet]. Treasure Island (FL): StatPearls Publishing, 2020 Jan. Available from: <https://www.ncbi.nlm.nih.gov/books/NBK554466/>.

The topic and the differential diagnosis are reviewed. Patients without symptoms do not require additional studies.

Geographic tongue and psoriasis: clinical, histopathological, immunohistochemical and genetic correlation – a literature review. Picciani BL, Domingos TA, Teixeira-Souza T, et al. *An Bras Dermatol* 2016; 91: 410–21.

Review and discussion on how geographic tongue and psoriasis share clinical, histological, and genetic features.

First-Line Therapies

• Avoidance of spicy food, mouthwashes, chewing gum, and breath mints	D
• Topical corticosteroids (e.g., fluocinonide 0.05% gel, dexamethasone elixir, triamcinolone 0.1% in oral base)	C
• Topical antihistamines (e.g., diphenhydramine elixir 12.5 mg/5 mL diluted 1:4 with water)	C
• Antiyeast therapy	E
• Swish-and-spit tacrolimus regimen twice daily (e.g., dissolve 1-mg tacrolimus capsule dissolved in 500 mL of water, swish for 2 minutes and spit)	C

Symptomatic benign migratory glossitis: report of two cases and literature review. Sigal MJ, Mock D. *Pediatr Dent* 1992; 14: 392–6.

Management with topical corticosteroids and topical antihistamines is discussed.

Effectiveness of the tacrolimus swish-and-spit treatment regimen in patients with geographic tongue. Aung-Din D, Heath M, Wechter T, et al. *JAMA Dermatol* 2018; 154: 1481–2.

Retrospective medical record review of 20 patients with geographic tongue receiving twice daily tacrolimus spit-and-swallow regimen. Patients were instructed to dissolve 1-mg tacrolimus capsule dissolved in 500 mL of water, then swish for 2 minutes, and then spit out the solution. The risk of systemic effects is minimal because inadvertent consumption of a single dose is approximately 0.01 mg of tacrolimus. Most patients were also on topical steroids, clotrimazole trenches, or gabapentin (100–200 mg daily).

Glossitis and other tongue disorders. Byrd JA, Bruce AJ, Rogers RS III. *Dermatol Clin* 2003; 21: 123–34.

A review of geographic and other tongue disorders.

Painful geographic tongue (benign migratory glossitis) in a child. Menni S, Boccardi D, Crosti C. *J Eur Acad Dermatol Venerol* 2004; 18: 737–8.

Prevalence of fungi in cases of geographic tongue and fissured tongue. Dudko A, Kurnatowska AJ, Kurnatowski P. *Ann Parasitol* 2013; 59: 113–7.

In this case series, fungal cultures most commonly grew *Candida* species, which were more sensitive to nystatin than miconazole. The prevalence of fungi was highest in those who do not brush the tongue.

Treatment of symptomatic geographic tongue with triamcinolone acetonide alone and in combination with retinoic acid: a randomized clinical trial. Najafi S, Gholizadeh N, Akhavan Rezayat E, et al. *J Dent* 2016; 13: 23–8.

Randomized, controlled trial comparing 28 patients, demonstrating that the combination of triamcinolone and retinoic acid was not more effective than triamcinolone alone. However, it lacks a placebo group and includes a small number of patients.

Treatment of symptomatic benign migratory glossitis: a systematic review. De Campos WG, Esteves CV, Fernandes LG, et al. *Clin Oral Investig* 2018; 22: 2487–93.

Eleven studies were included, which consisted of 150 patients. Of all treatments for geographic tongue, only 8 of 150 cases had reported improvement with substantial heterogeneity in treatments tried. Most common treatments included topical steroids, topical tacrolimus, and topical diphenhydramine.

Second-Line Therapies

• Topical anesthetics	C
• Topical tretinoin	E
• Discontinue dentifrices and other oral flavoring agents	D
• Topical tacrolimus	E
• Pregabalin	E

The treatment of geographic tongue with topical Retin-A solution. Helfman RJ. *Cutis* 1979; 24: 179–80.

The use of topical Retin-A solution is described in three cases.

Anecdotally, we have found that tretinoin gel is longer acting and better tolerated by patients.

Geographic tongue treated with topical tacrolimus. Ishibashi M, Tojo G, Watanabe M, et al. *J Dermatol Case Rep* 2010; 4: 57–9.

Topical tacrolimus 0.1% ointment twice daily for 2 weeks cleared symptoms in two cases.

Geographic tongue that responds to the treatment of pregabalin: can it be a new treatment choice? Kurtipek GS, Sari N, Akyurek FT. *Dermatol Ther* 2019; 32: e12776.

Case report of using pregabalin oral therapy (25mg twice daily for the first month, then 25mg daily).

Third-Line Therapy

• Cyclosporin	E

Successful treatment with cyclosporine administration for persistent benign migratory glossitis. Abe M, Sogabe Y, Syuto T, et al. *J Dermatol* 2007; 34: 340–3.

Unusually symptomatic geographic tongue treated with 3 mg/kg/day, tapering to 1.5 mg/kg/day.

Gianotti–Crosti syndrome

Vijay Zawar, Antonio A.T. Chuh

MANAGEMENT STRATEGY

In its classical clinical presentation, Gianotti–Crosti syndrome (GCS) is not difficult to diagnose with a presentation of a young child with symmetrical, erythematous, monomorphic papules, or vesicles, on the distal extensor extremities, and sometimes on the face and gluteal areas. Itching is usually slight to moderate. Subsidence within 2–6 weeks is the rule. Recurrences are exceptional. Regional lymphadenopathy is not uncommon. Non-icteric hepatitis may be associated in hepatitis B virus (HBV)-related GCS.

Atopic children are more predisposed to acquiring GCS. A prodrome involving the respiratory tract or gastrointestinal tract may be present.

HBV was associated with the earliest reported cases of GCS, especially in Italy and other European countries. However, Epstein–Barr virus (EBV) is now the predominant association worldwide. Many other viruses have also been implicated, including hepatitis A virus (HAV), hepatitis C virus, cytomegalovirus (CMV), Coxsackievirus, adenovirus, enterovirus, human herpesvirus-6B (HHV-6B), herpes simplex viruses, reovirus, varicella, roseola, rotavirus, respiratory syncytial virus, mumps, measles, parainfluenza, molluscum contagiosum, and human immunodeficiency virus (HIV). Non-viral microbial agents have also been implicated including *Borrelia burgdorferi*, *Mycoplasma pneumoniae*, *Mycobacterium avium intracellulare*, beta-hemolytic streptococci, meningococci, and *Bartonella henselae*. GCS has also been recognized following vaccinations, including oral poliomyelitis vaccine, and vaccines against diphtheria, pertussis, measles, HBV, and H1N1 influenza.

Abnormal liver enzymes and viral parameters may be present during active systemic infection involving the liver. However, chronic hepatitis is extremely rare.

GCS is typically a self-limiting disorder. Treatment is meant for symptomatic patients, consisting of oral antihistamines and topical soothing lotions like calamine. Emollients help children with an atopic background. Topical corticosteroids may be utilized for faster resolution of persistent inflammatory lesions in highly symptomatic patients. Systemic antibiotics may be required should pruritic lesions become secondarily infected.

Antiviral treatment has no role in managing GCS, as it does not resolve the dermatitis associated with proven active systemic viral disease.

Recurrences are exceptional. The long-term prognosis is good, with the possible exception of GCS patients associated with chronic active hepatitis due to HBV. Such patients should be assessed by expert hepatologists.

Diagnostic Criteria

A set of clinical diagnostic criteria has been validated in two independent studies, including positive and negative clinical features. Patients should exhibit all positive clinical features on at least one occasion or clinical encounter, and must not exhibit any negative clinical feature on any occasion or clinical encounter related to the rash. Additionally, no differential diagnosis should be considered more likely than GCS based on clinical judgment. If a lesional biopsy is performed, findings should be consistent with GCS.

Positive clinical features include:

- Symmetrical rash
- Monomorphic, flat-topped, pink-brown papules or papulovesicles, 1–10 mm in diameter
- At least three of the following four sites involved: (i) cheeks; (ii) buttocks; (iii) extensor surfaces of forearms; and (iv) extensor surfaces of legs
- Lasting for at least 10 days

Negative clinical features include:

- Extensive truncal lesions
- Scaly lesions

Box 91.1 Common Differential Diagnoses of Gianotti–Crosti syndrome

1. Atopic dermatitis
2. Papular urticaria
3. Scabies
4. Insect bite reaction
5. Lichenoid eruptions
6. Erythema multiforme
7. Drug rash
8. Henoch–Schönlein purpura
9. Acrodermatitis enteropathica

Specific Investigations

The diagnosis of GCS is usually based on clinical criteria alone. Laboratory investigations are characteristically not required unless the patient's clinical features suggest other possibilities as noted in the differential diagnosis of GCS.

- Liver enzymes
- Viral serologies: Epstein–Barr virus, hepatitis B, hepatitis A, hepatitis C, cytomegalovirus

Gianotti–Crosti syndrome. Brandt O, Abeck D, Gianotti R, et al. *J Am Acad Dermatol* 2006; 54: 136–45.

EBV is now the most common cause of GCS. Other viruses have been associated with GCS, including HAV; CMV; HHV-6B; Coxsackie A16, B4, and B5; rotavirus; parvovirus B19, respiratory syncytial virus, mumps virus, and parainfluenza virus types 1 and 2. HIV also appears to be capable of triggering GCS. The associations between various immunizations and GCS have long been known. Despite the proven connection between HBV and GCS, immunization against HBV only rarely causes GCS.

Gianotti–Crosti syndrome in a child following hepatitis B virus vaccination. Karakas M, Durdu M, Tuncer I, et al. *J Dermatol* 2007; 34: 117–20.

A five-year-old boy presented with 1-month history of GCS. The lesions had appeared 3 weeks after a first dose of HBV recombinant vaccine.

Gianotti–Crosti syndrome in India is not associated with hepatitis B infection. Zawar V, Chuh A. *Dermatology* 2004; 208: 87.

Of 89 children clinically diagnosed as GCS, only one patient was HBsAg positive. The authors indicated that GCS was not significantly associated with HBV, at least in the Asian children.

A case-control study on the association of pulse oral polio-myelitis vaccination and Gianotti–Crosti syndrome. Zawar V, Chuh A. *Int J Dermatol* 2017; 56(1): 75–9.

The Indian government launched intensified immunization against polio in 1995 by administering oral polio vaccine on specified days annually to cover children under the age of five.

In this study, 116 cases of GCS were found to be associated with the pulse polio immunization program.

Gianotti–Crosti syndrome associated with cytomegalovirus antigenemia after bone marrow transplantation. Haki M, Tsuchida M, Kotsuji M, et al. *Bone Marrow Transplant* 1997; 20(8): 691–3. doi: 10.1038/sj.bmt.1700945.

In this case of a 3-year-old girl, GCS was related to CMV primary infection and was considered to be the presenting sign of the infection.

Atypical Gianotti–Crosti syndrome in two HIV and hepatitis B co-infected adults. Cocciolone R, Morey A, Panasiuk P. *Australas J Dermatol* 2011; 52: 32–56.

Atypical GCS in two unrelated adult male patients with coexistent hepatitis B and HIV infection are described. Immunoperoxidase studies suggested the presence of HBsAg within acute disseminated erythematous papulovesicular skin lesions.

First-Line Therapies

Topical

- Emollients E
- Antipruritic (calamine lotion) E

Systemic

- Antihistamines E

Second-Line Therapies

Topical

- Corticosteroids (low potency; e.g., hydrocortisone cream) E
- Antibiotics (if secondarily infected) E

Systemic

- Antihistamines (chlorpheniramine maleate, hydroxyzine, cetirizine) E
- Antibiotics (if secondarily infected; e.g., ampicillin, amoxicillin, erythromycin, cephalexin) E

Recurrent Gianotti–Crosti syndrome. Metelitsa AI, Fiorillo L. *J Am Acad Dermatol* 2011; 65: 876–7.

A two-year-old boy presented with GCS. Two weeks after onset of the eruption, he was immunized with influenza vaccination and new lesions appeared at the immunization site. Investigations revealed a positive urine culture for CMV and positive IgM against EBV. He was treated with hydrocortisone cream, and the eruption resolved. Twelve months later, he presented with a similar eruption at the site of influenza vaccination. Because GCS is a mild and self-limiting disease, further vaccinations are not contraindicated.

Third-Line Therapies

Topical

- Corticosteroids (mid- to high potency; e.g., mometasone, betamethasone propionate) E
- Antibiotics E

Systemic

- Corticosteroids (short course; prednisone, prednisolone) E

Antiviral agents

- Interferons (only if related to HBV infection) E
- Lamivudine (only if related to HBV infection) E
- Ribavirin E
- Aciclovir (only if related to susceptible viruses) E

Gianotti–Crosti syndrome in two adult patients. Ting PT, Barankin B, Dytoc MT. *J Cutan Med Surg* 2008; 12(3): 121–5.

This was a report of two otherwise healthy adults presenting with GCS. The authors used a potent topical steroid in one case and an additional short course of oral prednisone in another.

Efficacy of ribavirin in a case of long lasting and disabling Gianotti–Crosti syndrome. Zawar V, Chuh A. *J Dermatol Case Rep* 2008; 2: 63–6.

A six-year-old girl presented with a history of a pruritic rash consistent with GCS after a febrile illness with common cold symptoms. Remission was not achieved despite several medications: topical emollients, topical and systemic corticosteroids, topical and systemic antibiotics, and oral histamines. A course of oral ribavirin at a dose of 300 mg daily for 5 days led to dramatic remission 5 days later.

Successful treatment of hepatitis B-associated leukocytoclastic vasculitis with lamivudine treatment in a child patient. Surmeli Onay O, Baskin E, Ozçay F, et al. *Rheumatol Int* 2007; 27: 869–72.

A child diagnosed clinically as GCS was investigated and led to a final diagnosis of leukocytoclastic vasculitis, which successfully resolved with lamivudine treatment.

Gonorrhea

Ted Rosen, Avi Bitterman

Gonorrhea is a common and potentially severe sexually transmitted disease caused by the Gram-negative aerobic diplococcus *Neisseria gonorrhoeae*. This organism primarily infects the mucous membranes of the urethra, endocervix, rectum, and pharynx. The disease can also become disseminated, causing petechial or acral pustular skin lesions, tenosynovitis, arthralgia, true septic arthritis, perihepatitis, and, less commonly, endocarditis or meningitis.

MANAGEMENT STRATEGY

Individuals with gonorrhea should be treated as promptly as possible (1) to prevent regional infection such as epididymitis or pelvic inflammatory disease leading to infertility or ectopic pregnancy; (2) to prevent disseminated gonococcal infection, which occurs in about 1%–3% of cases; and (3) to stop transmission to sexual partners. Prompt management has become especially important due to a resurgence in incidence of gonococcal disease in the United States and increasing multidrug antimicrobial resistance worldwide.

Gonococcal urethritis is typically characterized by mucopurulent to frankly purulent discharge along with a burning sensation during urination. Dysuria may be the only symptom.

Gonococcal cervicitis is characterized by a mucopurulent or purulent endocervical exudate. However, a cervical discharge is not specific for a gonococcal infection, and gonococcal infection of the cervix is often asymptomatic.

Pharyngeal infection is asymptomatic in more than 90% of cases, but when symptomatic it presents as a pharyngitis of variable severity.

Rectal infection is prevalent in homosexual men, causing anal discharge and pain. In women, rectal infection results from spread through vaginal secretions and does not necessarily imply anal intercourse.

Patients infected with *N. gonorrhoeae* are often coinfecting with *Chlamydia trachomatis* and should be treated with *azithromycin* to cover this organism, with or without diagnostic evidence of chlamydial disease. Patients with gonorrhea have engaged in unprotected intercourse and, therefore, always should be tested for both syphilis and HIV.

Patients should be instructed to return for evaluation if symptoms persist or recur after therapy and to abstain from sexual intercourse until they and their sexual partners are cured. Because reinfection is so common, the Centers for Disease Control (CDC) recommends that all patients with known gonorrhea return for retesting 3 months posttreatment. A test of cure 3–4 weeks post-treatment is no longer recommended.

Antimicrobial resistance is a real and increasing threat, and treatment options for gonococcal disease are increasingly limited. To abate further spread of resistant strains of *N. gonorrhoeae*, physicians should strongly encourage patient referral of any sexual partner within the preceding 60 days for evaluation and treatment and obtain culture(s) to evaluate individual antimicrobial susceptibility in any patient whose symptoms do not resolve with initial treatment.

Specific Investigations

Men

- Microscopic examination of Gram-stained urethral secretions
- Culture on Thayer–Martin medium
- Non-culture test based upon immunodiagnosics, as available

Women

- Culture on Thayer–Martin medium
- Non-culture test based upon immunodiagnosics, as available

Diagnosis and treatment of urethritis in men. Brill JR. Am Fam Physician 2010; 1; 81: 873–8.

In the context of male urethritis without discharge, recommended tests include urinalysis with microscopy in conjunction with venereal disease research laboratory or rapid plasma regain test, in addition to HIV and hepatitis B testing. If urine test results are negative, treatment should be deferred unless the patient is at high risk of sexually transmitted infections and is unlikely to return for treatment. Gonorrhea is uncommon in patients without discharge.

Sexually transmitted diseases treatment guidelines, 2015. Workowski KA, Bolan GA; Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 1–137.

Because of its high specificity (>99%) and sensitivity (>95%), a Gram stain of a male urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular Gram-negative diplococci can be considered diagnostic for infection with *N. gonorrhoeae* in symptomatic men. Culture is the most widely available option for diagnosis in asymptomatic men, in women, and in non-genital sites (rectum and pharynx). Non-culture tests cannot provide antimicrobial susceptibility results, but can rapidly and accurately confirm a clinical diagnosis.

Screening tests to detect *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections – 2002. Johnson RE, Newhall WJ, Papp JR, et al. MMWR Recomm Rep 2002; 51: 1–38.

Non-culture tests called nucleic acid hybridization tests and nucleic acid amplification tests (NAATs) have been developed. Commercial NAATs differ in their amplification methods and their target nucleic acid sequences. The majority of commercial NAATs have been cleared by the Food and Drug Administration to detect *C. trachomatis* and *N. gonorrhoeae* in endocervical swabs and urethral swabs from men. The sensitivity of NAATs might be less when

using urine than when using an endocervical swab. Testing of rectal and oropharyngeal specimens with NAATs is not recommended.

First-Line Therapies for Uncomplicated Gonorrhea of the Cervix, Urethra, Rectum, Pharynx, and Conjunctiva

- Ceftriaxone 250 mg intramuscularly (IM) in a single dose + azithromycin 1 g orally **B**
- Only if ceftriaxone is NOT immediately available: cefixime 400 mg orally in a single dose + azithromycin 1 g orally **B**

Sexually transmitted diseases treatment guidelines, 2015. Workowski KA, Bolan GA; Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 1–137.

The minimum concentrations of cefixime needed to inhibit in vitro growth of the *N. gonorrhoeae* strains circulating in the United States and many other countries have progressively increased since 2006. This suggests that the effectiveness of cefixime might be waning. In addition, treatment failures with cefixime (or other similar oral cephalosporins) have been reported in Asia, Europe, South Africa, and Canada. As a result, the CDC no longer recommends the routine use of cefixime as a first-line regimen for treatment of gonorrhea at any anatomic site in the United States. Ceftriaxone in a single injection of 250 mg is a safe, effective dose for uncomplicated gonococcal infection at all anatomic sites. However, ceftriaxone failures have also been rarely reported. Consequently, only one regimen, dual treatment with ceftriaxone and azithromycin, is currently recommended for gonorrhea treatment at all anatomic sites in adults. All patients with gonorrhea should also be treated with azithromycin to (1) treat possible coinfection with *Chlamydia trachomatis*; and (2) gain additive microcidal effects for *N. gonorrhoeae*.

First *Neisseria gonorrhoeae* strain with resistance to cefixime causing gonorrhoea treatment failure in Austria, 2011. Unemo M, Golparian D, Sary A, et al. Euro Surveill 2011; 16: 1–3.

Globally the susceptibility of *N. gonorrhoeae* to antimicrobial therapy, including first-line treatment options ceftriaxone and cefixime, is decreasing.

Epidemiological trends of antibiotic resistant gonorrhoea in the United Kingdom. Whittles LK, White PJ, Paul J, et al. Antibiotics (Basel) 2018; 7(3): 60.

In the UK, gonococcal resistance to tetracycline, ciprofloxacin, and penicillin is high, with resistance levels in 2016 at 41%, 34%, and 14%, respectively. Resistance to cefixime peaked at 6% in 2010 but has fallen to 2% since cefixime was removed from the recommended first-line treatments.

Second-Line Therapies (No Advantage over First-Line Therapies)

- Ceftriaxone 500 mg IM as a single dose + azithromycin 1 g orally **B**
- Cefixime 2 g IM with probenecid 1 g orally + azithromycin 1 g orally **B**
- Cefotaxime 500 mg IM as a single dose + azithromycin 1 g orally **B**

***Neisseria gonorrhoeae* with high-level resistance to azithromycin: case report of the first isolate identified in the United States.** Katz AR, Komeya AY, Soge OO, et al. CID 2012; 54: 841–3.

Eight isolates with reduced susceptibility to azithromycin were identified in Hawaii followed by laboratory documentation of the first isolate with high-level azithromycin resistance in California. Previously, strains with high-level resistance had been documented in Argentina, Scotland, England, Wales, and Ireland.

Update to CDC's sexually transmitted diseases treatment guidelines 2006: fluoroquinolones no longer recommended for treatment of gonococcal infections. Centers for Disease Control and Prevention. MMWR Morb Mortal Wkly Rep 2007; 56: 332–6.

Due to the increasing resistance, the CDC no longer recommends the use of fluoroquinolones for patients who acquired their infection in the United States, Asia, or the Pacific Islands. Recent data suggest that resistant strains comprise about 13% of all American-acquired isolates. Fluoroquinolones remain off the recommended treatment list for gonorrhea 10 years later.

Surveillance of antibiotic resistance in *Neisseria gonorrhoeae* in the WHO Western Pacific and South East Asian Regions, 2009. WHO Western Pacific and South East Asian Gonococcal Antimicrobial Surveillance Programmes. Commun Dis Intell 2011; 35: 2–7.

Recent data from China, Hong Kong, Japan, and elsewhere in Asia also demonstrate a very high rate of fluoroquinolone resistance. Australia and New Zealand are experiencing 35%–45% of isolates being quinolone resistant.

Annual report of the Australian Gonococcal Surveillance Programme, 2010. Australian Gonococcal Surveillance Programme. Commun Dis Intell 2011; 35: 229–36.

Penicillin has been removed from the standard treatment regimen in Australia because of nationwide isolate resistance (up to 44% in some regions). However, in remote areas of Australia with extremely high disease rates, treatment with penicillin often remains effective. The same is also true in other industrialized countries.

Gentamicin compared with ceftriaxone for the treatment of gonorrhoea (G-ToG): a randomised non-inferiority trial. Ross JDC, Brittain C, Cole M, et al. Lancet 2019; 393: 2511–20.

A randomized controlled trial ($n=328$) failed to find non-inferiority of a single dose of gentamycin 240 mg IM compared with a single dose of ceftriaxone 500 mg IM in adults with uncomplicated genital, pharyngeal, or rectal gonorrhea. When comparing ceftriaxone with gentamycin, clearance rates for genital, pharyngeal, and rectal infections were 98% vs. 94%, 96% vs. 80%, and 98% vs. 90%, respectively. In the context of cephalosporin-resistant gonococcal infection or in patients allergic to cephalosporins, gentamycin may be a useful alternative. However, gentamycin is not appropriate as a first-line treatment for gonorrhea.

***Neisseria gonorrhoeae* antimicrobial susceptibility surveillance — The Gonococcal Isolate Surveillance Project, 27 sites, United States, 2014.** Kirkcaldy RD, Harvey A, Papp JR, et al. MMWR Surveill Summ 2016; 65: 1–19.

This is the first report to present comprehensive surveillance data from the US Gonococcal Isolate Surveillance Project and summarize gonococcal susceptibility over time, as well as underscore the public health implications of emerging cephalosporin

resistance. Antimicrobial susceptibility patterns vary by geographic region within the United States and by sex of sexual partner. For example, the percentage of isolates resistant to tetracycline, ciprofloxacin, penicillin, or all three antimicrobials was greater in isolates from men who have sex with men than from men who exclusively have sex with women. Because dual therapy with ceftriaxone plus azithromycin is the only recommended gonorrhea treatment, increases in azithromycin and cephalosporin minimal inhibitory concentrations are cause for concern that resistance to these antimicrobial agents might be emerging. Reduced azithromycin susceptibility (defined as minimum inhibitory concentration ≥ 2.0 mcg/mL) increased from 0.6% in 2013 to 2.5% in 2014. It is unclear whether increases in the percentage of isolates with reduced susceptibility to azithromycin mark the beginning of an adverse trend.

SPECIAL CONSIDERATIONS

Pharyngeal Infection

Sexually transmitted diseases treatment guidelines, 2015. Workowski KA, Bolan GA; Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 1–137.

Few antimicrobial regimens, including those involving oral cephalosporins, can reliably cure >90% of gonococcal pharyngeal infections. The recommended treatment for uncomplicated gonococcal infections of the pharynx is ceftriaxone 250 mg IM in a single dose and azithromycin 1 g orally in a single dose.

Disseminated Gonococcal Infection

Hospitalization is recommended for initial therapy. The experts recommend ceftriaxone 1 g intramuscularly or intravenously every 24 hours as the initial regimen, plus azithromycin 1 g orally as a single dose. The provider can switch to an oral agent guided by antimicrobial susceptibility testing 24–48 hours after substantial clinical improvement, for a total treatment course of at least 7 days. Acceptable alternative therapies include cefotaxime or ceftizoxime, with both drugs given in a dosage of 1 g intravenously every 8 hours, along with a single dose of azithromycin (1 g).

Antibiotics for treating gonorrhoea in pregnancy. Comuñán-Carrasco G, Peña-Martí GE, Martí-Carvajal AJ. Cochrane Database Syst Rev 2018; CD011167.

A Cochrane review found two randomized controlled trials regarding the treatment of gonorrhea in pregnancy. One trial compared ceftriaxone 125 mg IM with cefixime 400 mg oral, and the other trial assessed a higher dose of ceftriaxone 250 mg IM versus either one dose of amoxicillin 3 g oral plus probenecid 1 g oral, or spectinomycin 2 g IM. Spectinomycin data was not included as it is no longer available in the USA. Cure rates were as follows: ceftriaxone 125 mg IM (95.2%), cefixime 400 mg

(96.2%), amoxicillin 3 g plus oral probenecid 1 g (89.3%), ceftriaxone 250 mg IM (95.5%). There was not enough evidence to support one particular regimen over another.

The CDC currently recommends dual therapy of ceftriaxone 250 mg IM in a single dose and azithromycin 1 g orally in a single dose as first-line treatment for pregnant women infected with N. gonorrhea.

Ophthalmia Neonatorum

To prevent gonococcal ophthalmia neonatorum, a prophylactic agent should be instilled into both eyes of all newborn infants; this procedure is, in fact, required by law in most states. Prophylaxis consists of erythromycin (0.5%) ophthalmic ointment in each eye in a single application at birth. Ocular prophylaxis is warranted because it can prevent sight-threatening gonococcal ophthalmia, has an excellent safety record, is easy to administer, and is inexpensive. Gonococcal ophthalmia is strongly suggested when typical Gram-negative diplococci are identified in conjunctival exudate, justifying presumptive treatment after appropriate cultures have been obtained. The recommended regimen is ceftriaxone 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg. Local treatment, with or without systemic antibiotics, is inappropriate.

Men Who Have Sex with Men

Gonorrhea screening among men who have sex with men: value of multiple anatomic site testing, San Diego, California, 1997–2003. Gunn RA, O'Brien CJ, Lee MA, et al. Sex Transm Dis 2008; 35: 845–8.

This population should be screened annually for gonorrhea infection at the urethral, pharyngeal, and rectal sites.

The CDC also now recommends annual screening for N. gonorrhoeae infection for all sexually active women aged <25 years and for older women at increased risk for infection (e.g., those who have a new sex partner, more than one sex partner, a sex partner with concurrent partners, or a sex partner who has a sexually transmitted infection [STI]). Additional risk factors for gonorrhea include inconsistent condom use among persons who are not in mutually monogamous relationships, previous or coexisting sexually transmitted infections, and exchanging sex for money or drugs. Individuals who fall into those categories should also be screened annually.

Treatment Failure

Patients with suspected treatment failure or persons infected with a strain found to demonstrate in vitro resistance should consult an infectious disease specialist, where the use of gentamicin or gemifloxacin may be entertained. Patients should be retreated with at least 250 mg of ceftriaxone IM or IV and ensure partner treatment. The situation should be promptly reported to public health agencies.

Graft-versus-host disease

Melissa Hoffman, Robert G. Micheletti

Graft-versus-host disease (GVHD) is the most significant source of morbidity and mortality among survivors of allogeneic hematopoietic stem cell transplantation, occurring in 30%–70% of transplant recipients. Affecting the skin, liver, gastrointestinal tract, and other organs, it occurs when donor immune cells (the graft) recognize the transplant recipient (host) as foreign, resulting in inflammation and end organ damage. Of the organs involved, the skin is the most common and often the most severely affected.

MANAGEMENT STRATEGY

The risk, timing, presentation, and treatment of GVHD depend on many factors, including the type of transplant, the degree of human leukocyte antigen (HLA) mismatch, donor and recipient sex, the intensity of pretransplant conditioning, and the GVHD prophylactic regimen used. Evolution of transplant strategies, such as reduced-intensity conditioning, increasing age of some transplant recipients, novel prophylaxis and treatment regimens, and donor lymphocyte infusion, together with improved recognition of overlap phenomena and late-onset acute GVHD, have blurred the classic understanding of a temporally defined disease. Acute and chronic GVHD are best differentiated on the basis of clinical manifestations because features of either may occur at any time posttransplant. Atypical manifestations, particularly of chronic GVHD, can mimic other dermatologic diseases and present a diagnostic dilemma; input of a dermatologist and skin biopsy, when appropriate, can help shape diagnosis and management.

Initial management of GVHD includes adjustment of GVHD prophylaxis. Optimization of organ-specific supportive care and *topical therapies* may be sufficient for mild cutaneous GVHD, whereas in more severe disease, maximizing topical care can minimize the need for systemic immunosuppression and related side effects. For moderate or severe GVHD, *systemic corticosteroids* are first-line therapy, but in many cases GVHD becomes steroid

refractory or dependent. Evidence for second- and third-line therapies is derived from small trials or series and is frequently contradictory. The optimal approach in patients with steroid-refractory acute or chronic GVHD is therefore not known. Commonly used agents with reported activity and adequate safety profiles include *calcineurin inhibitors*, *extracorporeal photopheresis*, *mycophenolate mofetil*, *mTOR inhibitors*, *ruxolitinib*, and several others. Additional skin-directed therapies such as *narrowband ultraviolet B (NB-UVB)* and *psoralen and ultraviolet A (PUVA)* phototherapy can benefit some patients.

Future work to identify effective therapies, using standardized criteria, is needed. In addition to aiding diagnosis and optimizing skin-directed therapies, dermatologists can play an important role in assessment of response, severity scoring, and research.

ACUTE GVHD

Specific Investigations

- Skin biopsy
- Medication history
- Liver function tests
- Complete blood count
- Serum chemistry
- Biomarker panel (investigational)
- Consider viral testing (e.g., cytomegalovirus)
- Consider colonoscopy/endoscopy

Clinical differentiation of acute cutaneous graft-versus-host disease from drug hypersensitivity reactions. Byun HJ, Yang JJ, Kim BK, et al. *J Am Acad Dermatol* 2011; 65: 726–32.

Cutaneous manifestations of acute GVHD are generally non-specific. However, a morbilliform eruption involving the face (including pinnae), palms, and soles is suggestive of acute GVHD (aGVHD), as is the presence of diarrhea or hyperbilirubinemia, typically developing within 2–3 days of rash onset. Absence of these findings favors a diagnosis of drug hypersensitivity reaction but does not rule out GVHD.

Quantitative analysis of eosinophils in acute graft-versus-host disease compared with drug hypersensitivity reactions. Weaver J, Bergfeld WF. *Am J Dermatopathol* 2010; 32: 31–4.

Interface dermatitis with basilar vacuolization and dyskeratotic keratinocytes with satellite cell necrosis are characteristic but non-specific histologic findings of GVHD. Only significant tissue eosinophilia (≥ 16 eosinophils per 10 high-powered fields) safely excludes aGVHD in favor of drug hypersensitivity reaction. Therefore, the decision to diagnose and treat aGVHD should not depend on skin biopsy findings.

An early-biomarker algorithm predicts lethal graft-versus-host disease and survival. Hartwell M, Ozbek U, Holler E, et al. *JCI Insights* 2017; 2: e89798.

Serum biomarkers to help diagnose and predict the severity and outcome of GVHD are under investigation but are not yet available for clinical use. A biomarker algorithm based on blood samples taken 7 days after hematopoietic stem cell transplantation identifies patients at high risk for lethal GVHD and non-relapse mortality. The algorithm uses ST2 and REG3 α concentrations to identify a high-risk group with 28% non-relapse mortality, compared with a low-risk group with non-relapse mortality of 7% ($p < 0.001$).

First-Line Therapies

- Topical corticosteroids **D**
- Systemic corticosteroids (methylprednisolone 1–2 mg/kg/day) **B**

Topical corticosteroids, along with sensitive skin care measures and optimization of prophylactic medications (e.g., ciclosporin, tacrolimus, methotrexate), may be sufficient therapy for mild cutaneous grade I aGVHD (defined as cutaneous GVHD involving ≤50% body surface area [BSA] without liver or gastrointestinal [GI] involvement).

Effectiveness and safety of lower dose prednisone for initial treatment of acute graft-versus-host disease: a randomized controlled trial. Mielcarek M, Furlong T, Storer BE, et al. Haematologica 2015; 10: 842–8.

For patients with grade II or higher aGVHD (skin involvement >50% BSA or with any liver or GI involvement), systemic corticosteroids are the mainstay of initial therapy, typically 2 mg/kg/day prednisone equivalent in divided doses, followed by gradual taper. A randomized controlled trial comparing standard vs. lower dose (0.5–1 mg/kg/day) glucocorticoids showed that initial treatment of aGVHD with lower-dose prednisone may be sufficient.

Second-Line Therapies

- Ruxolitinib **B**
- Mycophenolate mofetil **C**
- Extracorporeal photopheresis **C**
- Etanercept **C**
- Calcineurin inhibitors (tacrolimus, ciclosporin) **C**
- α1-antitrypsin **C**

For patients with glucocorticoid-resistant acute GVHD, ruxolitinib is now the favored second-line agent on the basis of superior efficacy data and side-effect profile.

Ruxolitinib for glucocorticoid-refractory acute graft-versus-host disease. Zeiser R, von Bubnoff N, Butler J, et al.; REACH2 Trial Group. N Engl J Med 2020; 382: 1800–10.

In this randomized, multicenter, phase 3 trial of 309 patients with glucocorticoid-refractory aGVHD, those assigned to receive ruxolitinib 10 mg twice daily had response rates superior to those receiving alternative therapies, such as mycophenolate mofetil, sirolimus, etc. (62% versus 39%, respectively; OR 2.64, 95% CI 1.65–4.22). Ruxolitinib is now approved by the US Food and Drug Administration (FDA) for treatment of steroid-refractory acute GVHD.

Etanercept, mycophenolate, denileukin, or pentostatin plus corticosteroids for acute graft-versus-host disease: a randomized phase 2 trial from the Blood and Marrow Transplant Clinical Trials Network. Alousi AM, Weisdorf DJ, Logan BR, et al. Blood 2009; 114: 511–7.

In this randomized, phase II trial, the addition of mycophenolate to systemic corticosteroids resulted in higher complete response and overall survival rates and fewer infectious complications than did prednisone combined with etanercept, pentostatin, or denileukin diftitox.

Phase 3 clinical trial of steroids/mycophenolate mofetil vs steroids/placebo as therapy for acute GVHD: BMT CTN 0802. Bolaños-Meade J, Logan BR, et al. Blood 2014; 124: 3221–7.

Although mycophenolate mofetil appears to be more effective than other second-line agents for aGVHD (except ruxolitinib) and is commonly used for this purpose, its actual efficacy appears to be limited. This phase III randomized, double-blind trial was ended early for futility after showing no benefit to therapy with glucocorticoids plus mycophenolate versus glucocorticoids alone.

Etanercept plus methylprednisolone as initial therapy for acute graft-versus-host disease. Levine JE, Paczesny S, Mineishi S, et al. Blood 2008; 111: 2470–5.

A regimen of etanercept plus corticosteroids was more likely to achieve complete response (69% vs. 33%) and 100-day survival (82% vs. 66%) than were steroids alone.

α1-Antitrypsin infusion for treatment of steroid-resistant acute graft-versus-host disease. Magenau J, Goldstein S, Peltier D, et al. Blood 2018; 131: 1372–9.

A total of 40 patients were treated with α1-antitrypsin for up to 4 weeks at a dose of 60 mg/kg every 4 days in this prospective, multicenter phase II trial. The overall response rate was 65% (26/40 patients). Of these patients, 14 had a complete response, and 12 had a partial response. At 30 days posttreatment cessation, a sustained response was observed in 73% (19 of 26) of the responders.

Extracorporeal photopheresis versus anticytokine therapy as a second-line treatment for steroid-refractory acute GVHD: a multicenter comparative analysis. Jagasia M, Greinix H, Robin M, et al. Biol Blood Marrow Transplant 2013; 19: 1129–33.

A retrospective analysis of 98 patients with steroid-refractory aGVHD receiving photopheresis revealed superior complete response rates (54% vs. 20%) and survival compared with those receiving anticytokine therapy (etanercept or inolimomab). The safety profile of extracorporeal photopheresis was excellent.

Third-Line Therapies

- Pentostatin **C**
- Anti-CD52 antibody (alemtuzumab) **C**
- mTOR inhibitors (sirolimus) **C**
- Infliximab **C**
- Interleukin-2 receptor antibodies (basiliximab) **C**
- Mesenchymal stem cells **B**
- Methotrexate **C**
- Tocilizumab **C**
- Antithymocyte globulin **C**
- Denileukin diftitox **C**
- PUVA **C**
- Narrowband UVB **C**

Diagnosis and management of acute graft-versus-host disease. Dignan FL, Clark A, Amrolia P, et al. Br J Haematol 2012; 158: 30–45.

Evidence-based guidelines for aGVHD are reviewed. Pentostatin, alemtuzumab, mesenchymal stem cells, and methotrexate are among third-line therapies used after second-line agents have failed or in the context of clinical trials. Most such drugs have limited or negative/conflicting data.

Other agents with a possible therapeutic role in steroid-refractory aGVHD include infliximab, anti-IL-2 receptor antibodies, tocilizumab, antithymocyte globulin, and others.

Basiliximab for the treatment of steroid-refractory acute graft-versus-host disease after unmanipulated HLA-mismatched/haploidentical hematopoietic stem cell transplantation. Wang JZ, Liu KY, Xu LP, et al. *Transplant Proc* 2011; 43: 1928–33.

The chimeric IL-2 receptor antagonist basiliximab yielded a therapeutic response in 46/53 patients with steroid-refractory aGVHD.

Effective treatment of steroid and therapy-refractory acute graft-versus-host disease with a novel mesenchymal stromal cell product (MSC-FFM). Bader P, Kuçi Z, Bakhtiar S, et al. *Bone Marrow Transplant* 2018; 53: 852–62.

This study included 69 patients with treatment-refractory acute GVHD treated with mesenchymal stromal cells (MSC-FFM). On day 28, the overall response was 83%, 22 (32%) with a complete response and 35 (51%) with a partial response.

Sirolimus for treatment of steroid-refractory acute graft-versus-host disease. Hoda D, Pidala J, Salgado-Vila N, et al. *Bone Marrow Transplant* 2010; 45: 1347–51.

Sirolimus was initiated in 34 patients with steroid-refractory aGVHD. The overall response rate was 76%, with 44% achieving complete response. Complications included myelosuppression and hemolytic uremic syndrome.

Narrowband ultraviolet B phototherapy for treatment of steroid-refractory and steroid-dependent acute graft-versus-host disease. Feldstein JV, Bolaños-Meade J, Anders VL, et al. *J Am Acad Dermatol* 2011; 65: 733–8.

Of 14 patients with skin-predominant, steroid-refractory or dependent aGVHD, 11 had a complete or partial response, suggesting NB-UVB phototherapy is a potentially effective and low-risk skin-directed therapy for selected patients with aGVHD.

CHRONIC GVHD

Specific Investigations

- Skin biopsy
- Liver function tests
- Complete blood count
- Quality-of-life assessment
- Range of motion/physical therapy evaluation
- Pulmonary function tests
- Schirmer test
- Evaluation of other organs (ocular, oral, genital, gastrointestinal, musculoskeletal)

National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and staging working group report. Filipovich AH, Weisdorf D, Pavletic S, et al. *Biol Blood Marrow Transplant* 2005; 11: 945–56.

Cutaneous signs that are considered diagnostic of chronic GVHD (cGVHD) include poikiloderma; lichen planus-like lesions; and lichen sclerosis-like, morphea-like, and sclerotic features. Standardization of response criteria, staging, and grading are detailed.

Atypical manifestations of graft-versus-host disease. Cornejo CM, Kim EJ, Rosenbach M, et al. *J Am Acad Dermatol* 2015; 72: 690–5.

Numerous common and atypical manifestations of GVHD may be seen. Biopsy or additional investigations may help confirm a diagnosis of cGVHD in patients without diagnostic features.

First-Line Therapies

• Systemic corticosteroids	B
• Systemic corticosteroid and calcineurin inhibitor	C

Organ-specific management and supportive care in chronic graft-versus-host disease. Dignan FL, Scarisbrick JJ, Cornish J, et al. *Br J Haematol* 2012; 158: 62–78.

The choice of initial therapy depends on disease severity, organ involvement, and other factors. Organ-specific supportive care (e.g., emollients, sun protection), topical corticosteroids, and topical calcineurin inhibitors (tacrolimus and pimecrolimus) are skin-directed therapies that can help minimize the need for toxic systemic agents. There are no randomized controlled trials of these therapies for cGVHD, but they are used widely and considered best practice.

Diagnosis and management of chronic graft-versus-host disease. Dignan FL, Amrolia P, Clark A, et al. *Br J Haematol* 2012; 158: 46–61.

For those with moderate or severe cGVHD, corticosteroids are first-line systemic therapy, usually beginning at a daily dose of 1 mg/kg prednisone tapered slowly based on clinical response. There are no randomized studies comparing standard to higher or lower steroid doses. Optimization of skin-directed therapies may enable dose reduction in those with skin-limited cGVHD.

Therapy for chronic graft-versus-host disease: a randomized trial comparing cyclosporine plus prednisone versus prednisone alone. Koc S, Leisenring W, Flowers ME, et al. *Blood* 2002; 100: 48–51.

Initial treatment with prednisone plus ciclosporin may reduce some steroid-related toxicities compared with treatment with prednisone alone, but there is no difference in mortality or time at which therapy can be discontinued. Randomized trials of other agents for the initial treatment of cGVHD have failed to show benefit compared with prednisone alone.

Second-Line Therapies

• Calcineurin inhibitors (tacrolimus, ciclosporin)	C
• Extracorporeal photopheresis	C
• Mycophenolate mofetil	C
• Ruxolitinib	C
• Rituximab	B
• mTOR inhibitors (sirolimus, everolimus)	C
• Ibrutinib	C
• UVB, NB-UVB	C
• PUVA, UVA1	C

Consensus conference on clinical practice in chronic GVHD: second-line treatment of chronic graft-versus-host disease. Wolff D, Schleuning M, von Harsdorf S, et al. *Biol Blood Marrow Transplant* 2011; 17: 1–17.

Additional therapy is warranted for those with cGVHD that progresses despite 1 mg/kg/day prednisone for 2 weeks, fails to respond after 4–6 weeks of therapy, or flares with attempts to taper below 0.5 mg/kg/day. Initial second-line therapy should include agents with documented activity and adequate safety

profiles, such as calcineurin inhibitors, extracorporeal photopheresis, mycophenolate mofetil, mTOR inhibitors, imatinib, or rituximab. Unfortunately, without available predictors of response, 'trial and error' is the only way to determine efficacy of a particular agent or combination regimen for a given patient.

Extracorporeal photopheresis for the treatment of acute and chronic graft-versus-host disease in adults and children: best practice recommendations from an Italian Society of Hemapheresis and Cell Manipulation (SIdEM) and Italian Group for Bone Marrow Transplantation (GITMO) consensus process. Pierelli L, Perseghin P, Marchetti M, et al. *Transfusion* 2013; 53: 2340–52.

Among 735 patients with steroid-resistant or dependent cGVHD included for review, photopheresis resulted in a response rate of 50%–65% (complete response 30%–35%). Approximately 25%–35% of patients were able to taper steroid use significantly.

Efficacy of mycophenolate mofetil in the treatment of chronic graft-versus-host disease. Lopez F, Parker P, Nademane A, et al. *Biol Blood Marrow Transplant* 2005; 11: 307–13.

Eighteen of 24 (75%) patients receiving mycophenolate mofetil as second-line therapy responded to treatment, and 14 of 22 (64%) patients on prednisone were able to taper the dose of steroids. Complications included gastrointestinal side effects, hematologic toxicities, and infectious episodes.

Ruxolitinib in corticosteroid-refractory graft-versus-host disease after allogeneic stem cell transplantation: a multicenter survey. Zeiser R, Burchert A, Lengerke C, et al. *Leukemia* 2015; 29: 2062–8.

In a multicenter retrospective study, 35 of 41 (85%) patients with steroid-refractory cGVHD responded to the JAK1/2 inhibitor ruxolitinib. Relapse rate was low at 6% (2/35). Complications included cytopenias and cytomegalovirus reactivation.

Rituximab-based first-line treatment of cGVHD after allogeneic SCT: results of a phase 2 study. Malard F, Labopin M, Yakoub-Agha I, et al. *Blood* 2017; 130: 2186–95.

This prospective, multicenter, phase II study included 24 patients with a new diagnosis of cGVHD. Rituximab was added to the first-line treatment of corticosteroids and ciclosporin. At 1 year, the overall response rate was 83%, including seven patients with a complete response and 13 with a partial response. Fourteen patients were able to taper off corticosteroids, and four reduced the dose by $\geq 30\%$.

Therapy of sclerodermatous chronic graft-versus-host disease with mammalian target of rapamycin inhibitors. Jedlickova Z, Burlakova I, Bug G, et al. *Biol Blood Marrow Transplant* 2011; 17: 657–63.

Thirty-four patients with severe scleroderma-like cGVHD had an overall response rate of 76% to sirolimus or everolimus. Hyperlipidemia, poor wound healing, cytopenias, infections, and thrombotic microangiopathy were seen in a minority.

Ibrutinib for chronic graft-versus-host disease after failure of prior therapy. Miklos D, Cutler CS, Arora M, et al. *Blood* 2017; 130: 2243–50.

This phase 1b/2 study evaluated the safety and efficacy of ibrutinib in 42 patients with cGVHD who had failed treatment with systemic corticosteroids. The overall response rate was 67%, with 21% of patients having a complete response and 45% having a partial response. Of the 28 patients with a response, 20 (71%) had a sustained response for 20 or more

weeks. Responders were able to lower corticosteroid doses successfully. Based on these results, the FDA approved ibrutinib for the treatment of adults with cGVHD who have failed one or more systemic therapy.

Graft-versus-host disease: Part II. Management of cutaneous graft-versus-host disease. Hymes SR, Alousi AM, Cowen EW. *J Am Acad Dermatol* 2012; 66: 535.

PUVA, PUVA bath, UVB, NB-UVB, and UVA1 have all shown efficacy for cGVHD in small series. UVB and NB-UVB may work best for lichen planus–like manifestations, whereas PUVA and UVA1 penetrate more deeply and are better suited for scleroderma-like disease.

Third-Line Therapies

1 Systemic

• Pulse corticosteroids	C
• Interleukin-2	B
• Imatinib	B
• Pentostatin	B
• Thalidomide	C
• Low-dose methotrexate	C
• Hydroxychloroquine	C
• Infliximab	C
• Etanercept	C
• Alefacept	C
• Alemtuzumab	C
• Cyclophosphamide	C
• Etreinate/isotretinoin/acitretin	C
• Clofazimine	C
• Thoracoabdominal irradiation	C
• Mesenchymal stromal cell therapy	C

2 Oral GVHD

• Topical corticosteroids	C
• Topical calcineurin inhibitors	C
• Intraoral PUVA	C
• Oral UVB	C

Efficacy, durability, and response predictors of low-dose interleukin-2 therapy for chronic graft-versus-host disease. Koreth J, Kim HT, Jones KT, et al. *Blood* 2016; 128: 130–7.

Low-dose IL-2 stimulates T-regulatory cell expansion. Of 33 evaluable patients with steroid-refractory cGVHD in this phase 2 trial, 20 (61%) had clinical response by week 12, and 10 (30%) had stable disease.

Long-term outcome and prospective validation of NIH response criteria in 39 patients receiving imatinib for steroid-refractory chronic GVHD. Olivieri A, Cimminiello M, Corradini P, et al. *Blood*. 2013; 122: 4111–8.

In a prospective trial of imatinib for steroid-refractory cGVHD, 20 of 39 (51.3%) patients responded per NIH criteria.

Phase II study of pentostatin in patients with corticosteroid-refractory chronic graft-versus-host disease. Jacobsohn DA, Chen AR, Zahurak MJ, et al. *J Clin Oncol* 2007; 25: 4255–61.

Fifty-eight heavily pretreated patients (median four prior regimens) with cGVHD were given pentostatin 4 mg/m² every 2 weeks for 12 doses. The overall response rate was 32 of 58 (55%), with major improvements seen in 31 patients. Survival was 70% at 2 years, with infectious complications predominant.

Granuloma annulare

Bridget E. Shields, Misha Rosenbach

Granuloma annulare (GA) is an inflammatory cutaneous disease thought to be driven by immune mechanisms. Previous studies have suggested that some variants of GA represent delayed-type (type IV) hypersensitivity reactions to an unknown variety of antigenic triggers. GA may occur as an isolated, idiopathic entity but has also been described in association with multiple systemic processes. Diabetes, dyslipidemia, and thyroid disease are the most commonly reported associated conditions (though contrary studies exist as well); however, GA has also been reported in association with infections and, rarely, some malignancies. This relationship may be coincidental rather than correlative. GA-associated infections include human immunodeficiency virus (HIV), infectious hepatitis, and *Borrelia burgdorferi* most commonly; however, conflicting evidence surrounding the strength of these associations exists. GA developing in the setting of hepatitis C infection, and improving with interferon- α therapy, has been reported and screening for hepatitis C is recommended. GA has developed after bacillus Calmette-Guérin, hepatitis B, tetanus and diphtheria toxoid, and anti-tetanus vaccination. The health benefits of vaccinations greatly outweigh the exceedingly rare and potential risks of GA development in all cases. GA has developed as an isotopic response at prior sites of herpes zoster infection. While a temporal relationship between GA and malignancy has occasionally been reported, recent studies suggested there is no consistent causative link. Expert consensus remains that age appropriate screening is indicated, but extended malignancy screening should be considered in older patients with extensive GA, or those with widespread, atypical (such as palmar plaques), or recalcitrant disease.

GA encompasses a spectrum of disease and may be localized GA (LGA) or generalized GA (GGA). Children may present with subcutaneous GA, which often self-resolves in adolescence. LGA is the most common variant and is characterized by pink to red, arciform and annular, non-scaly papules and plaques on the extremities. Other variants include perforating, patch, and palmoplantar forms of GA. Histology shows palisading (about one-third of cases) or interstitial (about two-thirds of cases) granulomatous inflammation with a central core of necrobiotic collagen surrounded by a lymphohistiocytic infiltrate, typically with mucin.

MANAGEMENT STRATEGY

LGA is often diagnosed clinically, but a skin biopsy may be required to exclude other entities or confirm the diagnosis of less common variants. Patients with GA may benefit from screening for diabetes, hyperlipidemia, thyroid disease, and hepatitis C.

Approximately half of LGA cases are self-limiting within 2 years. As most patients are asymptomatic, reassurance that the disease is benign and may resolve spontaneously is sufficient. For patients with symptomatic or cosmetically sensitive lesions, treatment may be desired. There have been numerous reported treatment options for GA; unfortunately, a review of GA publications shows the median number of patients per study was one over a 25-year period.

LGA may be treated with topical or intralesional steroids. Super-potent topical steroids under occlusion with a hydrocolloid dressing, changed weekly, can be used for up to 6 weeks. Alternatively, intralesional triamcinolone injections may be used at intervals of 6–8 weeks. Liquid nitrogen cryotherapy can be repeated every 3–4 weeks as required. Treatment of refractory lesions includes photodynamic therapy, ultraviolet A1 (UVA1) phototherapy, intralesional interferon, and laser therapy; large, tumid lesions may rarely require excision. Recalcitrant lesions can also be treated with some of the treatments described below for generalized disease.

Generalized GA may be persistent, and its unsightly appearance causes patients to seek active treatment. *Antimalarial therapy* is often effective in GGA; initial reports were with *chloroquine*, though *hydroxychloroquine* is also effective and confers a more favorable side-effect profile. *Phototherapy* can be an effective treatment. While both *psoralen and ultraviolet A (PUVA)* and *UVA1 phototherapy* have been reported, *narrowband phototherapy* is also effective and may be used, but relapses can occur. Intertriginous, patch-type GA may be particularly responsive to phototherapy. *Isotretinoin* and *dapsone* have been associated with improvement or clearance of generalized GA. Topical tacrolimus and pimecrolimus have been used, with some reports describing greater success in generalized disease than in the localized variety. Other reported treatments for this condition include *laser*, *fumaric acid esters*, *methotrexate*, *chlorambucil*, *ciclosporin*, *hydroxyurea*, *doxycycline*, *pulsed triple-antibiotic therapy*, *systemic corticosteroids*, *adalimumab*, *infliximab*, *anthralin*, *vitamin E*, *allopurinol*, *nicotinamide*, *pentoxifylline*, *apremilast*, and *defibrotide*. Biopsy alone has reportedly improved patch GA and GGA. New, emerging reports describe response to *oral and topical tofacitinib*, with JAK-inhibitors showing promise for multiple granulomatous diseases.

Specific Investigations

- Check glycated hemoglobin (HbA1c)
- Thyroid stimulating hormone
- Fasting lipid panel
- Consider hepatitis C screening for at risk patients

The relationship between GA and diabetes remains unclear; however, screening HbA1c in patients with risk factors or symptoms of glucose intolerance should be considered. Hyperlipidemia and thyroid disease are both seen at increased rates in patients with granulomatous diseases, including GA, and are easy to screen for with low risk, cost effective tests.

Generalized granuloma annulare: clinical and laboratory findings in 100 patients. Dabski K, Winkelmann RK. J Am Acad Dermatol 1989; 20: 39–47.

Retrospective review identifying GGA in 20% of 100 biopsy-proven cases of GA at a tertiary referral institution.

Localized granuloma annulare is associated with insulin-dependent diabetes mellitus. Muhlemann MF, Williams DR. Br J Dermatol 1984; 111: 325–9.

Retrospective study of 557 insulin-dependent diabetics. Sixteen patients had GA, significantly more than the 0.9 cases that might have been expected.

Laboratory abnormalities in granuloma annulare: a case-control study. Veraldi S, Bencini PL, Drudi E, et al. Br J Dermatol 1997; 136: 652–3.

Retrospective case-control study of 61 patients showing significantly increased risk of insulin-dependent diabetes in patients with GA. Higher prevalence of diabetes mellitus (DM) identified in patients with LGA versus GGA.

Lack of an association between granuloma annulare and type 2 diabetes mellitus. Nebesio CL, Lewis C, Chuang TY. Br J Dermatol 2002; 146: 122–4.

Study of 126 patients with GA in which no association was found between GA and DM in comparison to controls with psoriasis. Notably, potential associations between DM and psoriasis have recently been identified.

LOCALIZED GRANULOMA ANNULARE

First-Line Therapies

- Intralesional corticosteroids **B**
- Cryotherapy **B**
- Topical corticosteroids **E**

Granuloma annulare and necrobiosis lipoidica treated by jet injector. Sparrow G, Abell E. Br J Dermatol 1975; 93: 85–9.

Comparison of 45 patients with LGA treated with intralesional injection of triamcinolone 5 mg/mL or sterile saline over 6- and 8-week intervals. Of those treated with steroid injection, 68% experienced complete clearance versus 44% in the sterile saline group. Partial clearance was higher in the saline group (33%) versus in the steroid group (24%), and less than 50% of patients in both groups had recurrence of GA.

Successful outcome of cryosurgery in patients with granuloma annulare. Blume-Peytavi U, Zouboulis CH, Jacobi H, et al. Br J Dermatol 1994; 130: 494–7.

In a study of 31 patients with GA, 22 patients were treated with liquid nitrogen and nine with nitrous oxide. After a single freeze-thaw cycle, 81% of GA lesions treated with liquid nitrogen cleared. Four cases had persistent atrophic scars at sites of treatment.

Granuloma annulare of childhood successfully treated with potent topical corticosteroids previously unresponsive to tacrolimus ointment 0.1%: report of three cases. Rallis E, Stavropoulou E, Korfitis C. Clin Exp Dermatol 2009; 34: e475–6.

Twice-daily application of clobetasol propionate 0.05% or mometasone furoate 0.1% without occlusion for 2–3 weeks led to complete remission of LGA in three children.

Successful treatment of chronic skin diseases with clobetasol propionate and a hydrocolloid occlusive dressing. Volden G. Acta Derm Venereol 1992; 72: 69–71.

One in three cases of GA showed a complete response after 4 weeks of treatment with clobetasol propionate under occlusion.

Second-Line Therapies

- Pulsed dye laser **C**
- 308-nm excimer laser **E**
- Topical photodynamic therapy **D**
- Topical imiquimod **E**
- Topical dapsone **E**
- Topical tacrolimus **E**
- Topical pimecrolimus **E**
- Scarification **E**
- Surgery **E**
- UVA1 **E**
- Intralesional interferon **E**
- Pulsed monthly rifampicin, ofloxacin, and minocycline **D**
- Topical tofacitinib **E**

Treatment of granuloma annulare with the 595 nm pulsed dye laser (PDL), a multicenter retrospective study with long-term follow-up. Passeron T, Fusade T, Vabres P, et al. J Eur Acad Dermatol Venereol 2013; 27: 785–8.

Five patients with LGA and eight patients with GGA were treated with three sessions of PDL. A significant response was seen only in the localized forms while GGA showed weak improvement, with a high recurrence rate.

Granuloma annulare treated with excimer laser. Bronfenbrenner R, Ragi J, Milgraum S. J Clin Aesthet Dermatol 2012; 5: 43–5.

A 73-year-old woman with an over 40-year history of GGA underwent treatment with excimer laser on the dorsal hands. The regimen comprised fluence of 300 mJ/cm² with five doses per treatment session. After 15 treatments there was complete resolution with no recurrence at treated sites at 6-month follow-up.

Photodynamic therapy for granuloma annulare: more than a shot in the dark. Weisenseel P, Kuznetsov AV, Molin S, et al. Dermatology 2008; 217: 329–32.

Seven patients with GA were treated with three sessions of photodynamic therapy with topical aminolevulinic acid (ALA-PDT) and an interval of 2–4 weeks between each session. In two patients, GA cleared completely; in two patients, the skin lesions improved markedly; and in three patients, no response was observed.

A retrospective analysis of real-life practice of off-label photodynamic therapy using methyl aminolevulinate (MAL-PDT) in 20 Italian dermatology departments. Part 1: inflammatory and esthetic indications. Calzavara-Pinton PG, Rossi MT, Aronson E, et al. J Photochem Photobiol Sci 2013; 12: 148–57.

Retrospective observational study of patients treated with MAL-PDT in Italian hospital centers. Nine out of 13 patients with GA showed improvement.

Successful treatment of granuloma annulare with imiquimod cream 5%: a report of four cases. Badavanis G, Monastirli A, Pasmatzis E, et al. Acta Derm Venereol 2005; 85: 547–8.

Four patients with multiple lesions of LGA treated with imiquimod 5% cream once daily. The majority of lesions cleared within 12 weeks of treatment with no recurrence observed at 18 months follow-up. *There is also a report of GA worsening after treatment of adjacent warts with imiquimod.*

Management of periocular granuloma annulare using topical dapsone. Kassardjian M, Patel M, Shitabata P, et al. J Clin Aesthet Dermatol 2015; 8: 48–51.

A 41-year-old male with arciform LGA of the right upper eyelid and lateral canthus was treated with dapsone 5% gel applied twice daily, with significant improvement at 3 weeks.

Periorbital granuloma annulare successfully treated with tacrolimus 0.1% ointment. Gomez-Moyano E, Vera-Casaño A, Martinez S, et al. *Int J Dermatol* 2014; 53: e156–7.

A 6-year-old child with LGA of the upper eyelid was successfully treated with topical tacrolimus 0.1% ointment twice daily. Significant improvement was noticed at 6 weeks with sustained response.

Multiple localized granuloma annulare: ultraviolet A1 phototherapy. Frigerio E, Franchi C, Garutti C, et al. *Clin Exp Dermatol* 2007; 32: 762–4.

Four patients responded to high-dose UVA1, starting with 60 J/cm² on day 1, followed by fixed daily doses of 100 J/cm² five times weekly for 3 weeks.

Treatment of granuloma annulare by local injections with low dose recombinant human interferon gamma. Weiss JM, Muchenberger S, Schöpf E, et al. *J Am Acad Dermatol* 1998; 39: 117–9.

Three patients achieved clearance of LGA with intralesional rHu-interferon- γ 2.5 $\times$ 10⁵ IU/lesion on 7 consecutive days continued three times weekly for 2 weeks. Two similar GA lesions were treated as controls with 0.9% normal saline or via corticosteroid under occlusion without improvement. No flu-like symptoms or blood chemistry changes were noted.

Triple antibiotic combination therapy may improve but not resolve granuloma annulare. Simpson B, Foster S, Ku JH, et al. *Dermatol Ther* 2014; 27(6): 343–7.

Open-label prospective study of 21 patients with at least five lesions of LGA who received once-monthly rifampin (400mg), ofloxacin (400mg), and minocycline (100mg) for 6 months with improvement measured on the Granuloma Annulare Severity Index (GASI) scoring system. Fifteen patients completed the study and 10 subjects achieved at least 50% reduction in GASI. Six subjects had no change or worsening of their GA. Mean GASI scores decreased significantly by 15 points ($p < 0.01$) although number and LGA subtypes were not detailed. Clinical significance remains unknown.

Treatment of granuloma annulare with tofacitinib 2% ointment. Damsky W, King BA. *JAAD Case Rep* 2020; 6(1): 69–71.

A 69-year-old man with a 1-year history of LGA was treated with tofacitinib 2% ointment twice daily. After 15 weeks there was marked improvement and near resolution in all treated lesions. One lesion was not treated and did not improve. No adverse effects were noted.

GENERALIZED (DISSEMINATED) GRANULOMA ANNULARE

First-Line Therapies

• UVA1	B
• PUVA	C
• Narrowband ultraviolet B (NB-UVB)	D
• Isotretinoin	C
• Oral dapsone	C
• Hydroxychloroquine	C
• Chloroquine	C
• Topical photodynamic therapy	E

UVA1 phototherapy for disseminated granuloma annulare. Schnopp C, Tzaneva S, Mempel M, et al. *Photodermatol Photoimmunol Photomed* 2005; 21: 68–71.

Twenty patients with disseminated GA underwent phototherapy with UVA1 (340–400nm), which provided good to excellent results in half of patients and satisfactory responses in the majority of patients. Discontinuation of treatment was followed by early recurrence.

Psoralen and ultraviolet A in the treatment of granuloma annulare. Browne F, Turner D, Goulden V. *Photodermatol Photoimmunol Photomed* 2011; 27: 81–4.

A retrospective study of 33 patients treated with twice-weekly PUVA resulted in clearance in 50% of patients and good improvement in 16%, 25% with moderate benefit, and 9% with no improvement. Seventy-nine percent remained in remission at 6 months but only 32% remained in remission at 12 months.

The efficacy of PUVA and narrowband UVB phototherapy in the management of generalized granuloma annulare. Cunningham L, Kirby B, Lally A. *J Dermatolog Treat* 2016; 27(2): 136–9.

Retrospective review of 20 female patients with GGA treated with PUVA and NB-UVB. Twelve patients underwent 15 courses of PUVA (oral or bath) and 10 patients were treated with NB-UVB for 12 treatments (2 patients had both). Minimal residual disease or clearance was noted for 8 of 12 patients after PUVA resulting in a 6-month (7 patients) to 1-year (2 patients) remission. Minimal residual disease or clearance was reported for 7 patients treated with NB-UVB and remission was for 6 months (3 patients) to greater than 1 year (2 patients).

Generalized granuloma annulare in a patient with type 2 diabetes mellitus: successful treatment with isotretinoin. Sahin M, Türel-Ermertcan A, Öztürkcan S, et al. *J Eur Acad Dermatol Venereol* 2006; 20: 111–4.

A 49-year-old man with type 2 DM and GGA was treated with isotretinoin at 5 mg daily, leading to complete resolution without relapse beyond 3-month follow-up.

The response of generalized granuloma annulare to dapsone. Czarnecki DB, Gin D. *Acta Derm Venereol* 1986; 66: 82–4.

Six patients (11–76 years old) with GGA were treated with dapsone 100 mg daily resulting in complete clinical response. Five cleared within 8 weeks and four remained clear for 20 months after stopping treatment.

Efficacy of dapsone on disseminated granuloma annulare: a case report and review of the literature. Martín-Sáez E, Fernández-Guarino M, Carrillo-Gijón R, et al. *Actas Dermosifilogr* 2008; 99: 64–8.

A patient with GGA showed clinical improvement taking dapsone 100 mg daily for 2 months with clearance at 15 months without recurrence several months after treatment discontinuation.

Treatment of generalized granuloma annulare with hydroxychloroquine. Cannistraci C, Lesnoni La Parola I, Falchi M, et al. *Dermatology* 2005; 211: 167–8.

Four of nine patients achieved complete remission when treated with hydroxychloroquine for 4 months with the following regimen: 9 mg/kg/day for 2 months, 6 mg/kg/day for month 3, and 2 mg/kg/day for month 4. One child was treated with 50% of the dose delineated.

Long lasting interstitial generalized granuloma annulare on sun-exposed areas. Andreu-Barasoain M, Gomez de la Fuente E, Pinedo F, et al. Photodermatol Photoimmunol Photomed 2012; 28: 216–8.

Case report of photodistributed GGA that responded to chloroquine with multiple recurrences when off the medication.

Antimalarials for control of disseminated granuloma annulare in children. Simon M, Van Den Driesch P. J Am Acad Dermatol 1994; 31: 1064–5.

Six children achieved complete clearance of their GGA within 6 weeks of treatment with 3–6 mg/kg/day hydroxychloroquine and remained clear for 2.5 years of follow-up.

Generalized granuloma annulare treated with methylaminolevulinate photodynamic therapy. Piaserico S, Zattra E, Linder D, et al. Dermatology 2009; 218: 282–4.

Three patients with persistent generalized GA responded to MAL-PDT.

Second-Line Therapies

• Topical corticosteroids	E
• Systemic corticosteroids	E
• Topical pimecrolimus	E
• Tofacitinib	E
• Topical tacrolimus	E
• Fumaric acid esters	C
• Chlorambucil	D
• Doxycycline	E
• Allopurinol	E
• Nicotinamide	E
• Pentoxifylline	E
• Apremilast	E
• Oral calcitriol	E
• Monthly rifampicin, ofloxacin, and minocycline	D
• Ciclosporin	E
• Methotrexate	E
• Hydroxyurea	E
• Defibrotide	E
• Anthralin	E
• Adalimumab	D
• Infliximab	E
• Etanercept	E
• Laser (neodymium-doped yttrium aluminum garnet [Nd:YAG])	E
• Oral vitamin E and leukotriene inhibitor	E
• Topical vitamin E	E

A contact dermatitis reaction to clobetasol propionate cream associated with resolution of recalcitrant, generalized granuloma annulare. Agarwal S, Berth-Jones J. J Dermatol Treat 2000; 11: 279–82.

A 22-year-old woman with GGA developed contact sensitization to clobetasol propionate cream during treatment of her GA, raising the possibility that this reaction may have played a therapeutic role.

Generalized granuloma annulare presenting as arcuate dermal erythema. Miličić V, Ravić-Nikolić A, Jovović-Dagović B, et al. Acta Dermatovenereol Alp Pannonica Adriat 2010; 19: 25–7.

A case report describing treatment of GGA with a 7-day course of intramuscular methylprednisolone (40 mg daily dose) and

low-dose oral prednisone (20 mg daily, then 10 mg daily over 2 months).

Systemic corticosteroids may exacerbate preexisting diabetes.

Pimecrolimus 1% cream in the treatment of disseminated granuloma annulare. Rigopoulos D, Prantsidis A, Christofidou E, et al. Br J Dermatol 2005; 152: 1364–5.

An adult improved with twice-daily treatment for 3 months.

Successful treatment of disseminated granuloma annulare with topical tacrolimus. Jain S, Stephens CJM. Br J Dermatol 2004; 150: 1042–3.

Four patients were treated with twice-daily application of tacrolimus 0.1% ointment. At 6 weeks, two patients showed clearance and the remaining two patients showed significant improvement. There was no evidence of recurrence 6 weeks after treatment discontinuation.

Janus kinase inhibition induces disease remission in cutaneous sarcoidosis and granuloma annulare. Damsky W, Thakral D, McGeary MK, et al. J Am Acad Dermatol 2020; 82(3): 612–21.

A 66-year-old woman with refractory GGA was treated with tofacitinib 5 mg twice daily, resulting in complete or near-complete clinical remission within 6–10 months and histologic resolution of granulomatous inflammation. Molecular analysis showed normalization of the IFN- γ gene expression signatures in previously affected skin.

Therapy of noninfectious granulomatous skin diseases with fumaric acid esters. Breuer K, Gutzmer R, Völker B, et al. Br J Dermatol 2005; 152: 1290–5.

Thirteen patients with generalized GA were treated with Fumaderm, 1 tablet daily for 1 week, increased to 3–6 tablets per day. Eight patients experienced improvement of disease. Treatment courses were between 3 months and greater than 14 months.

Fumaric acid esters in combination with oral PUVA may result in further improvement.

Generalized granuloma annulare: response to doxycycline. Duarte AF, Mota A, Pereira MA, et al. J Eur Acad Dermatol Venereol 2009; 23: 84–5.

A woman with GA achieved almost complete resolution after treatment with doxycycline 100 mg/day for 10 weeks.

Treatment of disseminated granuloma annulare with allopurinol: case report. Mazzatenta C, Ghilardi A, Grazzini M. Dermatol Ther 2010; 23(Suppl 1): S24–7.

Allopurinol 300 mg twice daily is an alternative treatment for GGA in therapy-resistant patients.

Response of generalized granuloma annulare to high dose niacinamide. Ma A, Medenica M. Arch Dermatol 1983; 119: 836–9.

A patient with GGA experienced resolution of her lesions after 6 months of treatment with niacinamide 1500 mg daily.

Successful treatment of generalized granuloma annulare with pentoxifylline. Nambiar KG, Jagadeesan S, Balasubramanian P, et al. Indian Dermatol Online J 2017; 8: 218–20.

A 60-year-old woman with GGA was treated with pentoxifylline at 400 mg three times daily with response within 1 month, dramatic improvement at 3 months, and no recurrence at 6 months.

Given the favorable safety profile of pentoxifylline, it should be considered as an adjunct treatment.

Granuloma annulare responsive to oral calcitriol. Boyd AS. *Int J Dermatol* 2012; 51: 120–2.

One patient described improvement in pruritus at 1 month, and improvement in appearance was noted at 3 months with 0.25 mcg oral calcitriol daily.

Refractory generalized granuloma annulare treated with oral apremilast. Bishnoi A, Raj D, Vinay K, et al. *JAMA Dermatol* 2019; 155(11): 1318–20.

Four patients with treatment-refractory GGA underwent therapy with oral apremilast at 30 mg twice daily. All patients exhibited a positive response after 6 to 8 weeks. All patients continued a maintenance dose of 30 mg once daily with sustained remission.

Disseminated granuloma annulare: efficacy of cyclosporine therapy. Spadino S, Altomare A, Cainelli C, et al. *Int J Immunopathol Pharmacol* 2006; 19: 433–8.

Four patients with GGA were treated with cyclosporin 4 mg/kg/day and achieved complete clearance within 3 weeks with no relapses in the 12 months following treatment.

Successful treatment of disseminated granuloma annulare with methotrexate. Plotner AN, Mutasim DF. *Br J Dermatol* 2010; 163: 1123–4.

A patient with GGA experienced resolution of the majority of lesions with methotrexate 15 mg weekly and daily folic acid supplementation for 6 weeks. Discontinuation of methotrexate upon two occasions for surgical procedures resulted in a recurrence of disease within 1 month.

Treatment of recalcitrant granuloma annulare (GA) with adalimumab: a single-center, observational study. Min MS, Lebwohl M. *J Am Acad Dermatol* 2016; 74: 127–33.

Seven patients with generalized GA were administered adalimumab 80 mg subcutaneously, followed by 40 mg every other week, 1 week after initiation. Patients were asked to return in 1 and 3 months. Adalimumab was either discontinued with disease clearance or patient wish or escalated to weekly injections if minimal improvement was noted after 3 months. In cases in which lesions recurred after discontinuing adalimumab, patients were permitted to restart therapy. All seven patients experienced clearance, with two requiring weekly injections. Three patients maintained remission at 40 months after discontinuation of treatment.

Antitumor necrosis factor- α treatment with infliximab for disseminated granuloma annulare. Murdaca G, Colombo BM, Barabino G, et al. *Am J Clin Dermatol* 2010; 11: 437–9.

A 62-year-old woman was administered infliximab intravenously at a dosage of 5 mg/kg at weeks 0, 2, and 6 and thereafter at monthly intervals for 10 additional months. The majority of her GGA lesions improved within 8 weeks and resolved within 10 months of treatment.

Rapid improvement of recalcitrant disseminated granuloma annulare upon treatment with the tumor necrosis factor- α inhibitor, infliximab. Hertl MS, Haendle I, Schuler G, et al. *Br J Dermatol* 2005; 152: 552–5.

A 59-year-old woman with type 1 diabetes and a 4-year history of recalcitrant generalized GA was administered infliximab at 5 mg/kg/day at weeks 0, 2, and 6 and thereafter at a monthly interval for an additional 4 months. The majority of disease cleared within 4 to 6 weeks. New lesions were not seen in follow-up to 16 months.

Resolving granuloma annulare with etanercept. Shupack J, Siu K. *Arch Dermatol* 2006; 142: 394–5.

A case report of improvement in GGA after 12 weeks of treatment with etanercept at 50 mg biweekly.

Conflicting evidence exists regarding the treatment of GGA with etanercept.

Fractional photothermolysis for the treatment of granuloma annulare: a case report. Karsai S, Hammes S, Rütten A, et al. *Lasers Surg Med* 2008; 40: 319–22.

Remission of four lesions (in a patient with GGA) after two to three treatment sessions with a 1440-nm Nd:YAG laser.

Granuloma annulare successfully treated using fractional photothermolysis with a 1,550-nm erbium-doped yttrium aluminum garnet fractionated laser. Liu A, Hessel CL, Moy RL, et al. *Lasers Surg Med* 2008; 40(5): 319–22.

A 60-year-old with GGA underwent treatment with fractional photothermolysis using a 1550-nm Er:YAG fractionated laser. Eleven treatments were performed at 1-month intervals with 80%–90% improvement. A total energy of 5.8–6.8 kJ was used at a setting of 70 J/cm², with 8–14 passes over each lesion.

Treatment of disseminated granuloma annulare with a 5-lipoxygenase inhibitor and vitamin E. Smith KJ, Norwood C, Skelton H. *Br J Dermatol* 2002; 146: 667–70.

Three patients were treated with vitamin E 400 IU daily and zileuton 2400 mg daily. All responded within 3 months with complete clinical clearing.

Disseminated granuloma annulare as a presentation of acquired immunodeficiency syndrome (AIDS). McGregor JM, McGibbon DH. *Clin Exp Dermatol* 1992; 17: 60–2.

Patient undergoing treatment of AIDS with zidovudine with the associated resolution of cutaneous lesions.

Generalized granuloma annulare associated with chronic hepatitis B virus infection. Ma H, Zhu W, Yue X. *J Eur Acad Dermatol Venereol* 2006; 20: 186–9.

Generalized GA resolved after 3 months of treatment with interferon- α for hepatitis B.

Granuloma faciale

Nevianna Bordet

Granuloma faciale is a rare, benign, chronic inflammatory dermatosis caused by a localized form of cutaneous vasculitis. It presents primarily in middle-aged Caucasian males, usually as an asymptomatic single lesion on the face. Extensive involvement of the nose can mimic rhinophyma. Multiple lesions occur in up to one-third of patients. Extrafacial granuloma faciale is rare and usually found in association with facial lesions. The etiology of granuloma faciale is unclear.

Lesions are red-brown, violaceous, or flesh-colored plaques or nodules with accentuation of follicular openings giving a 'peau d'orange' appearance. Clinical diagnosis is difficult. Differential diagnosis includes sarcoid, lupus, lymphocytoma cutis, persistent insect bite reactions, leishmaniasis, and lymphoma. The histologic differential diagnosis includes erythema elevatum diutinum and angiolymphoid hyperplasia with eosinophilia.

MANAGEMENT STRATEGY

Granuloma faciale is notoriously resistant to treatment and spontaneous remission is unusual. Because it is rare, there are no formal trials of therapy. Treatment modalities can be divided into destructive techniques (*cryotherapy*, *laser*, *surgical excision*) and antiinflammatory approaches. The optimal treatment depends on the size and extent of lesions.

Granuloma faciale treatment: a systematic review. Lindhaus C, Elsner P. *Acta Derm Venereol* 2018; 98: 14–8.

In the last few years, there have been increasing numbers of case reports of successful treatment with topical calcineurin

inhibitors for isolated or multiple lesions, and a recent systematic review of 94 patients recommended this as first-line treatment and pulsed-dye laser for drug-resistant lesions.

Specific Investigations

- Skin biopsy
- Hematology (full blood count)
- Dermoscopy

Histologic findings include a dense eosinophilic and neutrophilic infiltrate, often perivascular, affecting the upper and sometimes deep dermis. The epidermis is spared, and there is a grenz zone. Telangiectasia is common. Vasculitis with leukocytoclasia is reported. Dermal fibrosis is often seen.

Granuloma faciale: a clinicopathologic study of 66 patients. Ortonne N, Wechsler J, Bagot M, et al. *J Am Acad Dermatol* 2005; 53: 1002–9.

Peripheral blood eosinophilia is sometimes found.

Dermoscopic patterns of common facial inflammatory skin disease. Lallas A, Argenziano G, Apalla Z, et al. *J Eur Acad Dermatol Venereol* 2014; 28: 609–14.

Dermoscopy is increasingly used to aid diagnosis in granuloma faciale. Follicle abnormalities such as dilated follicular openings, perifollicular whitish halo, follicular keratotic plugs, and linear slightly arborizing vessels in a parallel arrangement are the most commonly described dermoscopic criteria.

First-Line Therapies

• Corticosteroids	D
• Calcineurin inhibitors	D
• Cryotherapy	D
• Laser therapy	D

Granuloma faciale treated with intradermal dexamethasone. Arundell FD, Burdick KH. *Arch Dermatol* 1960; 82: 437–8.

This paper reports response to dexamethasone, but triamcinolone acetonide and triamcinolone hexacetonide have also been used. Patients should be warned of the risk of skin atrophy and pigment change.

Granuloma faciale: is it a new indication for pimecrolimus? A case report. Eetam I, Ertekin B, Unal I, et al. *J Dermatol Treat* 2006; 17: 238–40.

A case report of a lesion showing 'dramatic recovery' after pimecrolimus cream 1% twice daily for 2 months.

Granuloma faciale: treatment with topical tacrolimus. Marcial J, Moreno A, Bordas X, et al. *J Am Acad Dermatol* 2006; 55: S110–1.

This and other papers describe response to topical tacrolimus, typically within a few months. In some patients, lesions had previously failed to respond to other therapies. Remission for up to 2 years is described.

Assessment of the efficacy of cryosurgery in the treatment of granuloma faciale. Panagiotopoulos A, Anyfantakis V, Rallis E, et al. *Br J Dermatol* 2006; 154: 357–60.

Nine patients were treated with either the open-spray technique given as one or two freeze–thaw cycles of 20–30 seconds, or the cryoprobe given as one to three freeze–thaw cycles of 15–20 seconds, with retreatment at 1 and 3 months, resulted in clearance at 6 months. Two patients experienced hypopigmentation that resolved in 4 months. There was no recurrence within 2–4 years' follow-up.

Granuloma faciale: successful treatment of nine cases with a combination of cryotherapy and intralesional corticosteroid injection. Dowlati B, Firooz A, Dowlati Y. *Int J Dermatol* 1997; 36: 548–51.

Cryotherapy for 20–30 seconds was followed by triamcinolone acetonide 5 mg/mL intralesionally. Lesions cleared completely in all nine cases.

Granuloma faciale treated with pulsed-dye laser: a case series. Cheung S-T, Lanigan SW. *Clin Exp Dermatol* 2005; 30: 373–5.

Four patients who had all failed with cryotherapy were treated with pulsed-dye laser at 595 nm. In two patients the lesions resolved. Nasal lesions, especially flatter ones, seem to respond better to treatment.

Reports of granuloma faciale responding to argon laser and KTP laser are described in the literature, but the pulsed-dye laser is the type most frequently reported as achieving improvement.

Rhinophyma-like granuloma faciale successfully treated with carbon dioxide laser. Bakkour W, Madan V. *Br J Dermatol* 2014; 170: 474–5.

A patient who failed to respond to topical and intralesional steroids as well as 150 mg dapsone showed an excellent response with no recurrence at 18 months.

A handful of other case reports show benefit with carbon dioxide laser.

Second-Line Therapies

• Dapsone	D
• 5-Fluorouracil	E
• Surgery	E

On the efficacy of dapsone in granuloma faciale. Van de Kerkhof PCM. *Acta Derm Venereol* 1994; 74: 61–2.

A 4-cm plaque showed 'impressive improvement' with dapsone 200 mg daily. Dapsone needs careful monitoring, and many patients would not tolerate 200 mg daily.

Many authors mention dapsone as a treatment that has been tried but failed.

Granuloma faciale treated with topical dapsone: a case report. Babalola O, Zhang J, Kristjansson A, et al. *Dermatol Online J* 2014; 20: 25148282.

In a single patient, twice-daily topical dapsone 5% gel resulted in near-complete resolution at 9 months with no recurrence at 18 months.

Treatment of laser resistant granuloma faciale with intralesional triamcinolone acetonide and 5-fluorouracil

combination therapy. Norris DL, Apikian M, Goodman GJ. *J Cutan Aesthet Surg* 2015; 8: 111–3.

Case report of one patient who failed to respond to topical tacrolimus and pulsed-dye laser achieving 'an excellent response' with intralesional 0.8 mL 5-fluorouracil 50 mg/mL combined with 0.2 mL triamcinolone acetonide 10 mg/mL. No more than 2 mL per treatment should be used according to the authors.

Recurrent facial plaques following full-thickness grafting. Phillips DK, Hymes SR. *Arch Dermatol* 1994; 130: 1436–7.

Although surgery is mentioned in many papers, recurrence can occur even after full-thickness excision and grafting.

Third-Line Therapies

• Colchicine	E
• Ingenol mebutate	E
• Rituximab	E
• Topical PUVA	E

Granuloma faciale treated successfully with colchicine. Ohata C, Nakama T. *Acta Derm Venereol* 2019; 99: 833–4.

Failure to colchicine has been reported several times but this case reports that colchicine 0.5 mg/day for 1 week caused partial clearance and 1 mg/day for 2 weeks cleared granuloma faciale fully, with no recurrence at 16 months.

Granuloma faciale successfully treated with ingenol mebutate. Bobyr I, Campanati A, Consales V, et al. *Dermatol Ther* 2016; 29(5): 325–9.

Ingenol mebutate 0.015% gel, used to treat concomitant actinic keratosis, successfully cleared two adjacent small granuloma faciale (GF) plaques. Follow-up for 8 months showed no recurrence. In January 2020, following final results from a 3-year safety study indicating a higher occurrence of skin cancer, the European Medicines Agency suspended the marketing authorization (licence) for ingenol mebutate gel as a precaution while the evidence is reviewed.

Assessment of treatment of refractory granuloma faciale with intralesional rituximab. Morgado-Carrasco D, Giavedoni P, Mascaró JM, et al. *JAMA Dermatol* 2018; 154(11): 1312–5.

Three cases treated with 0.5–1 mL/cm² of intralesional rituximab (10 mg/mL) once monthly for at least 6 months resulted in complete clearance in two patients and partial response in the third. Treatment was well tolerated and the authors state that it was not costly due to the low doses of rituximab used.

Granuloma faciale: treatment with topical psoralen and UVA. Hudson LD. *J Am Acad Dermatol* 1983; 8: 559.

A 62-year-old man with a 1-month history of biopsy-proven granuloma faciale affecting the nasal alae responded to 24 J UVA given over 10 weeks, showing a very marked improvement with no evidence of residual lesion at 6 months.

There are old reports of treatment with intralesional gold and bismuth, radiotherapy, isoniazid, potassium arsenite, testosterone, and antimalarials, but within the past 30 years there have been no reports of successful response to these agents. A report of adalimumab treatment for 6 months in one patient did not lead to improvement.

Granuloma inguinale

Ted Rosen

Granuloma inguinale, or donovanosis, is an infection causing granulomatous and destructive ulceration of genital, inguinal, and perineal skin. Cervical lesions are rare but may clinically mimic carcinoma. Extragenital lesions occur in about 6% of cases. This disorder is extremely rare in Western Europe and the United States, but is still endemic or epidemic in India, Brazil, and Papua New Guinea, and uncommonly in South Africa and very rarely among the Aboriginal people in Australia. Diagnosis can be made clinically by an experienced physician in endemic regions, but this may be difficult in other areas of the world. The causative organism is *Klebsiella granulomatis*, an intracellular, encapsulated, Gram-negative coccobacillus.

The disease presents with a subcutaneous granuloma or nodule that develops into characteristically painless, progressive ulcerative lesions without regional lymphadenopathy. Lesions are ulcerogranulomatous, highly vascular (i.e., a beefy red appearance), and friable (bleed easily on contact).

MANAGEMENT STRATEGY

Patients with donovanosis should be treated to prevent the gradual worsening of the disease leading to genital deformity or (very rarely) life-threatening disseminated infection, to prevent transmission, and to prevent the risk of concomitant transmission of human immunodeficiency virus (HIV) infection.

In the absence of evidence from randomized, placebo-controlled trials, antibiotic treatment of donovanosis is based on the results of local clinical experience and individual case reports, typically involving relatively small numbers of patients.

The U.S. Centers for Disease Control and Prevention (CDC) (2015) currently recommends *azithromycin*, with many alternative regimens (e.g., *doxycycline*, *ciprofloxacin*, *erythromycin*, *trimethoprim-sulfamethoxazole*). Azithromycin is also recommended in the 2016 European Guideline on donovanosis. The addition of an aminoglycoside, such as *gentamicin*, is recommended by the CDC if lesions do not respond within the first few days.

Therapy should be continued for a minimum of 3 weeks and until all lesions have healed completely. This typically starts at the outside margins and progresses inward. Despite seemingly effective initial therapy, a relapse can occur 6–18 months later. *Surgical excision* may be necessary for extensive disease that is unresponsive to antibiotic therapy. It should be noted that squamous cell carcinoma has been reported concurrent with active donovanosis, complicating longstanding cases, and developing at sites of healed lesions.

Sexual partners of patients who have granuloma inguinale should be examined and treated if they had sexual contact with the patient during the 60 days preceding the onset of symptoms in the patient or have clinical signs and symptoms of the disease.

Specific Investigations

- Tissue smear or biopsy with Wright or Giemsa stains
- Screen for other sexually transmitted infections (e.g., HIV, syphilis)
- Culture (not readily available)
- Polymerase chain reaction (PCR; not readily available)
- Serologic testing (not readily available, and not sufficiently reliable)

Genital ulcer disease: accuracy of clinical diagnosis and strategies to improve control in Durban, South Africa. O'Farrell N, Hoosen AA, Coetzee KD, et al. *Genitourin Med* 1994; 70: 7–11.

The clinical diagnostic accuracy for donovanosis was relatively high (63% in men, 83% in women). Donovanosis ulcers bled on touch and were not usually associated with inguinal lymphadenopathy.

The changing epidemiology of genital ulcer disease in South Africa: has donovanosis been eliminated? Muller EE, Kularatne R. *Sex Transm Infect* 2020. doi: 10.1136/sextrans-2019-054316 [Epub ahead of print].

Recent research using molecular techniques indicates that donovanosis is now rare as a cause of genital ulcer disease in South Africa due to specific elimination programs. This parallels similar results of public health programs in Australia.

Donovanosis. Hart G. *Clin Infect Dis* 1997; 25: 24–32.

Confirmation involves demonstration of typical intracellular Donovan bodies within large mononuclear cells visualized in smears prepared from lesions or biopsy specimens. The large mononuclear cells are 25–90 mcg in diameter with a vesicular or pyknotic nucleus.

Sexually transmitted disease surveillance 2010. Centers for Disease Control and Prevention. US Department of Health and Human Services, Atlanta; 2011.

Cases are confirmed by demonstration of intracytoplasmic Donovan bodies in Wright- or Giemsa-stained smears or biopsies of granulation tissue in a clinically compatible case (one or more painless or minimally painful granulomatous lesions in the anogenital area).

A colorimetric detection system for *Calymmatobacterium granulomatis*. Carter JS, Kemp DJ. *Sex Transm Infect* 2000; 76: 134–6.

A PCR test that could be used by well-equipped laboratories; largely a research tool.

Squamous cell carcinoma complicating donovanosis not a thing of the past! Sethi S, Sarkar R, Garg V, et al. *Int J STD AIDS* 2014; 25: 894–7.

A reminder that squamous cell carcinoma has been associated with active and healed donovanosis.

First-Line Therapy

- Azithromycin

B

Donovanosis: treatment with azithromycin. Bowden FJ, Savage J. *Int J STD AIDS* 1998; 9: 61.

An Australian report of over 100 patients treated with azithromycin with no primary treatment failures. Regimens employed were 500 mg orally daily for 7 days or 1 g orally weekly for 4 weeks. The 1996–1997 edition of the Australian Antibiotic Guidelines lists azithromycin as the first-line agent for donovanosis. The drug is listed as a B1 agent in pregnancy, meaning that it can be used for the treatment of antenatal patients with the disease.

2016 European guideline on donovanosis. O'Farrell N, Moi H. *Int J STD AIDS* 2016; 27: 605–7.

Azithromycin 1 g orally weekly or 500 mg orally daily, for a minimum of 3 weeks and until complete healing is achieved, is recommended as first-line therapy. Second-line therapeutic recommendations parallel those enumerated by the CDC (see the next citation). Patients should be closely monitored for relapse up to 1.5 years after clinical resolution.

2018 UK national guideline for the management of donovanosis. O'Farrell N, Hoosen A, Kingston M. *Int J STD AIDS* 2018; 29: 946–8.

The British treatment guidelines precisely mimic the European guidelines of 2 years prior. The guidelines also point out the worldwide decrease in disease prevalence.

Centers for Disease Control and Prevention Sexually Transmitted Diseases Treatment Guidelines, 2015. Workowski KA. *Clin Infect Dis* 2015; 61(Suppl 8): S759–62.

The treatment of choice is azithromycin 1 g orally once per week or 500 mg daily for at least 3 weeks and until all lesions have completely healed. Alternative (second-line) therapies include doxycycline 100 mg orally twice a day for at least 3 weeks and until all lesions have completely healed, ciprofloxacin 750 mg orally twice a day for at least 3 weeks and until all lesions have completely healed, erythromycin base 500 mg orally four times a day for at least 3 weeks and until all lesions have completely healed, and trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day for at least 3 weeks and until all lesions have completely healed.

Second-Line Therapies

- Doxycycline
- Erythromycin
- Trimethoprim-sulfamethoxazole
- Ciprofloxacin

C
C
B
C

Clinico-epidemiologic features of granuloma inguinale in the era of acquired immune deficiency syndrome. Jamkhedkar PP, Hira SK, Shroff HJ, et al. *Sex Transm Dis* 1998; 25: 196–200.

Fifty patients (21 HIV positive and 29 HIV negative) treated with erythromycin 2 g orally daily. Healing took longer in the seropositive group (mean 25.7 vs. 16.8 days).

Granuloma inguinale. Rosen T, Tschen JA, Ramsdell W, et al. *J Am Acad Dermatol* 1984; 11: 433–7.

Twenty patients were safely and effectively treated with trimethoprim-sulfamethoxazole. It has been used extensively in India with consistently good results.

Third-Line Therapies

- Ceftriaxone
- Gentamicin
- Surgical treatment
- Norfloxacin
- Trovafloxacin
- Ampicillin
- Chloramphenicol
- Thiamphenicol

C
C
E
C
C
C
C
C

Ceftriaxone in the treatment of chronic donovanosis in Central Australia. Merianos A, Gilles M, Chuah J. *Genitourin Med* 1994; 70: 84–9.

Eight women and four men treated with daily injections of 1 g ceftriaxone diluted in 2 mL of 1% lidocaine. Clinical improvement was dramatic in most lesions, and four patients healed completely without recurrence after a total 7–10 g of ceftriaxone.

1998 guidelines for treatment of sexually transmitted diseases. Centers for Disease Control and Prevention. *MMWR Recomm Rep* 1998; 47: 1–116.

The CDC recommends the addition of gentamicin (1 mg/kg IV every 8 hours) if lesions do not respond within the first few days of therapy.

Surgical treatment of granuloma inguinale. Bozbor A, Erbil Y, Berber E, et al. *Br J Dermatol* 1998; 138: 1079–81.

Fistulas and abscesses unresponsive to antibiotics may require surgical treatment.

Treatment of donovanosis with norfloxacin. Ramanan CR, Sarma PSA, Ghorpade A, et al. *Int J Dermatol* 1990; 29: 298–9.

Ten patients treated with oral norfloxacin 400 mg twice daily showed complete healing in 2–11 days.

Trovafloxacin for the treatment of chronic granuloma inguinale. Hsu SL, Chia JK. *Sex Transm Infect* 2001; 77: 137.

One patient had complete resolution of lesions after 2 months of trovafloxacin 200 mg daily after previously failing doxycycline, ampicillin, erythromycin, trimethoprim-sulfamethoxazole, ceftriaxone, gentamicin, and chloramphenicol.

The diagnosis and treatment of donovanosis (granuloma inguinale). Richens J. *Genitourin Med* 1991; 67: 441–52.

Ampicillin is unreliable and not recommended as first-line therapy.

Donovanosis in Papua New Guinea. Maddocks I, Anders EM, Dennis E. *Br J Vener Dis* 1976; 52: 190–6.

Fifty cases treated with chloramphenicol 500 mg four times daily. Forty-three had complete or near-complete clinical and bacteriologic healing.

Chloramphenicol is effective, but risk of aplastic anemia limits its use to life-threatening disease.

Donovanosis treated with thiamphenicol. Belda W, Velho PE, Arnone M, et al. Braz J Infect Dis 2007; 11: 388–9.

Ten patients with donovanosis of the penis were treated with thiamphenicol 2.5 g orally on day 1 followed by 1 g daily for the next 14 days. In eight, including two HIV-positive patients, their lesions healed without recurrence.

Thiamphenicol is advantageous over chloramphenicol because of its once-daily administration and lack of reports of serious marrow toxicity.

SPECIAL CONSIDERATIONS

Pregnancy: Pregnant and lactating women should be treated with erythromycin with consideration for the addition of a parenteral

aminoglycoside. Azithromycin may also be safe and effective. Doxycycline should be avoided in the second and third trimesters of pregnancy because of the risk for discoloration of teeth and bones, but is compatible with breastfeeding. Ciprofloxacin presents a low risk to the fetus during pregnancy, but sulfonamides are associated with rare but serious kernicterus in those with G6PD deficiency and should be avoided in the third trimester and during breastfeeding.

HIV infection: Patients often require prolonged antibiotic treatment after the regimens cited earlier. The addition of gentamicin should be strongly considered.

Children: All guidelines agree that children should be treated with a short course of azithromycin dosed at 20 mg/kg. Infants born to mothers with donovanosis should be treated prophylactically with 3 days of azithromycin dosed at 20 mg/kg once daily.

97

Granulomatous cheilitis

Charlene Lam, Bryan E. Anderson

Granulomatous cheilitis is characterized by chronic, painless swelling of one or both lips, with histologic evidence of non-caseating granulomatous inflammation. Granulomatous cheilitis exists along the spectrum of orofacial granulomatosis, which encompasses localized disease (cheilitis granulomatosa, Miescher cheilitis) to multisystem disease (Melkersson–Rosenthal syndrome). Melkersson–Rosenthal syndrome describes the triad of recurrent orofacial edema, recurrent facial nerve palsy, and lingua plicata (fissured tongue). Many investigators consider isolated granulomatous cheilitis to be a monosymptomatic form of Melkersson–Rosenthal syndrome.

MANAGEMENT STRATEGY

The treatment of granulomatous cheilitis is very challenging. Because the etiology is unknown, a variety of therapeutic strategies with varying degrees of success have been attempted. No randomized clinical trials or comparative studies have been performed. Given the evanescent nature of the condition, treatment outcomes are difficult to assess. Spontaneous remission of granulomatous cheilitis rarely occurs, further confounding assessment of therapies. Furthermore, a recent retrospective study demonstrated long-term treatment with topical medications and/or combination therapy may be required.

The aim of treatment is to prevent permanent labial deformity. Conservative measures for acute granulomatous cheilitis involve symptomatic relief, including *cold compresses* and *oral antihistamines* to reduce erythema and *ointments* to protect against fissuring of the lips. Initial therapy frequently includes *corticosteroids*, either topical, intralesional, or systemic. Initial topical therapy may include either *triamcinolone* or *clobetasol* (compounded into Orabase). Intralesional steroids may be used in doses ranging from 10 to 40 mg/kg. Nerve blocks may reduce patient discomfort in cases where large volumes

at low concentrations are needed. Although short courses of prednisone (25–50 mg/day) will frequently improve tissue swelling, flares are often noted on cessation.

Clofazimine has been reported to treat granulomatous cheilitis successfully. Response to therapy has been variable. Possible side effects include transient orange-pink discoloration of the skin, nausea, and vomiting. Fatal enteropathy may occur but only at higher doses than those recommended for granulomatous cheilitis treatment. *Thalidomide* can also be considered, especially in refractory cases. Patients must be monitored for the development of peripheral neuropathy and warned of its teratogenicity. Monotherapy with *metronidazole*, *tetracyclines*, *azithromycin*, *hydroxychloroquine*, or *sulfasalazine*, although less well substantiated, may be attempted. These medications may be used with corticosteroids. The addition of *minocycline* 100 mg twice daily or *tetracycline* 500 mg daily may prevent rebound after prednisone discontinuation. The value of *dapsone* and topical *tacrolimus* in the treatment of granulomatous cheilitis is unclear. Biologics, including *infliximab* and *adalimumab*, have also been successful treatments.

Granulomatous cheilitis may become persistent. Patients who suffer from permanent esthetic deformity or functional impairment may benefit from cheiloplasty. Surgical intervention should be performed only when more conservative approaches have failed and when inflammation is quiescent. An important consideration for Melkersson–Rosenthal syndrome patients undergoing anesthesia for surgical intervention or any surgical procedures is the risk of urticarial reaction due to anesthetic triggers during the procedure. In the past, remission was maintained with the use of postoperative corticosteroid injections. More recent reports, however, have described long remissions after surgery, with no additional treatment needed.

Granulomatous cheilitis has characteristics that are associated with several conditions that may require evaluation, including Crohn disease, sarcoidosis, infections (tuberculosis, leprosy, deep fungal, human immunodeficiency virus (HIV), and syphilis), acquired or hereditary angioedema, cheilitis glandularis, and leukemic infiltrates. It is also important to rule out any provocative cause such as odontogenic infections or allergenic sensitizers. Orofacial granulomatosis is associated with Crohn disease, especially in children, and may precede even minimal gastrointestinal symptoms.

Initial biopsies of granulomatous cheilitis may reveal dilated lymphatic channels, non-specific inflammatory infiltrates, and edema. In the later stages, the classic non-caseating granulomas are found. Absence of granulomata on biopsy does *not* exclude the diagnosis of granulomatous cheilitis. Granulomatous cheilitis is primarily a clinical diagnosis.

Specific Investigations

- Biopsy for histopathologic examination: polarization and stains/cultures for fungi and acid-fast bacilli
- Complete blood count and chemistry profile, including serum calcium
- Angiotensin-converting enzyme level
- Chest radiograph
- C1-esterase inhibitor; C1-esterase inhibitor functional assays; C1, C2, and C4 levels
- Consultation with dental professional if odontogenic infection suspected
- Consultation with gastroenterologist if there are any gastrointestinal complaints
- Standard patch testing (metal, bakery, dental, and other specialized patch series may be required) and food allergy testing to determine whether an allergen is causative

Cheilitis granulomatosa (Miescher Melkersson Rosenthal Syndrome). Gossman W, Agrawal M, Jamil RT, et al. In: StatPearls [Internet]. Treasure Island (FL): StatPearls Publishing; 2020 Jan. Available from: <https://www.ncbi.nlm.nih.gov/books/NBK470396/>.

Orofacial granulomatosis. Miest R, Bruce A, Rogers RS. Clin Dermatol 2016; 34: 505–13.

This article reviews orofacial granulomatosis and provocative factors and discusses possible etiologies and differential diagnoses.

Characteristics of patients with orofacial granulomatosis. McCartan BE, Healy CM, McCreary CE, et al. Oral Dis 2011; 17: 696–704.

The largest review of clinical and laboratory findings in 119 patients with orofacial granulomatosis. Mean age of 28, with an equal male-to-female ratio. Almost all patients had clinical evidence of lip and/or facial swelling. Over 50% of biopsies showed granulomatous inflammation.

Melkersson–Rosenthal syndrome: a review of 36 patients. Greene RM, Rogers RS 3rd. J Am Acad Dermatol 1989; 21: 1263–70.

Cheilitis granulomatosa: overview of 13 patients with long-term follow-up: results of management. Int J Dermatol 2002; 41: 225–9.

Orofacial granulomatosis: clinical features and long-term outcome of therapy. Al Johani KA, Moles DR, Hodgson TA, et al. J Am Acad Dermatol 2010; 62: 611–20.

Anesthetic management of patients with Melkersson–Rosenthal syndrome. Tekin M, Kati I. J Anesth 2008; 22: 294–6.

Is orofacial granulomatosis in children a feature of Crohn’s disease? Khouri JM, Bohane TD, Say AS. Acta Paediatr 2005; 94: 501–4.

Orofacial granulomatosis as the initial presentation of Crohn’s disease in an adolescent. Bogenrieder T, Lehn N, Landthaler M, et al. Dermatology 2003; 206: 273–8.

Cutaneous Crohn’s disease mimicking Melkersson–Rosenthal syndrome: treatment with methotrexate. Tonkovic-Capin V, Galbraith SS, Rogers RS III, et al. J Eur Acad Dermatol Venereol 2006; 20: 449–52.

Asymptomatic granulomatous vulvitis and granulomatous cheilitis in childhood: the need for Crohn disease workup. Nabatian AS, Shah KN, Iofel E, et al. J Pediatr Gastroenterol Nutr 2011; 53: 100–1.

Orofacial granulomatosis: three case reports illustrating the spectrum of disease and overlap with Crohn’s disease. Smith VM, Murphy R. Clin Exp Dermatol 2013; 38: 33–5.

These articles highlight the possibility of Crohn disease presenting with, or subsequent to, the diagnosis of granulomatous cheilitis. Narbutt et al. note that although the treatment of granulomatous cheilitis can be mostly cosmetic, Crohn disease is a systemic illness with multiple potential complications.

Although there are many similar clinical and histologic features between oral Crohn disease and orofacial granulomatosis, its relationship

is controversial. Some contend that adolescent granulomatous cheilitis is a predictor of future Crohn disease. It is unknown what percentage of patients with granulomatous cheilitis will develop Crohn disease, but it may be prudent to discuss this issue with granulomatous cheilitis patients.

Melkersson–Rosenthal syndrome and cheilitis granulomatosa. A clinicopathologic study of thirty-three patients with special reference to their oral lesions. Worsaae N, Christensen KC, Schiødt M, et al. Oral Surg Oral Med Oral Pathol 1982; 54: 404–13.

The elimination of odontogenic infections led to inactivity of orofacial edema in 11 of 18 patients.

Contact hypersensitivity in patients with orofacial granulomatosis. Armstrong DKB, Biagonia P, Lamey PJ, et al. Am J Contact Dermatol 1997; 1: 35–8.

Ten of 48 patients showed positive reactions to an oral battery on standard patch testing. Of these 10, seven showed an improvement on an elimination diet. In most cases this was not a complete result.

Patch testing for food-associated allergies in orofacial granulomatosis. Fitzpatrick L, Healy CM, McCartan BE, et al. J Oral Pathol Med 2011; 40: 10–3.

Orofacial granulomatosis associated with hypersensitivity to dental amalgam. Tomka M, Machovcova A, Peldova D, et al. Oral Surg Oral Med Oral Pathol 2011; 112: 335–41.

First-Line Therapies

• Intralesional corticosteroids ± topical immunomodulators	C
• Oral corticosteroids	C

Long-term effectiveness of intralesional triamcinolone acetonide therapy in orofacial granulomatosis: an observational cohort study. Fedele S, Fung PPL, Bamashmous N, et al. Brit J Dermatol 2014; 170: 794–801.

This is the first retrospective observational cohort ($n = 22$) study demonstrating the long-term effectiveness of intralesional triamcinolone acetonide 40 mg/mL. Doses of 0.1 mL were injected into four equally distanced sites (left labial corner and next to median line, right corner and next to median line) per lip once a week for 3 weeks (one treatment course). The majority (14/22) of the patients were treated with one course and did not experience recurrence. There were no adverse effects.

Clinical behavior and long-term therapeutic response in orofacial granulomatosis patients treated with intralesional triamcinolone acetonide injections alone or in combination with topical pimecrolimus 1%. Mignogna MD, Pollio A, Leuci S, et al. J Oral Pathol Med 2013; 42: 763–81.

Triamcinolone acetonide 40 mg/mL diluted to 2:1 with saline (25 mg/mL) was injected every 2 weeks for a maximum of 3 months (six sessions). The majority (11/19) responded. The eight partial responders who were then administered topical pimecrolimus 1% twice daily achieved clinical remission.

Effectiveness of small-volume, intralesional, delayed-release triamcinolone injections in orofacial granulomatosis: a pilot study. Mignogna MD, Fedele S, Lo Russo L, et al. J Am Acad Dermatol; 2004; 51: 265–8.

In this pilot study, triamcinolone 40 mg/mL, with each injection amounting to 0.1 mL, was used weekly for two to three sessions. The needle was injected between the prolabium and labia mucosa, and directed to the oral mucosa to avoid atrophy and hypopigmentation of the labial skin.

With the growing evidence demonstrating the safety and efficacy of high-concentration, low volumes of intralesional steroids, the necessity of nerve blocks for low-concentration, large volumes of intralesional steroids is limited.

Melkersson–Rosenthal syndrome and orofacial granulomatosis. Rogers RS III. *Dermatol Clin* 1996; 14: 371–9.

Oral prednisone 1–1.5 mg/kg daily tapered over 3–6 weeks may be effective for more severe and symptomatic episodes of granulomatous cheilitis.

Second-Line Therapies

• Clofazimine	C
• Biologics, including infliximab, adalimumab	C
• Azithromycin/roxithromycin	D
• Minocycline/tetracycline ± oral corticosteroids	E
• Metronidazole ± intralesional corticosteroids	E
• Mycophenolate mofetil ± topical corticosteroids	E

Clofazimine as elective treatment for granulomatous cheilitis. Fernandez-Freire LF, Gotarredona AS, Wittel JB, et al. *J Drugs Dermatol* 2005; 4: 374–7.

Three patients with granulomatous cheilitis treated with clofazimine 200–300 mg daily for 3–6 months obtained regression. Side effects included hyperpigmentation of the skin and elevation of liver enzymes.

Cheilitis granulomatosa Miescher: treatment with clofazimine and review of the literature. Ridder GJ, Fradis M, Löhle E. *Ann Otol Rhinol Laryngol* 2001; 110: 964–7.

A 15-year-old girl's granulomatous cheilitis was treated with clofazimine 100 mg daily. Regression was noted after 30 days of treatment. Thereafter, 100 mg of clofazimine three times a week was given for 3 months. Her lip eventually returned to normal size. Follow-up for 6 years revealed no recurrence.

This article reviews several case reports and a case series of clofazimine therapy and discusses the great variability in response to therapy.

Melkersson–Rosenthal syndrome: clinical, pathologic, and therapeutic considerations. Sussman GL, Yang WH, Steinberg S. *Ann Allergy* 1992; 69: 187–94.

Clofazimine 100 mg four times weekly for 3–11 months was used to treat 10 patients with granulomatous cheilitis/Melkersson–Rosenthal syndrome. Complete remission occurred in five, partial clinical responses occurred in three, and two patients had no clinical response.

Other studies have reported efficacy with a regimen consisting of clofazimine 100 mg daily for 10 days, followed by 200–400 mg weekly for 3–6 months.

Experience with anti-TNF- α therapy for orofacial granulomatosis. Elliot T, Campbell H, Esudier M, et al. *J Oral Pathol Med* 2011; 40: 14–9.

A retrospective review of 14 patients treated with infliximab and adalimumab for orofacial granulomatosis with and without Crohn disease. Short-term remission was achieved with infliximab

in 10 of the patients. Of those patients, 8 and 4 of them remained responsive at 1 and 2 years, respectively. Two of the patients who failed infliximab responded to adalimumab.

Treatment of granulomatous cheilitis with infliximab. Barry O, Barry J, Langan S. *Arch Dermatol* 2005; 141: 1081–3.

A 24-year-old woman with recalcitrant granulomatous cheilitis was treated with infliximab. In order to reduce the risk of infusion reactions, hydrocortisone (200 mg) was administered intravenously before treatment. The patient had restoration of normal lip architecture. Infliximab infusions were continued to maintain remission.

Melkersson–Rosenthal syndrome: a form of pseudoangioedema. Kakimoto C, Sparks C, White AA. *Ann Allergy Asthma Immunol* 2007; 99: 185–9.

A 19-year-old woman with recalcitrant granulomatous cheilitis was treated with infliximab infusions. The patient improved after the second infusion and had complete resolution after the third. Because adverse effects developed, therapy was changed to adalimumab (40 mg subcutaneously [SC] weekly), with no evidence of relapse noted.

Successful treatment of granulomatous cheilitis with adalimumab. Ruiz Villaverde R, Sanchez Cano D. *Int J Dermatol* 2012; 51: 118–20.

A 46-year-old woman with recalcitrant granulomatous cheilitis was treated with adalimumab at 80 mg SC for the first week, 40 mg the second week, and then every 2 weeks. After the third dose, clinical improvement was noticed, and no relapse occurred after completing 6 months of treatment.

Orofacial granulomatosis responding to weekly azithromycin pulse therapy. Yadav S, Dogra S, De D, et al. *JAMA Dermatol* 2015; 151: 219–20.

A case series of five patients with idiopathic orofacial granulomatosis on azithromycin 500 mg PO daily for 3 consecutive days weekly demonstrated improvement after 1 month and significant improvement in 3 months.

Granulomatous cheilitis successfully treated with roxithromycin. Inui S, Itami S, Katayama I. *J Dermatol* 2008; 35: 244–5.

A 37-year-old man with granulomatous cheilitis was treated with 300 mg/day of roxithromycin. Swelling resolved in 6 weeks. Roxithromycin was tapered, and remission was achieved at 1-year follow-up.

Successful treatment of granulomatous cheilitis with roxithromycin. Ishiguro E, Hatamochi A, Hamasaki Y, et al. *J Dermatol* 2008; 35: 598–600.

A 13-year-old male with granulomatous cheilitis treated with roxithromycin 150 mg/day. No relapse was noticed after 6 months of follow-up.

Melkersson–Rosenthal syndrome in childhood: successful management with combination steroid and minocycline therapy. Stein SL, Mancini AJ. *J Am Acad Dermatol* 1999; 41: 746–8.

Two children with Melkersson–Rosenthal syndrome were treated successfully with minocycline and prednisone.

Tetracyclines would usually be contraindicated until the permanent dentition has erupted.

Minocycline in granulomatous cheilitis: experience with 6 cases. Veller Fornasa C, Catalano P, Peserico A. *Dermatology* 1992; 185: 220.

Six case reports of patients with granulomatous cheilitis treated with minocycline after failing other oral therapies (steroids, clofazimine, hydroxychloroquine, and surgery). Only one of the six patients responded to minocycline. The sole responder was later found to have chronic granulomatous disease.

Treatment and follow-up of persistent granulomatous cheilitis with intralesional steroid and metronidazole. Coskun B, Saral Y, Cicek D, et al. *J Dermatol Treat* 2004; 15: 333–5.

Cheilitis granulomatosa treated with metronidazole. Miralles J, Barnadas MA, de Moragas JM. *Dermatology* 1995; 191: 252–3.

A 30-year-old woman with monosymptomatic Melkersson–Rosenthal syndrome was successfully treated with metronidazole 750–1000 mg daily for an 8-month tapering course.

Metronidazole has also been useful in two patients with granulomatous cheilitis associated with Crohn disease. Treatment failures are also reported.

Orofacial granulomatosis successfully treated with mycophenolate mofetil. Antonyan AS, Pena-Robichaux V, McHargue CA. *J Am Acad Dermatol* 2014; 70: 137–9.

A 59-year-old woman with orofacial granulomatosis was successfully treated with mycophenolate mofetil 500 mg twice a day (BID) with significant improvement after 1 month and near-complete remission after 6 months of therapy.

Third-Line Therapies	
• Cheiloplasty ± postoperative intralesional corticosteroids	C
• Thalidomide	E
• Hydroxychloroquine	E

Plastic surgical solutions for Melkersson–Rosenthal syndrome: facial liposuction and cheiloplasty procedures. Tan O, Atik B, Calka O. *Ann Plast Surg* 2006; 56: 268–73.

This article discusses surgical procedures in four patients, including reduction cheiloplasty consisting of mucosa, submucosa, and tangential muscle resection; crescent-shaped commissuroplasty; and facial liposuction. Mean follow-up duration was 13.7 months. No postoperative steroids were given, and there was no evidence of relapse in the follow-up period.

Cheilitis granulomatosa: successful treatment with combined local triamcinolone injections and surgery. Krutchkoff D, James R. *Arch Dermatol* 1978; 114: 1203–6.

A man with granulomatous cheilitis was treated with triamcinolone injections, followed by upper and lower cheiloplasty. Four months later, repeat cheiloplasty of the upper lip revealed granulomas were more numerous and larger than those observed initially. Postoperative corticosteroid injections maintained remission. The authors recommend postoperative corticosteroid injections to prevent exaggerated recurrences.

Long-term results after surgical reduction cheiloplasty in patients with Melkersson–Rosenthal syndrome and cheilitis granulomatosa. Ellitsgaard N, Andersson AP, Worsaae N, et al. *Ann Plast Surg* 1993; 31: 413–20.

A reduction cheiloplasty was performed on 13 patients. All were satisfied with their results, despite postoperative disease activity in six patients.

Lip reduction cheiloplasty for Miescher’s granulomatous macrocheilitis (cheilitis granulomatosa) in childhood. Oliver DW, Scott MJL. *Clin Exp Dermatol* 2002; 27: 129–31.

Lip reduction cheiloplasty provided successful treatment of granulomatous cheilitis in an 11-year-old boy, suggesting surgery can be safely undertaken in young children.

Effectiveness of surgical treatment of severe macrocheilia in a patient with orofacial granulomatosis. Vassallo C, Rivetti MM, Birroni V. *Clin Exp Dermatol* 2017; 42: 887–9.

After minimal improvement with diaminodiphenyl sulfone and slight improvement with oral clofazimine (discontinued due to elevated liver enzymes) and a lip twice the normal size with associated functional difficulties, cheiloplasty was undertaken and doxycycline was continued for 3 months with no recurrence at 3-year follow-up.

Treatment of Miescher’s cheilitis granulomatosa in Melkersson–Rosenthal syndrome. Camacho F, Garcia-Bravo B, Carriosa A. *J Eur Acad Dermatol Venereol* 2001; 15: 546–9.

The authors conclude the best treatment for resistant granulomatous cheilitis is surgery with immediate injection of triamcinolone, followed by a course of oral tetracycline.

Typically, cheiloplasty reduction procedures are possible when lesions are fixed and indurated without active disease with the exception of functional difficulties.

Successful treatment of granulomatous cheilitis with thalidomide. Thomas P, Walchner M, Ghoreschi K, et al. *Arch Dermatol* 2003; 139: 136–8.

A 39-year-old woman was treated with thalidomide 100 mg daily for 6 months. Lip swelling almost completely resolved. Thalidomide was reduced to 100 mg every other day for 2 months and then stopped. One year later, the patient’s condition was stable with no signs of relapse.

Baseline and follow-up neurologic assessments need to be done with thalidomide.

Thalidomide in treatment of refractory orofacial granulomatosis. Eustace K, Clowry J, Kirby B, et al. *Br J Dermatol* 2014; 171: 423–5.

Cheilitis granulomatosa: report of six cases and review of the literature. Allen CM, Camisa C, Hamzeh S, et al. *J Am Acad Dermatol* 1990; 23: 444–50.

Hydroxychloroquine 200–400 mg daily has been reported to be efficacious in granulomatous cheilitis. Chloroquine therapy has not been successful in Melkersson–Rosenthal syndrome.

Hailey–Hailey disease

Tabrez Sheriff, Benjamin S. Daniel,
Dedee F. Murrell

Hailey–Hailey disease (HHD; benign familial pemphigus) is a rare genodermatosis first described by the Hailey brothers in 1939. It is characterized by recurrent flares of vesicles, painful blistering, erosions, and weeping plaques, particularly involving the flexural areas. Frequent secondary infections are common. Symptoms usually begin in the second to fourth decades. The disease is generally localized, although widespread and severe involvement can occur. The most commonly affected sites are intertriginous areas like the axillae, groin, neck, and inframammary folds. The disease can exhibit an isomorphic response and affect areas of trauma or sites of inflammation from other diseases.

HHD is an autosomal dominant condition caused by loss of function mutations in the *ATP2C1* gene at 3q22.1. The gene encodes the adenosine triphosphate (ATP)-powered, magnesium-dependent calcium pump protein hSPCA1 on the Golgi membrane, which sequesters Ca^{2+} intracellularly into the Golgi apparatus. Calcium transport disruption can impair epidermal differentiation, barrier repair, cell–cell adhesion, and keratinocyte motility. The clinical and histopathologic picture can be similar to Darier disease and Grover disease.

MANAGEMENT STRATEGY

The management of HHD is accomplished through a combination of lifestyle modifications and medical and/or surgical therapy.

General measures – because friction, heat, and moisture can often exacerbate lesions of HHD, patients can adopt lifestyle changes aimed at reducing sweat, friction, and bacterial colonization by wearing loose clothing, avoiding excessively hot

environments, or using absorbent pads in skin folds to reduce moisture.

First-line treatments for mild disease include topical antimicrobials, topical corticosteroids, or topical calcineurin inhibitors aimed at reducing inflammation and treating opportunistic infections. Polymicrobial infections with bacteria, yeasts, and viruses also appear to be exacerbating factors, and secondary infection with these organisms can significantly worsen the disease, causing a pungent odor. Options for topical antimicrobials include clindamycin 1% cream, gentamicin 0.1% cream, mupirocin 2% cream, or antifungals such as ketoconazole 2%. If secondary infection with herpes simplex is suspected, *appropriate oral antiviral therapy* should be instituted.

Moderate-to-high potency topical corticosteroids can be used up to twice daily, although caution must be exercised with long-term use, particularly in intertriginous folds, due to the higher risk of skin atrophy in these areas. Combining antiinfective therapy with *topical corticosteroids* seems to be particularly helpful, but corticosteroids alone may reduce the severity of lesions. Topical calcineurin inhibitors such as tacrolimus 0.1% can be applied twice daily as an alternative for long-term use both as monotherapy or adjunctive therapy to topical corticosteroids. Some success has also been recorded with topical *calcitriol* and *topical fluorouracil*. Intralesional injection of botulinum toxin type A into the axillae or inguinal folds has also demonstrated efficacy as adjunctive therapy in reducing sweating and maceration. If there is not an expected response to topical therapy, clinicians should consider patch testing, as these patients commonly develop allergic contact dermatitis.

Second-line treatments for more severe cases include oral antibiotics, systemic therapies, and surgical or destructive methods. Antibiotic selection is based on culture sensitivities but intermittent courses of oral tetracyclines have proven beneficial due to their additional antiinflammatory property.

Systemic therapies have demonstrated efficacy in case reports. Options include dapsone, ciclosporin 2.5–3.5 mg/kg/day, methotrexate 15 mg/week, acitretin 25 mg/day, glycopyrrolate 1 mg/day, oral tacrolimus, and afamelanotide 16 mg sustained release subcutaneously. Short courses of oral prednisone should be administered with caution due to the potential of rebound of the disease activity upon withdrawal and risk for long-term dependence.

Surgical modalities including *cryotherapy*, *excision with grafting*, *dermabrasion*, and CO_2 and other lasers may also be beneficial in some patients, specifically for localized disease. *Electron beam therapy* has been reported for recalcitrant disease. There are few reports of treatment with biologic agents with limited benefit.

The chronic, relapsing nature of HHD has led to emerging treatments such as *oral magnesium* supplementation and *oral low-dose naltrexone*. Both are demonstrating increasing efficacy in refractory cases of Hailey–Hailey disease.

Low-dose naltrexone 1.5 mg–4.5 mg daily has demonstrated disease clearance and tolerability in multiple small case series within a 4-month period. The mechanism of action in Hailey–Hailey disease has not been validated; however, one hypothesis suggests some influence on intracellular calcium homeostasis and an antiinflammatory response. Similarly, magnesium supplementation of up to 300 mg daily has evidence of rapid disease clearance within a 4-week period.

Specific Investigations

- Biopsy
- Microbiologic cultures for bacteria, yeast, and herpesvirus
- Consider patch testing to topical preparations

First-Line Therapies

- Topical antimicrobials and systemic antibiotics **C**
- Topical corticosteroids **C**

Hailey–Hailey disease: the clinical features, response to treatment and prognosis. Burge SM. Br J Dermatol 1992; 126: 275–82.

In this series of 58 patients, 86% of patients found combinations of topical corticosteroids and antimicrobial agents helpful at the first sign of a flare.

Familial benign chronic pemphigus and doxycycline: a review of 6 cases. Le Saché-de Peufeilhoux L, Raynaud E, Bouchardeau A, et al. J Eur Acad Dermatol Venereol 2014; 28: 370–3.

This is a review of six patients who received oral doxycycline 50–100 mg/day. Two patients had complete remission, and two patients had significant improvement with mild flares during 4 years of follow-up.

The first article remains a key review of clinical and therapeutic aspects of this disease. We recommend that patients who are failing topical therapies are started on doxycycline as first-line systemic therapy.

Second-Line Therapies

- Topical calcineurin inhibitors **E**
- Calcitriol **E**
- Systemic corticosteroids **E**
- Naltrexone **C**
- Dapsone **E**
- Magnesium **E**
- Ciclosporin **E**
- Botulinum toxin **E**
- Carbon dioxide laser **E**

Topical tacrolimus ointment is an effective therapy for Hailey–Hailey disease. Sand C, Thomsen HK. Arch Dermatol 2003; 139: 1401–2.

A 67-year-old man was cleared with once-daily tacrolimus 0.1% within 1 month and was maintained with as-needed use.

Familial benign chronic pemphigus (Hailey–Hailey disease): use of topical immunomodulators as a modern treatment option. Tchernev G, Cardoso JC. Rev Med Chil 2011; 139: 633–7.

This is a report of a 51-year-old male responding well to pimecrolimus 1% cream twice daily.

Treatment of Hailey–Hailey disease with topical calcitriol. Bianchi L, Chimenti M, Giunta A. J Am Acad Dermatol 2004; 51: 475–6.

This report showed complete clearance of lesions for 3 months after completing 1 month of twice-daily calcitriol 3 mcg/g ointment.

Generalized Hailey–Hailey disease. Marsch WC, Stüttgen G. Br J Dermatol 1978; 99: 553.

The use of systemic corticosteroids was successful in controlling extensive disease, but cessation of therapy resulted in significant rebound.

Benign familial chronic pemphigus treated with dapsone. Sire DJ, Johnson BL. Arch Dermatol 1971; 103: 262.

Three 21- to 64-year-old patients were cleared with 100–200 mg of dapsone daily and one was maintained on 50 mg every other day.

Benign familial pemphigus (Hailey–Hailey disease) responsive to low dose ciclosporin. Nanda A, Khawaja F, Harbi R, et al. Indian J Dermatol Venereol Leprol 2010; 76: 422–4.

The reported patient was treated with 2.5 mg/kg/day and achieved a lasting remission with topical tacrolimus for maintenance.

Remission of refractory benign familial chronic pemphigus (Hailey–Hailey disease) with the addition of systemic ciclosporin. Varada S, Ramirez-FORT MK, Argobi Y, et al. J Cutan Med Surg 2015; 19: 163–6.

This patient had improvement on 2.8 mg/kg/day but nearly cleared on 3.8 mg/kg/day and had significant improvement in pain and pruritus.

Botulinum toxin type A as an adjuvant treatment modality for extensive Hailey–Hailey disease. Koeysers WJ, Van Der Geer S, Krekels G. J Dermatolog Treat 2008; 19: 251–4.

Diminution of the hyperhidrosis that exacerbates Hailey–Hailey disease may also be accomplished by utilizing oral glycopyrrolate.

Carbon dioxide laser treatment for Hailey–Hailey disease: a retrospective chart review with patient-reported outcomes. Hochwalt PC, Christensen KN, Cantwell SR, et al. Int J Dermatol 2015; 54: 1309–14.

Thirteen patients with refractory disease were treated with CO₂ laser, and all patients had no recurrence in the treated areas. Seventy percent had new disease outside of treated sites that responded to additional treatments.

Tacrolimus, pimecrolimus, and calcitriol are at least safe and good options for steroid-sparing maintenance therapy. Dapsone is generally safe and may work in certain patients. Ciclosporin can be used safely if doses do not exceed 5 mg/kg and patients are properly monitored. There are now a number of reports suggesting that botulinum toxin and CO₂ laser may be less invasive and efficacious options for refractory local disease.

Third-Line Therapies

- Surgical excision (with healing by secondary intention or by grafting) **E**
- Dermabrasion **E**
- Laser therapy (excluding CO₂ laser – see earlier) **E**
- Superficial irradiation (grenz rays or electron beam) **E**
- Methotrexate **E**
- Oral retinoids **E**
- Topical 5-fluorouracil **E**
- Biologics **E**
- Photodynamic therapy **E**
- Narrowband ultraviolet B therapy **E**
- Low-dose naltrexone **E**
- Oral magnesium chloride **E**

Surgical treatment of familial benign chronic pemphigus. Crotty CP, Scheen SR, Masson JK, et al. Arch Dermatol 1981; 117: 540–2.

This is a report of five patients who had excision followed by split-thickness skin grafting. Three patients had no recurrence in treated areas, and one patient had mild recurrence after 8 years.

Refractory Hailey-Hailey disease successfully treated with sandpaper dermabrasion. LeBlanc KG Jr, Wharton JB, Sheehan DJ. *Skinmed* 2011; 9: 263-4.

A 53-year-old female had a lasting improvement on the neck and popliteal fossae after fine sandpaper dermabrasion down to the superficial dermis; however, she did have recurrence in the axillae.

Successful treatment of refractory Hailey-Hailey disease with a 595-nm pulsed dye laser: a series of 7 cases. Hunt KM, Jensen JD, Walsh SB, et al. *J Am Acad Dermatol* 2015; 72: 735-7.

This report showed varying amounts of improvement of clinical lesions in six of seven patients treated with 595-nm pulsed dye laser.

Effective treatment of Hailey-Hailey disease with a long-pulsed (5 ms) alexandrite laser. Awadalla F, Rosenbach A. *J Cosmet Laser Ther* 2011; 13: 191-2.

A 35-year-old male had complete clearance after 13 treatments with long-pulsed alexandrite laser for 1 year with occasional short courses of topical hydrocortisone. The fluences ranged from 12 to 20 J/cm² with 10- to 15-mm spot sizes.

Persistent improvement of previously recalcitrant Hailey-Hailey disease with electron beam therapy. Narbutt J, Chrusciel A, Rychter A, et al. *Acta Derm Venereol* 2010; 90: 179-82.

Three patients had improvement of lesions after 20 Gy in 10 fractions to 90% isodose to each axilla without recurrence in 38 months of follow-up.

Methotrexate for refractory Hailey-Hailey disease. Vilarinho C, Ventura F, Brito C. *J Eur Acad Dermatol Venereol* 2010; 24: 106.

A 42-year-old woman showed near clearance after 3 months of oral methotrexate 15 mg weekly and had no recurrence in 2 years of follow-up.

Vesiculobullous Hailey-Hailey disease: successful treatment with oral retinoids. Hunt MJ, Salisbury EL, Painter DM, et al. *Australas J Dermatol* 1996; 37: 196-8.

A 56-year-old male had significant improvement after 6 weeks of 25 mg of daily etretinate. The patient was recurrence free 2 months after completing a 6-month course.

Successful treatment of Hailey-Hailey disease with acitretin. Berger EM, Galadari HI, Gottlieb AB. *J Drugs Dermatol* 2007; 6: 734-6.

A 64-year-old male had significant improvement after 6 months of 25 mg of daily acitretin.

Successful treatment of Hailey-Hailey disease with topical 5-fluorouracil. Dammak A, Camus M, Anyfantakis V, et al. *Br J Dermatol* 2009; 161: 967-8.

A 43-year-old male was treated with 5-fluorouracil 5% cream three times weekly for 3 months, followed by weekly applications

for 3 months, and showed near clearance for 6 months after completion of therapy.

Case reports of etanercept in inflammatory dermatoses. Norman R, Greenberg RG, Jackson JM. *J Am Acad Dermatol* 2006; 54 (Suppl 2): S139-42.

A 47-year-old woman was treated with subcutaneous etanercept 25 mg weekly for 1 month, then increased to 50 mg for 6 months, and then to 75 mg weekly to improve response. She showed dramatic improvement in 10 months and continued to improve.

Experience with photodynamic therapy in Hailey-Hailey disease. Fernandez Guarino M, Ryan AM, Perez-Garcia B, et al. *J Dermatol Treat* 2008; 19: 288.

Three patients were treated with methyl aminolevulinic acid for 3 hours and then exposed to 7.5 min of 630 nm red light. The patients had a lot of pain and did not have significant improvement.

Successful therapeutic use of targeted narrow-band ultraviolet B therapy for refractory Hailey-Hailey disease. Hamada T, Umemura H, Aoyama Y, et al. *Acta Derm Venereol* 2013; 93: 110-1.

This report showed efficacy of narrowband ultraviolet B (NB-UVB) therapy conflicting with previous reports of exacerbation with UV light.

Surgery can be definitive and should be considered for refractory localized disease. Many authors report some recurrences, either around the edges of the treated areas or on further friction or trauma. Treatment is invasive, and the trauma of dressings may exacerbate the disease, so proper patient selection is important. The rest of the modalities in this section have few reports demonstrating their efficacy. They should be reserved for very recalcitrant disease in appropriate patients.

Treatment of Hailey-Hailey disease with low-dose naltrexone. Albers LN, Arbiser JL, Feldman RJ. *JAMA Dermatol* 2017; 153(10): 1018-20. doi:10.1001/jamadermatol.2017.2446.

Three patients with severe Hailey-Hailey disease recalcitrant to multiple therapies, treatment with low-dose naltrexone at 3 mg and, in two of the patients, titrated to 4.5 mg nightly, was attempted and resulted in clinical resolution within 2 months. Lesions flared when stopping low-dose naltrexone and cleared within a few days on rechallenge.

Oral magnesium chloride: a novel approach in the management of Hailey-Hailey disease. Barde NG, Mishra DB, Ingole SO. *Indian J Dermatol Venereol Leprol* 2017; 83: 259.

A 34-year-old woman was treated with 70 mL of oral magnesium chloride containing 300 mg of elemental magnesium. A significant improvement in the skin lesions was noted after 15 days of treatment and an almost complete remission of signs and symptoms was obtained after 4 weeks. No side effects were reported by the patient, except for the unpleasant taste of the solution. The patient's quality of life significantly improved. The pre- and post-treatment serum levels of electrolytes, in particular, calcium, magnesium, and zinc, were within normal limits. The patient is still on treatment for 4 months, with sustained remission.

Hand and foot eczema (endogenous, dyshidrotic eczema, pompholyx)

Surina Frey, Margaret L. Snyder,
Emma Guttman-Yassky, Andreas Wollenberg

The hands and feet are essential tools in daily activities. The bipedal gait and manual activity of *homo sapiens* result in high exposure of these areas to numerous allergens and irritants. The palmar and plantar skin have a similar skin structure with a thick corneal layer, thus creating a special situation regarding penetration characteristics of topical therapies.

Cases of hand and foot eczema can be classified regarding their etiology, clinical presentation, and chronicity. Hand and foot eczema can be triggered by endogenous factors, such as atopy or contact to exogenous factors, such as irritants or allergens.

A clinical classification of the disease is most commonly based on morphology, ranging from pompholyx and dyshidrotic eczema to hyperkeratotic and fissured skin lesions. The clinical presentation is quite variable, and transitional as well as overlapping forms are often present. Pruritus and pain are frequent symptoms, especially if fissures are present. Secondary infection is common.

The acute, recurrent, and persistent course of the hand and foot eczema will largely determine the choice of treatment modalities.

MANAGEMENT STRATEGY

Diagnostic procedures should be performed either to exclude the common differential diagnoses of hand and foot dermatitis such as dermatomycoses and psoriasis, or to reveal potential trigger factors of irritant and allergic contact eczema. The presence of lesions on both hands and feet is associated with chronic and more severe hand eczema, as well as a hyperkeratotic subtype of hand eczema.

Before starting any treatment, avoidance strategies and measures for known irritants and allergens should be employed. This

may include a nickel-free diet and complete cessation of smoking for nickel-sensitized patients. Moreover, patient education programs and adherence improving techniques are helpful components of an effective management system.

Possible treatment options include topical agents, ultraviolet (UV) phototherapy, and systemic therapy. Dry and fissured skin lesions are best treated with highly lipophilic ointments, possibly combined with occlusive or semi-occlusive dressings to increase penetration. Keratolytic agents such as urea or salicylic acid are helpful in hyperkeratotic eczema, whereas moist and oozing skin may benefit from hydrophilic creams or gels. Desiccative agents have shown value in dyshidrotic forms of eczema. Antiseptics should be considered to avoid superinfection, especially in erosive or fissured lesions.

Topical corticosteroids of medium to high potency are the mainstay of all topical therapies of hand eczema. The topical *calcineurin inhibitor* *tacrolimus* may also be effective, especially for long-term treatment, but should not be combined with UV therapy. *Pimecrolimus* has shown less efficacy.

Calcipotriol ointment may show beneficial effects in chronic hand eczema, especially in the hyperkeratotic subtype, and may reflect a topical steroid-sparing alternative.

Adjuvant use of oral *antihistamines* has demonstrated only a slight effect on pruritus. Oral *antibiotics*, such as first generation cephalosporins, may be added in case of severe bacterial infection.

Psoralen-UVA (PUVA) therapy is the most effective UV-light treatment option for chronic, recurrent hand and foot eczema. *UVA phototherapy* or *narrowband UVB (NB-UVB) phototherapy* may also be useful.

Systemic treatment is frequently required in severe, refractory, or persistent hand and foot eczema. Systemic corticosteroids are recommended for short-term use only. *Prednisone* 0.5–1.0 mg/kg/day tapered over 2 weeks is a typical regimen. Systemic retinoids such as *alitretinoin* or *acitretin* are helpful if pregnancy prevention programs are followed strictly. Classic immunosuppressants such as *methotrexate*, *azathioprine*, and *mycophenolate mofetil* have been tried successfully. *Ciclosporin* may be especially useful in atopic hand eczema, and is approved in many countries for severe atopic dermatitis. Interestingly, a case has also been reported of improvement with oral apremilast.

New emerging therapies include *dupilumab*, a monoclonal antibody blocking the IL-4/IL-13 pathway. Topical Janus kinase (JAK) inhibitors such as *delgocitinib* may improve chronic hand eczema despite its subtype, and should be useful in therapy-refractory chronic hand eczema. Oral JAK inhibitors will undoubtedly be useful for hand eczema in the future.

Intradermal localized *botulinum toxin A* will reduce sweating and may therefore be helpful as adjuvant therapies in dyshidrotic forms.

Specific Investigations

- Patch testing
- Skin prick testing
- Bacterial and mycological diagnostics

Factors associated with combined hand and foot eczema.

Agner T, Aalto-Korte K, Andersen KE, et al. *J Eur Acad Dermatol Venereol* 2017; 31: 828–32.

About 30% of all hand eczema patients presented with concomitant foot eczema. Hyperkeratotic lesions, a long duration, and high severity of the hand eczema were associated with combined foot involvement.

Patch test results of hand eczema patients: relation to clinical types. Boonstra MB, Christoffers WA, Coenraads PJ, et al. *J Eur Acad Dermatol Venereol* 2015; 29: 940–7.

The retrospective study including 1571 patients revealed nickel sulfate, cobalt, fragrances, and preservatives as the most common causative allergens in hand eczema. Contact allergy was more prevalent in patients with recurrent vesicular hand eczema.

First-Line Therapies

• Topical corticosteroids	A
• Topical JAK inhibitors	A
• Topical calcineurin inhibitors	B
• Emollients	B
• Keratolytics (if hyperkeratotic)	D
• Oral antibiotics (if infected)	D

Hand eczema: treatment. Elsner P, Agner T. *J Eur Acad Dermatol Venereol* 2020; 34 (Suppl 1): 13–21.

Broad review on the treatment of hand eczema and new emerging therapeutic targets.

Efficacy and safety of topical delgocitinib in patients with chronic hand eczema: data from a randomized, double-blind, vehicle-controlled phase IIa study. Worm M, Bauer A, Elsner P, et al. *Br J Dermatol* 2020; 182(5): 1103–10.

A total of 91 patients with chronic hand eczema were randomized to receive delgocitinib ointment or vehicle for 8 weeks. Of the patients receiving delgocitinib, 46% achieved a Physician's Global Assessment of disease severity (PGA) of clear or almost clear with 2-point reduction from baseline compared with 15% receiving placebo ($p=0.0009$). Additionally, mean Hand Eczema Severity Index (HECSI) score was lower with delgocitinib than with placebo (13.0 vs. 25.8; $p=0.0003$).

Topical tacrolimus (FK 506) and mometasone furoate in treatment of dyshidrotic palmar eczema: a randomized, observer-blinded trial. Schnopp C, Remling R, Mohrenschlager M, et al. *J Am Acad Dermatol* 2002; 46: 73–7.

In 16 patients with dyshidrotic hand eczema, topical tacrolimus 0.1% ointment applied twice daily showed an efficacy comparable to 0.1% mometasone furoate ointment after 4 weeks.

Efficacy and safety of pimecrolimus cream 1% in mild-to-moderate chronic hand dermatitis: a randomized, double-blind trial. Hordinsky M, Fleischer A, Rivers JK, et al. *Dermatology* 2010; 221: 71–7.

Less than 30% of 652 patients showed improved skin and reduced itch upon topical therapy with pimecrolimus 1% cream applied twice daily with overnight occlusion over 6 weeks.

Second-Line Therapies

• Alitretinoin	A
• Acitretin	B
• Topical PUVA (cream or bath)	B
• UVA and NB-UVB	B
• Intradermal botulinum A toxin	C

Efficacy and safety of oral alitretinoin (9-*cis* retinoic acid) in patients with severe chronic hand eczema refractory to topical corticosteroids: results of a randomized, double-blind,

placebo-controlled, multicentre trial. Ruzicka T, Lynde CW, Jemec GB, et al. *Br J Dermatol* 2008; 158: 808–17.

Alitretinoin 30 mg administered daily for 12–24 weeks improved skin lesions and subjective symptoms in 48% of 409 patients with chronic hand eczema.

Alitretinoin and acitretin in severe chronic hand eczema: results from a retrospective daily practice study. Politiek K, Christoffers WA, Coenraads PJ, et al. *Dermatol Ther* 2016; 29: 364–71.

Acitretin is effective as well, but more difficult to maintain, and patients discontinue more frequently due to side effects.

An observer-blinded randomized controlled pilot trial comparing localized immersion psoralen-ultraviolet A with localized narrowband ultraviolet B for the treatment of palmar hand eczema. Brass D, Fouweather T, Stocken DD, et al. *Br J Dermatol* 2018; 179: 63–71.

Both immersion PUVA and NB-UVB therapy applied twice weekly over 12 weeks resulted in improvement of skin lesions in 23 patients with hand eczema, but more patients in the PUVA group reached the primary outcome of a clear or almost clear PGA.

Comparison of localized high-dose UVA1 irradiation versus topical cream psoralen-UVA for treatment of chronic vesicular dyshidrotic eczema. Petering H, Breuer C, Herbst R, et al. *J Am Acad Dermatol* 2004; 50: 68–72.

Twenty-four of 27 patients treated with UVA1 irradiation and cream PUVA on one hand, respectively, showed a comparable improvement in chronic dyshidrotic eczema after 3 weeks of treatment.

Treatment of dyshidrotic hand dermatitis with intradermal botulinum toxin. Swartling C, Naver H, Lindberg M, et al. *J Am Acad Dermatol* 2002; 47: 667–71.

Seven of 10 patients treated with intradermal botulinum toxin A showed improved skin and reduced itch.

Third-Line Therapies

• Ciclosporin	A
• Methotrexate	D
• Azathioprine	C
• Mycophenolate mofetil	E
• Topical calcipotriol	C
• Dupilumab	B
• Apremilast	E

Drug survival of cyclosporine in the treatment of hand eczema: a multicentre, daily use study. Christoffers WA, Politiek K, Coenraads PJ, et al. *J Eur Acad Dermatol Venereol* 2016; 30: 63–6.

In this study, 62.9% of 102 patients presented good improvement after 3 months of cyclosporin (max. dosage 5 mg/kg/day) in different up- and down-dosing regimens. Patients with vesicular hand eczema responded best.

Low-dose oral methotrexate treatment for recalcitrant palmo-plantar pompholyx. Egan CA, Rallis TM, Meadows KP, et al. *J Am Acad Dermatol* 1999; 40: 612–4.

Five patients with refractory pompholyx received methotrexate (12.5–22.5 mg) weekly, resulting in a reduction or discontinuation of concomitant systemic prednisone use.

Azathioprine treatment and drug survival in patients with chronic hand eczema – results from daily practice. Oosterhaven JAF, Politiek K, Schuttelaar M-LA. *Contact Dermatitis* 2017; 76: 304–7.

A retrospective analysis on 30 patients with chronic hand eczema showed that azathioprine therapy can be effective, but side effects led to discontinuation of 15 out of 30 patients during the first 3 months.

Dyshidrotic eczema treated with mycophenolate mofetil. Pickenacker A, Luger TA, Schwarz T. *Arch Dermatol* 1998; 134: 378–9.

Single case report of a patient with refractory dyshidrotic eczema and complete resolution after initiation of mycophenolate mofetil at a dose of 1.5 g twice daily followed by 1 g/day for 1 year.

Calcipotriol ointment shows comparable efficacy to topical steroids in chronic hand eczema. Juntongjin P, Pongprasert R. *Dermatol Ther* 2019; 32: e12956.

Topical calcipotriol ointment (0.005%) showed comparable effects on chronic hand eczema as desoximetasone ointment with up to 75% reduction of skin lesions.

Chronic hand eczema and hepatogenic pruritus with good response to apremilast. Navarro-Trivino FJ, Cuenca-Barrales C, Vega-Castillo JJ, et al. *Dermatol Ther* 2019 Apr 1; 32(3): e12879. doi: 10.1111/dth.12879 [Epub ahead of print].

A 65-year-old man with chronic hand eczema for 5 years and concomitant non-alcoholic hepatic steatosis who could not tolerate alitretinoin due to elevation in transaminases had complete clearance of skin lesions after 1 month of treatment with apremilast 30 mg Q12HR.

A retrospective review of dupilumab for hand dermatitis. Lee N, Chipalkatti N, Zancanaro P, et al. *Dermatology* 2019; 235: 187–8.

A reevaluation of 66 AD patients with and without hand involvement on dupilumab; both groups showed improvement of symptoms.

Effect of dupilumab on hand eczema in patients with atopic dermatitis: an observational study. Oosterhaven JAF, Voorberg AN, Romeijn GLE, et al. *J Dermatol* 2019; 46: 680–5.

Forty-seven AD patients with concomitant chronic hand eczema and dupilumab therapy showed improvement of skin lesions over a period of 16 weeks with 60% reaching a 75% improvement of the Hand Eczema Severity Score. Concomitant use of topical corticosteroids and calcineurin inhibitors was allowed throughout the study.

Dupilumab for the treatment of dyshidrotic eczema in 15 consecutive patients. Waldman RA, DeWane ME, Sloan B, et al. *J Am Acad Dermatol* 2020; 82: 1251–2.

Fifteen non-AD patients with refractory dyshidrotic hand eczema received dupilumab. All reached partial and 40% reached complete response to treatment.

Dyshidrotic eczema treated with dupilumab: report of 2 cases. Weston G, Strober B. *J Am Acad Dermatol* 2018; 79(3): AB114.

Two adults with dyshidrotic eczema refractory to various combinations of topical and systemic treatments with complete clearance of lesions after 8–16 weeks of dupilumab (600 mg loading dose followed by 300 mg every other week).

Hemangiomas

Yamila Goenaga-Vázquez, Adelaide A. Hebert

Hemangiomas are a neoplastic proliferation of endothelial cells that are generally benign but have been associated with local tissue damage, functional impact, and ulceration. The true incidence is unknown but is reported as approximately 5% in Caucasian infants. Hemangiomas occur more frequently in Caucasian female infants with a predilection for premature infants, especially of low birth weight or multiple gestations. Most hemangiomas arise spontaneously during infancy, but an autosomal-dominant pattern of inheritance has rarely been reported.

MANAGEMENT STRATEGY

Cutaneous hemangiomas appear in the first few weeks of life and reach 80% of size by 3 months, with spontaneous involution in most cases by age 10. Early evaluation and treatment are critical to limit the patient's functional impairment and disfigurement. About half of children with hemangiomas have normal skin after involution, but the rest may have residual changes, including telangiectasias, atrophy, fibrofatty residuum, and scarring.

Differentiating benign common hemangiomas from other vascular anomalies is essential, as the pathophysiology, treatment modalities, and prognoses are significantly different. Vascular malformations and tumors, such as the kaposiform hemangioendothelioma (KE) and tufted angioma (TA), differ from hemangiomas in both clinical and histologic appearance as well as growth rate and involutional tendencies. In particular, KE and TA are associated with Kasabach–Merritt syndrome and the accompanying coagulopathy, whereas common hemangiomas are not. The majority of common hemangiomas occur as solitary lesions but

can be a sign of multisystem involvement such as diffuse neonatal hemangiomatosis, LUMBAR syndrome (lower body congenital infantile hemangiomas (IHs) and other skin defects, urogenital anomalies and ulceration, myelopathy, bony deformities, anorectal malformations and arterial anomalies, and rectal anomalies), and PHACES syndrome (posterior fossa malformation, large segmental hemangiomas, arterial lesions, cardiac anomalies, eye abnormalities, and sternal cleft/supraumbilical raphe).

Although the natural course of hemangiomas is self-limited, pharmaceutical intervention is indicated for most hemangiomas due to the potential for rapid growth and potential ulceration and scarring, disfigurement or functional impairment (e.g., compress or obstruct vital structures such as the larynx, eyes, ears, and nose). IHs associated with structural anomalies (e.g., in PHACES or LUMBAR syndromes) also warrant therapy. After identifying an IH, the clinician should facilitate evaluation by a hemangioma specialist within weeks 3–8 of the newborn's life as the most rapid growth of superficial hemangiomas typically occurs between 5.5 and 7.5 weeks of age (termed the proliferative phase).

Topical and systemic β -blockers have become the preferred first-line therapy in very early or small hemangiomas. Oral propranolol hydrochloride solution was approved by the US Food and Drug Administration (FDA) in 2014 for use in infants with an escalating starting dose of 1.2 mg/kg/day to a target dose of 3.4 mg/kg/day divided into two daily doses. Treatment typically is continued for at least 6 months and often is maintained until 12 months of age or longer. Adverse events are rare but may include the masking of hypoglycemia, hypotension, and bradycardia. Administering the medication after feeding and monitoring the heart rate and blood pressure after dose increases can help reduce these seldom-encountered side effects. Bronchial hyperreactivity is another rare but possible side effect, especially in susceptible individuals. Other β -blockers, such as atenolol and nadolol, have been shown to be effective for the treatment of IHs in small clinical trials, and are probably associated with fewer side effects in comparison to propranolol. Timolol, available as a solution or a gel, has been shown in small randomized clinical trials to be safe and effective for superficial, small, thin non-ulcerated IHs with twice-daily topical application.

Surgical excision, either alone or in combination with corticosteroids or β -blockers, may also be employed in certain cases such as large IHs located periorbitally or on the nasal tip, or for the treatment of residual skin changes after involution. Cyclophosphamide, vincristine, bleomycin, and interferon are considered obsolete therapies since the advent of propranolol.

Specific Investigations

- Ultrasound with Doppler
- Magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA)
- Biopsy with immunohistochemistry

The diagnosis of a hemangioma is made clinically but the following clinical scenarios warrant imaging: IHs ≥ 5 cm on the face may need to be imaged with contrast-enhanced MRI and with MR angiography of the head and neck to rule out PHACES syndrome. IHs ≥ 5 cm on the midline back and perineal region or with segmental morphology in children ≤ 3 months of age should be imaged with ultrasound of the spine and with color Doppler ultrasound of the abdomen and pelvis to rule out LUMBAR syndrome. Atypical lesions appearing after 6 months of age and ≥ 5 cutaneous IHs also warrant further imaging. IHs that are

segmental, especially if multiple, may raise suspicion for the presence of visceral hemangiomatosis. There is no defined approach for follow-up imaging intervals for superficial IHs; however, liver and visceral involvement might be followed with MR or ultrasound every 2–3 months to assess response to therapy.

The changing face of complicated infantile hemangioma treatment. Menapace D, Mitkov M, Towbin R, et al. *Pediatric Radiol* 2016; 46: 1494–1506.

This article reviews the 2014-updated International Society for the Study of Vascular Anomalies classification for vascular anomalies, focusing on the management of IHs with regard to indications for imaging. Imaging should only be performed if the diagnosis of IH is uncertain or associated anatomic abnormalities are suspected.

GLUT1: a newly discovered immunohistochemical marker for juvenile hemangiomas. North PE, Waner M, Mizeracki A, et al. *Hum Pathol* 2000; 31: 11–22.

Immunohistochemical staining can serve as a useful adjunct to distinguish between IHs and other common vascular malformations or vascular neoplasms that present during infancy. GLUT1 (glucose transporter 1) stain is shown to be highly specific and uniformly positive in the endothelial vasculature of IHs. Staining for placenta-associated vascular antigens Fc gamma RII, Lewis Y antigen (LeY), and merosin in IHs has shown a high specificity and holds promise for the development of an IH-specific immunohistochemical panel.

First-Line Therapies

• Systemic β -blockers	A
• Topical β -blockers	B
• Topical corticosteroids	D
• Intralesional corticosteroids	B
• Systemic corticosteroids	B

A randomized, controlled trial of oral propranolol in infantile hemangioma. Léauté-Labrèze C, Hoeger P, Mazereeuw-Hautier J, et al. *N Engl J Med* 2015; 372: 735–46.

A randomized, double-blind, multicenter trial of 460 infants to assess the efficacy of oral propranolol in treating IHs. In the first stage, the infants were randomized to receive either a placebo or one of four propranolol regimens of either 1 mg/kg/day or 3 mg/kg/day of propranolol for a duration of 3 or 6 months. After an interim analysis, new infants were treated with either a placebo or 3 mg/kg/day of propranolol for 6 months. Sixty percent of all infants receiving this regimen had complete or nearly complete resolution of the target hemangioma.

Clinical practice guideline for the management of infantile hemangiomas. Krowchuk DP, Frieden IJ, Mancini AJ, et al. *Pediatrics* 2019; 143: 1.

This is a comparative effectiveness review of potential benefits and harms of diagnostic modalities and pharmacologic and surgical treatments for IHs.

Interventions for infantile haemangiomas of the skin. Novoa M, Baselga E, Beltran S, et al. *Cochrane Database Syst Rev* 2018; 4: CD006545.

This review updates the evidence on the effects of different interventions for the management of IHs. Twelve interventions, 28 studies, and 30 comparisons were included. Oral propranolol

and topical timolol maleate are more beneficial than placebo in terms of clearance or other measures of resolution, or both, without an increase in harm. The authors found no evidence of a difference between oral propranolol and topical timolol maleate with regard to reducing hemangioma size but are uncertain if there is a difference in safety.

Clinical management of IHs depends on the following risk factors, among others: the grade of complication, presence of comorbidities, clinician experience, and patient factors.

Pharmacologic interventions for infantile hemangioma: a meta-analysis. Chinnadurai S, Fonnesbeck C, Snyder KM, et al. *Pediatrics* 2016; 137: e2015389.

In this meta-analysis, 18 studies were included assessing relative expected rates of IH clearance associated with β -blockers and steroids. Oral propranolol had the largest mean estimate of expected clearance relative to oral corticosteroids and control. Corticosteroids demonstrated moderate effectiveness at reducing size/volume.

Efficacy of intralesional steroid injection in head and neck hemangioma: a systematic review. Prasetyono TO, Djoenaedi I. *Ann Plast Surg*. 2011; 66: 98–106.

This is a systematic review done during the period 1996–2008 evaluating the efficacy of intralesional steroid injections in head and neck hemangiomas. The study included 22 prospective and retrospective case reviews. From 749 patients, a total of 71% of patients demonstrated excellent clinical response, 23.4% good, 2.96% poor, 2% no response, and 0.6% were lost to follow-up. The authors concluded that this treatment modality is a good and safe alternative.

Topical timolol maleate treatment of infantile hemangiomas. Puttgen K, Lucky A, Adams D, et al. *Pediatrics* 2016; 138.

This multicenter retrospective cohort study of 731 patients evaluated the efficacy of topical timolol. At 6–9 months of treatment, 92.3% of patients had improved color and 76.6% had improvement in size, extent, and volume. The best response to therapy occurred in superficial hemangiomas <1 mm thick.

RCT of timolol maleate gel for superficial infantile hemangiomas in 5- to 24-week-olds. Chan H, McKay C, Adams S, et al. *Pediatrics* 2013; 131: e1739–47.

In this randomized control trial studying the efficacy of timolol compared with placebo, 41 infants with superficial IHs without ulceration not proximal to mucosal surfaces were recruited and randomly assigned to placebo and treatment (timolol maleate 0.5% gel) groups. A significantly higher proportion of treated IHs had reduced in size by >5% at weeks 20 and 24 ($p < 0.02$) than those in the placebo arm. Topical timolol maleate 0.5% gel with a maximum dose of 0.5 mg/day provided a safe and effective option for small superficial IHs that had not ulcerated and were not on or proximate to mucosal surfaces.

Comparison of efficacy and safety between propranolol and steroid for infantile hemangioma: a randomized clinical trial. Kim KH, Choi TH, Choi Y, et al. *JAMA Dermatol* 2017; 153:529–36.

In this small, non-inferiority RCT 34 children aged 0.3–8.2 months with hemangiomas located predominantly on the face were randomly assigned to treatment with propranolol 2 mg/kg/day in three divided doses or prednisolone 2 mg/kg/day in a single dose for 16 weeks. A response to treatment was achieved by 96% and 92% of patients in the propranolol and systemic

corticosteroid groups, respectively. Adverse effects were generally mild and occurred with equal frequency in both groups.

Atenolol treatment for infantile haemangioma. Tasani M, Glover M, Martinez AE, et al. *Br J Dermatol* 2017; 176: 1400–2.

This series of 19 patients with IHs were treated with atenolol following cessation of propranolol due to adverse effects. Eighty-nine percent of patients reported good response of the IH with atenolol treatment. Sleep disturbance disappeared within 48 h after starting treatment with atenolol in 93% of patients and 100% of patients who were converted to atenolol due to bronchial hyperreactivity reported reduction of at least 50% in the frequency of episodes requiring bronchodilator treatment.

Atenolol is a selective β -blocker that spares the β_2 -adrenergic receptors and does not cross the blood–brain barrier, which may account for fewer respiratory and central nervous system (CNS) side effects (e.g., sleep disturbances), respectively.

Topical timolol as adjunct therapy to shorten oral propranolol therapy for infantile hemangiomas. Mannschreck DB, Huang AH, Lie E, et al. *Pediatric Dermatology* 2019; 36: 283–9.

A retrospective chart review of 559 patients with IH seen at the pediatric dermatology clinic of a tertiary care center between December 2008 and January 2018. Children were grouped by treatment received: propranolol only, timolol only, propranolol to timolol, timolol to propranolol to timolol, and timolol to propranolol. Among all patients treated with propranolol, those who received propranolol followed by timolol received the shortest duration of oral propranolol and were the youngest at the time of propranolol completion.

Ultrapotent topical corticosteroid treatment of hemangiomas of infancy. Garzon MC, Lucky AW, Hawrot A, et al. *J Am Acad Dermatol* 2005; 52: 281–6.

A retrospective review of 34 patients with hemangiomas treated with class I topical steroids showed good response in 35%, partial response in 38%, and no response in 27%. Treatment protocols varied between patients.

Second-Line Therapies

• Surgical excision	D
• Pulsed-dye laser	B
• Becaplermin gel for ulcerated lesions	D

Surgical treatment of facial infantile hemangiomas: an analysis based on tumor characteristics and outcomes. Goldenberg DC, Hiraki PY, Marques TM, et al. *Plast Reconstr Surg* 2016; 137: 1221–31.

A retrospective case review of 74 patients treated surgically was analyzed to evaluate outcomes based on tumor-related clinical features. Surgery was performed during the proliferative phase in 58.1% of patients and growth-related deformity was the main indication. The best candidates for emergency surgery were non-responders to pharmacologic therapy with segmental periorbital hemangiomas, whereas those undergoing elective surgery were patients with localized lip, nasal, or eyelid hemangiomas in the proliferative phase. Although most patients with IHs should be managed with pharmacotherapy, surgery remains an option. The exact algorithm of when to operate remains controversial.

Response of ulcerated perineal hemangiomas of infancy to becaplermin gel, a recombinant human platelet-derived growth factor. Metz BJ, Rubenstein MC, Levy ML, et al. *Arch Dermatol* 2004; 140: 867–70.

Eight infants were treated with becaplermin gel 0.01% for ulcerated perineal hemangiomas of infancy. Rapid ulcer healing occurred in all patients within 3–21 days (average, 10.25 days). The rapid healing achieved with 0.01% becaplermin gel allows a reduction in the risk of secondary infection, pain, and the need for hospitalization, as well as in the costs that often accumulate from multiple follow-up visits and long-term therapy.

Third-Line Therapy

• Imiquimod	C

A phase II, open-label study of the efficacy and safety of imiquimod in the treatment of superficial and mixed infantile hemangioma. McCuaig CC, Dubois J, Powell J, et al. *Pediatr Dermatol* 2009; 26: 203–12.

This is a phase II, open-label, non-comparative study of imiquimod applied for 16 weeks, with posttherapy follow-up 16 weeks later (8 months total). Sixteen infants with a mean age at entry of 4.1 months were enrolled. At the 4-month posttreatment visit, 11 of 14 subjects had improvement in erythema. Treatment was generally well tolerated with low systemic exposure. Improvement was observed in hemangioma coloration, but not lesion size, suggesting effects were limited to the superficial component.

Hereditary angioedema

Tabi A. Leslie

Hereditary angioedema (HAE) is a rare genetic disorder characterized by debilitating, disfiguring, and potentially fatal attacks of edema. There are three types of HAE: type I HAE (HAE-1) and type II HAE (HAE-2), the most common forms, are autosomal dominantly inherited with a prevalence of 1:50,000 due to mutations in the C1-esterase inhibitor (C1-INH) gene on chromosome 11q12-q13.1. De novo mutations of the gene controlling C1-INH (*SERPING1*) can occur, accounting for approximately 25% of C1-INH-HAE cases. HAE-1 is characterized by a quantitative abnormality of the C1-INH (low antigen and low functional levels), which accounts for 85% of HAE patients. HAE-2 is due to a functional defect of the inhibitor of the C1-INH (with normal protein concentration); this comprises about 15% of patients. HAE-1/2 are mediated by the protease kallikrein and the nonapeptide bradykinin, acting on B₂ receptors and 98% of cases have low C4, rising to nearly 100% during attacks. The third type of HAE, previously known as HAE type III (or the estrogen-dependent type), is now referred to as *HAE with normal C1-INH* (HAE nC1-INH). Less prevalent than HAE-1/2, this type is associated with a positive family history, occurring predominantly in women, with no detectable abnormality of C1-INH or other complement components. A mutation in the gene encoding for factor 12 (*F12*), which encodes for the coagulation factor XII (FXII or Hageman factor), has been identified in some of these families. HAE attacks are characterized by sudden, unpredictable swellings of subcutaneous and submucosal tissues, including abdominal organs, genitals, face, and the upper airway. The angioedema is often asymmetrical and may sometimes be painful rather than pruritic. HAE is not associated with urticarial wheals, as it is not mast cell mediated, but a prodromal erythema marginatum rash

can occur. Acute abdominal pain simulating an 'acute abdomen' is an important presentation in any type of HAE, and fatalities are possible due to laryngeal obstruction.

MANAGEMENT STRATEGY

Therapy for HAE is dependent on three considerations:

- Relief of acute angioedema attacks especially preservation of the airway (also known as on-demand therapy)
- Long-term prophylaxis for minimizing overall frequency and/or severity of attacks
- Short-term prophylaxis for the prevention of relapse due to dental and surgical interventions

ACUTE ANGIOEDEMA

Acute presentations of HAE are treated optimally with intravenous (IV) *plasma-derived (pd) C1-INH concentrate* (Berinert, Cinryze). This treatment is safe, and no proven cases of viral transmission have been reported. Reduction in swelling is usually significant within minutes and substantial within 2–3 hours. A *recombinant C1-INH* preparation (Ruconest) is now available. Patients should be taught to self-administer for a more rapid resolution of symptoms and to prevent further progression of the attack. The kallikrein–bradykinin mediator pathway is the target of current approaches to treatment of acute HAE. The swellings of HAE are mediated by bradykinin, a product of the action of kallikrein on its substrate kininogen. Bradykinin acts on B₂ receptors, and its specific antagonist *icatibant* subcutaneously has been proven effective in acute attacks of HAE. Icatibant may be the preferred therapy because it is given subcutaneously, preferably in the abdominal area, and can be administered in a domiciliary setting by health care professionals or even by self-administration after appropriate training. *Ecallantide*, a kallikrein inhibitor administered as subcutaneous injections, has been proven to be safe and effective for acute attacks. *Fresh frozen plasma (FFP)*, which contains C1-INH, can be used in an emergency if concentrate is unavailable. However, FFP carries a higher risk of inadvertent viral transmission (HIV, hepatitis) and theoretically could exacerbate angioedema due to the presence of C1-esterase substrate. Laryngeal edema may require *tracheostomy*, *intubation*, and/or other life-support measures. Patients are routinely admitted for 24 hours after acute episodes, as life-threatening relapses are common.

LONG-TERM PROPHYLAXIS

Long-term prophylaxis should be considered in those patients with at least one or more attacks of angioedema per month and in those with severe symptoms. However, patients could have infrequent attacks and still present with laryngeal edema. Even first-episode angioedema can be fatal. Prophylactic treatment with IV pd C1-INH (Cinryze) is currently the first-line therapy and can lead to less severe symptoms and even attack prevention. Pd C1-INH is also now available as a subcutaneous therapy (Haegarda), which may be preferred as a more convenient method than IV with superior steady state plasma concentrations of C1-INH. Other treatments include the 17 α -alkylated 'attenuated' androgens (*danazol*) used as second-line prophylactic medications that may be effective in preventing angioedema in some patients with HAE-1/2. The lowest effective dose of androgen should be used to obtain clinical remission. Side effects include hirsutism, deepening of voice, and menorrhagia. These attenuated androgens are unsuitable for long-term treatment of HAE in children and pregnant women, or the treatment of acute attacks. However, they are safe

and effective in adults, provided they are closely supervised with clinical biochemical and radiologic assessments. Liver function tests and lipid levels should be monitored, with liver ultrasound scans performed every 2 years. Other less effective prophylactic therapies have included antifibrinolytics (*tranexamic acid*) but should be avoided in patients with a history of thrombotic diseases. They are useful for short-term prophylaxis, especially for those where C1-INH is not available or other therapies are contraindicated. In patients with mild infrequent attacks, *avoidance of provoking factors*, including estrogens and angiotensin-converting enzyme (ACE) inhibitors, may be sufficient.

Lanadelumab, a fully human monoclonal antibody that provides targeted inhibition of plasma kallikrein, is now approved for prevention of HAE attacks.

A newer treatment currently under review, berotralstat (BCX7353), is a potent synthetic small molecule inhibitor of plasma kallikrein that offers the distinct advantage of oral administration. It has been shown to lower rates of HAE attacks and would be the first targeted oral therapy licensed for prophylaxis of HAE, representing a major advance in therapy.

SHORT-TERM PROPHYLAXIS (STP) FOR PREVENTION OF RELAPSE DUE TO DENTAL AND SURGICAL INTERVENTIONS

In all patients, prior to elective surgical, dental, or other invasive procedures, prophylaxis with pdC1-INH concentrate before the procedure is recommended. Due to the possibility of breakthrough attacks, additional on-demand treatment should be available. Second-line STP could include short courses of attenuated androgens when C1-INH is not available. If an emergency procedure is necessary, C1-INH concentrate or FFP can be administered beforehand. Patients with HAE should all wear a *Medic-Alert disk* stating the diagnosis and emergency treatment.

Specific Investigations

- Complement C4 level
- C1-INH protein
- C1-INH function

Hereditary angioedema. Busse PJ, Christiansen SC. *N Engl J Med* 2020; 382(12): 1136–48.

Both types HAE-1/2 are characterized by low serum C4 levels from activation of the complement cascade. The C4 level is typically reduced between attacks, and nearly undetectable during an attack; therefore, all patients with suspected HAE-1/2 should have serum C4 measured as an initial screening test. However, normal or high C4 level cannot exclude HAE. To confirm the diagnosis, tests include C1 inhibitor antigen levels and C1 inhibitor function. In HAE-1 the C1-INH protein level is low, while in HAE-2, the C1-INH protein level can be normal while C1 inhibitor function is low. C1q plasma levels are characteristically normal in HAE.

ACUTE ANGIOEDEMA

First-Line Therapies

• C1-INH concentrate	A
• Icatibant	A
• Ecallantide	A

C1 esterase inhibitor concentrate in 1085 Hereditary Angioedema attacks – final results of the I.M.P.A.C.T.2 study. Craig TJ, Bewtra AK, Bahna SL, et al. *Allergy* 2011; 66(12): 1604–11.

A group of 57 patients were treated for a total of 1085 attacks in various areas of the body during a 24-month study period. The median time to onset of symptom relief was 0.46 hours (h) and the median time to complete resolution of symptoms was 15.5 h. No inhibitory anti-C1-INH antibodies were detected in patients, and no other treatment related safety concerns. The study concluded that 20 U/kg C1-INH is a consistent, reliable, and safe treatment of successive HAE attacks in any area of the body.

Recombinant human C1-esterase inhibitor relieves symptoms of hereditary angioedema attacks: phase 3, randomized, placebo-controlled trial. Riedl MA, Bernstein JA, Li H, et al. *Ann Allergy Asthma Immunol* 2014; 112(2): 163–9.

In this trial 75 patients undergoing acute laryngeal, abdominal, facial, or peripheral attacks were randomized to treatment with recombinant human C1-INH ($n=44$) or saline placebo ($n=31$). In the rhC1-INH-treated patients, median time to beginning of symptom relief was 75 min vs. 303 min in placebo-treated patients ($p=0.003$). The median time to minimal symptoms was 240 min in the rhC1-INH-treated group vs. 362 min in the placebo-treated group ($p=0.005$). RhC1-INH was well tolerated, with no thromboembolic events or observations of neutralizing antibodies or anaphylaxis.

An analysis of the teaching of intravenous self-administration in patients with hereditary angio-oedema. Mühlberg H, Ettl N, Magerl M. *Clin Exp Dermatol* 2016; 41(4): 366–71.

A group of 18 patients were trained to self-administer intravenous pdC1-INH for acute treatment (or routine prevention) of HAE attacks. The median number of training sessions that patients required was 5 (range 2–30). After self-administration training, the median time to acute treatment was 15 min by patients, reduced from 270 min time to treatment by medical professionals.

Icatibant for multiple hereditary angioedema attacks across the controlled and open-label extension phases of FAST-3. Lumry WR, Farkas H, Moldovan D, et al. *Int Arch Allergy Immunol* 2015; 168(1): 44–55.

Out of 88 patients undergoing between one and five HAE attacks that were treated with icatibant at any location, the median times for onset of symptom relief (1.9–2.1 h), onset of primary symptom relief (1.5–2 h), and almost complete symptom relief (3.5–19.7 h) were consistent across the multiple attacks. Similar outcomes (1.0–2.0 h, 1.0–2.0 h, and 1.5–8.1 h, respectively) were observed for laryngeal attacks ($n=25$). Two serious adverse events that were attributed to icatibant were arrhythmia and non-cardiac chest pain.

Ecallantide (DX-88) for acute hereditary angioedema attacks: integrated analysis of 2 double-blind, phase 3 studies. Sheffer AL, Campion M, Levy RJ, et al. *J Allergy Clin Immunol* 2011; 128(1): 153–9. e4.

Integrated analysis of data from 143 unique patients treated within 8 hours for a moderate-to-severe HAE attack at any location of the body was evaluated. Results showed that 30 mg subcutaneous ecallantide demonstrated significantly greater reduction in Mean Symptom Complex Severity scores than placebo from baseline to 4 h after treatment/administration/dosing, as well as significantly greater increase in Treatment Outcome Score. Similarly, after 24 h, ecallantide resulted in significantly greater

symptomatic improvement over placebo. Safety analysis of 183 unique patients found similar incidence of adverse events (AEs) between ecallantide-treated patients (36%) and placebo-treated patients (34.6%).

Efficacy of different medical therapies for the treatment of acute laryngeal attacks of hereditary angioedema due to C1-esterase inhibitor deficiency. Bork K, Bernstein JA, Machnig T, et al. *J Emerg Med* 2016; 50(4): 567–80. e1.

Data from clinical studies, in which a total of 881 acute laryngeal attacks treated with either pdC1-INH, rhC1-INH, icatibant, or ecallantide, were reviewed and compared. The authors concluded that a single body-weight-adjusted dose of pdC1-INH (20 U/kg) provided the most reliable treatment response.

Second-Line Therapies

- Solvent detergent-treated plasma (SDP) **C**
- Fresh frozen plasma (FFP) **C**

Fresh frozen plasma for on-demand hereditary angioedema treatment in South Africa and Iran. Wentzel N, Panieri A, Ayazi M, et al. *World Allergy Organ J* 2019; 12(9): 100049.

This study retrospectively reviewed 176 acute attacks in 43 HAE patients in two low- and middle-income countries where FFP is the only on-demand treatment available. In total, 98 attacks were treated with FFP (median 400 mL), leading to resolution of symptoms in all but two, with median 4 hours to resolution. Five adverse reactions occurred (5%), including one episode of anaphylaxis, and there were no deaths.

LONG-TERM PROPHYLAXIS

First-Line Therapy

- Plasma-derived C1-INH **A**

Long-term outcomes with subcutaneous C1-inhibitor replacement therapy for prevention of hereditary angioedema attacks. Craig T, Zuraw B, Longhurst H, et al. *J Allergy Clin Immunol Pract* 2019; 7(6): 1793–802. e2.

A total of 126 patients were treated with a highly concentrated human plasma-derived C1-INH for subcutaneous injection (Haegarda) for a mean of 1.5 years, including 44 patients that were treated for more than 2 years. A sizeable and continual prophylactic effect was observed. Median annualized attack rates were 1.3 and 1.0 for the 40 IU/kg and 60 IU/kg groups, respectively, and median rescue medication use was 0.2 and 0.0 occasions per year. The majority of patients became free from debilitating disease symptoms during the treatment period, with 19 of the 25 patients who received 60 IU/kg (83%) being attack free during months 25–30 of the trial.

Second-Line Therapy

- Attenuated androgen (danazol) **B**

Critical appraisal of androgen use in hereditary angioedema: a systematic review. Riedl MA. *Ann Allergy Asthma Immunol* 2015; 114(4): 281–8. e7.

An evaluation of 15 studies categorized as level of evidence (LOE) 2, and multiple LOE 4 reports, found a high level of prophylactic efficacy for androgen use in HAE. There were occasionally reports of poor prophylactic response and a range of common AEs, including weight gain, headaches, elevations in liver function test results, serum lipid level, and creatine phosphokinase level, which were often correlated with dosage and treatment duration.

Third-Line Therapy

- Antifibrinolytic (tranexamic acid) **C**

Hereditary angioedema: an update on causes, manifestations and treatment. Longhurst HJ, Bork K. *Br J Hosp Med (Lond)* 2019; 80(7): 391–8.

While tranexamic acid is not as effective as androgens for prophylaxis in HAE patients, it has fewer side effects and is more commonly used in children. Efficacy data are lacking, and therefore its use is confined to when C1-INH is not available and androgens are contraindicated.

New Therapies for Long-Term Prophylaxis

- Lanadelumab (subcutaneous plasma kallikrein inhibitor – monoclonal antibody) **A**
- Berostralstat (oral plasma kallikrein inhibitor – synthetic small molecule) **A**

Effect of lanadelumab compared with placebo on prevention of hereditary angioedema attacks: a randomized clinical trial. Banerji A, Riedl MA, Bernstein JA, et al. *JAMA* 2018; 320(20): 2108–21.

In this double-blind, parallel group, placebo-controlled clinical trial, 125 patients with HAE-1/2 completed a 26-week treatment period. Compared with placebo, the mean differences in attack rate per month were –1.49 in the 150 mg every 4 weeks group ($p < 0.001$), –1.44 in the 300 mg every 4 weeks group ($p < 0.001$), and –1.71 in the 300 mg every 2 weeks group ($p < 0.001$). The lanadelumab treatment group experienced greater frequency of injection site reactions (31.4% placebo vs. 52.4% lanadelumab) and dizziness (0% placebo vs. 6.0% lanadelumab).

Oral plasma kallikrein inhibitor for prophylaxis in hereditary angioedema. Aygören-Pürsün E, Bygum A, Grivcheva-Panovska V, et al. *N Engl J Med* 2018; 379(4): 352–62.

The Angioedema Prophylaxis 1 (APeX-1) trial was completed by 72 patients with type I or type II HAE and a history of at least two attacks per month. Patients were randomly assigned to treatment with BCX7353 (berotralstat) 62.5 mg, 125 mg, 250 mg, or 350 mg once daily or placebo, supplied as capsules for daily administration for 28 days. The number of HAE attacks during the effective dosing period (8–28 days) was significantly lower in the 125 mg treatment group vs. the placebo group, with a 73.8% difference ($p < 0.001$). There were significant improvements in quality-of-life scores in the 125 mg and 250 mg groups ($p < 0.05$). Common adverse effects were mild gastrointestinal symptoms.

SHORT-TERM PROPHYLAXIS

First-Line Therapy

- C1-INH concentrate **B**

Short-term prophylactic use of C1-inhibitor concentrate in hereditary angioedema: findings from an international patient registry. Magerl M, Frank M, Lumry W, et al. *Ann Allergy Asthma Immunol* 2017; 118(1): 110–2.

The Berinert Registry collected data on individuals using plasma-derived, pasteurized, nanofiltered C1-INH concentrate (pnfC1-INH) between 2010 and 2014 at 37 sites across the United States and Europe. Of the 318 patients in the registry, 79 used pnfC1-INH as STP at least once. The median dose per infusion was 14.6 IU/kg or 1000 IU. Analyses of dose response suggest higher efficacy with weight-based doses of at least 15 IU/kg and absolute doses of 1500 U and above. Regardless of dose, there were 0.4 HAE attacks within 1 day after STP infusion, and 0.6 attacks within 2 days. The data from this large registry indicate that pnfC1-INH is safe and effective as STP for HAE patients undergoing surgical procedures.

Second-Line Therapies

• Attenuated androgen (danazol)	B
• FFP	C

The international WAO/EAACI guideline for the management of hereditary angioedema – the 2017 revision and update. Maurer M, Magerl M, Ansotegui I, et al. *Allergy* 2018; 73(8): 1575–96.

Attenuated androgen (danazol), used for 5 days prior to and 2–3 days after a surgical procedure, has previously been recommended for STP as an alternative to C1-INH concentrate. Their use is deemed to be safe in children; however, adverse effects are associated with long-term use, and frequent short courses may similarly lead to these side effects. FFP may be helpful. However, it is less safe than C1-INH concentrate, with increased risk of allo-sensitization, as well as transmission of bloodborne pathogens. While tranexamic acid has been previously used for STP, it is now not recommended.

TREATMENT IN CHILDREN

International consensus on the diagnosis and management of pediatric patients with hereditary angioedema with C1 inhibitor deficiency. Farkas H, Martinez-Saguer I, Bork K, et al. *Allergy* 2017; 72(2): 300–13.

Plasma-derived C1-INH (Berinert) is the first on-demand medication licensed for children of all ages with HAE. However, there are little data on its use in babies and very young children. Recombinant C1-INH (Ruconest) is currently licensed in the United

States for adolescents aged over 13 years, while its approval in Europe has been extended to include all children aged 2 years and over. Ecallantide (Kalbitor) is licensed in the United States for children 12 years and over. Icatibant (Firazyr) is approved in Europe for children and adolescents aged 2 years and over, but not yet in the United States.

For long-term prophylaxis in children with HAE-1/2, pdC1-INH may be the safest and therefore preferred approach. Cinryze is approved in United States and Europe for children aged 6 and over. Tranexamic acid (TA) is also favored in pediatrics because of its long-term safety profile. Attenuated androgens are not usually considered until after Tanner Stage 5, at which point they may be tried, aiming to achieve the minimum effective dose. Regular monitoring and follow-up are vital with all therapies. Lanadelumab (Takhzyro) has been approved in United States and Europe for children over 12 years.

HEREDITARY ANGIOEDEMA WITH NORMAL C1-INH

Hereditary angioedema with normal C1 inhibitor: update on evaluation and treatment. Magerl M, Garmeniz AE, Maas C, et al. *Immunol Allergy Clin North Am* 2017; 37(3): 571–84.

It is thought that swelling attacks in patients with HAE with normal C1-INH (HAE-nC1) are caused by bradykinin. ACE inhibitors, angiotensin II receptor antagonists, and estrogens, which are known to provoke attacks in affected women, should be avoided. So far there have been no prospective randomized controlled trials in HAE-nC1 patients and there are no licensed treatments. Antihistamine and corticosteroids are ineffective in acute attacks; however, on-demand treatment with C1-INH concentrate appears to be effective in many cases, to variable degrees. Icatibant has been reported to be effective in many patients, although there are also non-responders and delayed responders, and ecallantide has been used successfully for repeated on-demand treatment.

The effectiveness of STP therapies for HAE-nC1 is unclear, although C1-INH concentrate has been used repeatedly, mainly for deliveries. For long-term prophylaxis, TA seems to be more effective in patients with HAE-nC1 than those with HAE-1/2, for whom TA is unreliable. There have been excellent therapeutic responses to progestin reported in women with HAE-nC1. There are few data on attenuated androgens for long-term prophylaxis in HAE-nC1, perhaps because most patients are female. There is similarly little information on C1-INH concentrate, which has been reported to be effective, although more details on outcomes are needed.

Hereditary hemorrhagic telangiectasia

Mitchell S. Cappell, Oscar Lebwohl

From Lebwohl, MG. Atlas of the Skin and Systemic Disease Atlas of the Skin and Systemic Disease. © Churchill Livingstone 1995.

Hereditary hemorrhagic telangiectasia (HHT; or Osler-Weber-Rendu syndrome) is an autosomal dominant disease, producing a syndrome of multiple orocutaneous telangiectasias, especially on the face, lips, tongue, oral mucosa, and fingertips, together with multiple internal telangiectasias, especially on the mucosa of the nose and gastrointestinal (GI) tract. They generally slowly increase in size and number with age. GI lesions visible at endoscopy have similar characteristics as cutaneous lesions. The basic pathophysiology in HHT is a defect in the wall of small vessels that leads to direct arteriovenous communications without intervening capillaries. The prevalence of HHT is estimated at 1 per 6000 individuals. HHT is reliably diagnosed when three or more criteria are satisfied among a clinical tetrad (Curaçao criteria), listed in Table 102.1. HHT is possible or suspected when two criteria are satisfied. HHT is highly unlikely in adult patients satisfying only one or none of these criteria. About 90% of cases of HHT are due to underlying genetic mutations either in the gene encoding endoglin (ENG) that produces HHT1, or in the gene encoding activin receptor-like kinase (ACVRL1, previously called ALK-1) that produces HHT2. Three other genetic types of HHT have been described, including a rare type in which mutations of the SMAD4 gene cause an overlap syndrome of HHT and juvenile polyposis.

Patients with sporadic GI angiodysplasia are differentiated from patients with HHT by clinical presentation in old age, paucity of lesions, negative family history, and by exclusive GI involvement without epistaxis or intranasal telangiectasia.

MANAGEMENT STRATEGY

The two major clinical complications of HHT are frequent or severe epistaxis and GI bleeding from nasal and GI telangiectasias, respectively. The bleeding may be acute or chronic. Acute blood loss may cause hypovolemia and systemic hypotension, whereas chronic blood loss may cause iron-deficiency anemia. Vascular

Table 102.1 Clinical (Curaçao) criteria for diagnosis of hereditary hemorrhagic telangiectasia (HHT)

Organ or other parameter	Characteristic finding
Nose	Recurrent, spontaneous epistaxis
Mucocutaneous	Telangiectasias on lips, oral cavity, nasal mucosa, or fingers
Gastrointestinal	Mucosal telangiectasias (or visceral arteriovenous malformations)
Family history	One or more first-degree relatives with HHT

hemorrhage in HHT is related to the thin and fragile vessel walls of telangiectasia, and is unrelated to a hemorrhagic diathesis (e.g., abnormal international normalized ratio or thrombocytopenia). Internal shunts created by direct arteriovenous communications in HHT uncommonly cause clinical manifestations, including hypoxia or pulmonary hypertension from pulmonary arteriovenous shunts; cerebral ischemia, hemorrhage, or abscesses from intracerebral shunts; and portal hypertension, biliary tract disease, or high-output cardiac failure from intrahepatic shunts. Dermatologic telangiectasias are usually only a minor, cosmetic problem.

Severe bleeding requires hospitalization and insertion of two large-bore IV lines. Significant acute blood loss is treated with intravenous fluid resuscitation and transfusion of packed erythrocytes as needed. Chronic blood loss is treated with iron supplementation as needed.

Non-specific therapy for bleeding from HHT includes avoidance of aspirin, non-steroidal antiinflammatory drugs, other antiplatelet drugs, and anticoagulants; and administration of iron for patients with significant iron-deficiency anemia.

Nasal moisturizers and room humidification promote mucosal integrity and reduce nasal mucosal injury and epistaxis. Epistaxis is initially treated by non-specific local therapy such as nasal packing to tamponade the bleeding. Estrogen with progesterone is used to prevent or arrest chronic epistaxis by promoting vascular integrity. Mutations in the different forms of HHT result in highly elevated levels of vascular endothelial growth factor (VEGF) that can produce abnormal, immature vasculature containing telangiectasias. Bevacizumab, a recombinant humanized monoclonal antibody to VEGF, may reverse the telangiectasias occurring in HHT by inhibiting VEGF (antiangiogenesis). Several moderate-sized clinical trials have shown IV bevacizumab may significantly reduce epistaxis in patients with HHT. IV bevacizumab has rare risks, including hypertension, bleeding in other organs, and bowel perforation. Submucosal or topical intranasal administration of bevacizumab may avoid much of the systemic toxicity of IV therapy with similar efficacy.

Several studies have reported a markedly reduced incidence of chronic epistaxis from telangiectasias after instituting estrogen therapy, either alone or with progesterone, by promoting endothelial integrity. Despite controversy concerning efficacy, estrogen therapy should be considered before performing nasal surgery for chronic epistaxis because of its low risk and the risk of recurrent bleeding after surgery. Estrogen therapy is less desirable in males than in females because it can cause feminization.

Septal dermoplasty is indicated for severe, recurrent epistaxis, especially from the anterior nasal mucosa. Skin, removed from the upper thigh, is grafted on to the anterior nasal septum and floor to cover and protect the fragile mucosal telangiectasias from local trauma. The procedure is well tolerated using only local anesthesia, and complications, other than recurrent epistaxis, are rare. Septal dermoplasty is effective in >75% of cases. Failure results from inadequate graft coverage with bleeding from telangiectasias

at or beyond the border of the grafted area. Focal laser therapy can be used to ablate discrete bleeding intranasal lesions.

Chronic GI bleeding from telangiectasias may also be reduced by estrogen and progesterone therapy, as demonstrated in multiple individual case reports and small studies. Several studies have shown decreased GI bleeding from telangiectasia with *thalidomide* therapy. Several mechanisms have been proposed for this efficacy.

At endoscopy, actively bleeding, individual, GI telangiectasias are preferably treated with *endoscopic argon plasma coagulation* (APC), or alternatively with *endoscopic thermocoagulation* or *electrocoagulation*. APC is easier to apply endoscopically and is potentially safer due to more superficial tissue ablation. Nonetheless, all these endoscopic therapies are relatively safe and highly successful at achieving hemostasis when performed by experienced endoscopists. Non-bleeding lesions are generally not treated at endoscopy unless the lesions are particularly large and thus likely to bleed. However, patients with HHT often rebleed from other, untreated GI telangiectasias after an initial session of endoscopic therapy, and patients therefore require multiple sessions of endoscopic therapy to treat these other lesions.

Segmental bowel resection is reserved for severe active bleeding, localized to a single region and refractory to medical and endoscopic therapy. Where available, *angiographic embolization* can obviate the need for GI surgery. Surgery or angiographic embolization often provides only intermediate-term relief owing to formation of telangiectasias at other GI sites.

Some data support the use of *tamoxifen*, an estrogen antagonist, to prevent bleeding from telangiectasias in HHT. A few patients have responded to therapy with α -*interferon*, which has known antiangiogenic properties, but this therapy is currently experimental because of insufficient data.

Local non-specific therapy of *arterial ligation*, *cryosurgery*, *electrical cautery*, or *submucosal resection* provides temporary relief of epistaxis from HHT. However, these treatments can cause mucosal scarring, which diminishes the efficacy of subsequent septal dermoplasty. Topical intranasal therapy with vasoconstrictors or aminocaproic acid rarely produces scarring. Non-specific therapies are indicated only for temporary relief of acute bleeding. Life-threatening epistaxis refractory to septal dermoplasty is treated by surgical closure of one or both nostrils, depending on the bleeding source.

Aminocaproic acid promotes thrombosis and retards bleeding by inhibiting fibrinolysis. Oral aminocaproic acid therapy has had mixed success with HHT. This therapy rarely causes hypotension or rhabdomyolysis. Aminocaproic acid is a temporary, second-line therapy.

Specific Investigations for Epistaxis or GI Bleeding

For epistaxis or GI bleeding

- Serial hematocrit determinations – to assess severity of bleeding
- Serum iron, total iron binding capacity, and ferritin levels

For epistaxis

- Flexible nasal endoscopy
- Nasal examination using fine-caliber, rigid, nasal endoscope

For GI bleeding

- Esophagogastroduodenoscopy (EGD)
- Colonoscopy
- Capsule endoscopy or double-balloon enteroscopy
- Angiography – for ongoing bleeding after non-diagnostic endoscopic examinations

For epistaxis, bleeding severity is determined by inspection, vital signs, and laboratory tests. The bleeding site is precisely localized by nasal examination with a fine-caliber rigid tube (endoscope) using spot suction, and bright, shadow-free illumination with a headlight, head mirror, or cold fiberoptic illumination. Flexible nasal endoscopy is a recently popular alternative technique. For GI bleeding, the bleeding severity is indicated by patient history, vital signs, physical findings, rectal examination, and nasogastric aspiration. Serial hematocrit determinations guide requirements for transfusions of packed erythrocytes. The bleeding site and source are conclusively diagnosed by GI endoscopy. Iron studies will determine the need for iron supplementation.

Upper GI bleeding, usually manifested by hematemesis or melena, should be investigated by esophagogastroduodenoscopy (EGD). Lower GI bleeding, usually manifested by hematochezia or fecal occult blood, and occasionally by melena, should be investigated by colonoscopy. Barium contrast radiography or virtual colonoscopy are not helpful due to the macular nature of telangiectases. Small intestinal bleeding, usually manifested by hematochezia, melena, or fecal occult blood, can be investigated by capsule endoscopy after exclusion of upper and lower GI bleeding by EGD and colonoscopy, respectively. Double-balloon enteroscopy is often used at tertiary medical centers instead of capsule endoscopy to investigate small intestinal bleeding because of its greater diagnostic sensitivity and ability to perform therapy, despite its greater costs.

Telangiectasias are distinguished from lesions due to endoscopic trauma by identification during endoscopic intubation, as opposed to identification during endoscopic extubation with trauma; by a finely reticular (fern-like) internal structure due to a vascular tuft; by an irregular (fern-like) border as opposed to a round border with trauma, by an abrupt lesion margin as opposed to an indistinct margin with trauma; and by lesions lying flush (coplanar) with mucosa. Additionally, colonic lesions from endoscopic trauma usually occur at sharp colonic turns, during endoscopic looping, or after endoscopic suctioning.

Angiography is indicated for active GI bleeding if EGD and colonoscopy fail to diagnose the source of bleeding. The angiographic hallmarks of telangiectasias are a vascular tuft or tangle resulting from the local aggregation of irregular vessels; an early and intensely filling vein resulting from direct arteriovenous connection without intervening capillaries; and persistent opacification beyond the normal venous phase (slowly emptying vein), attributed to vascular tortuosity. Telangiectasias bleed only intermittently, and extravasation of contrast material from telangiectasias is infrequently detected at angiography.

Systematic screening in hereditary hemorrhagic telangiectasia: a review. Kroon S, Snijder RJ, Faughnan ME, et al. *Curr Opin Pulm Med* 2018; 24: 260–8.

Clinically oriented review of the genetics, pathophysiology, clinical presentation, and diagnosis of HHT.

Liver disease in patients with hereditary hemorrhagic telangiectasia. Garcia-Tsao G, Korzenik JR, Young L, et al. *N Engl J Med* 2000; 343: 931–6.

Review of clinical findings caused by intrahepatic shunts with HHT, including eight patients with high-output cardiac failure, six patients with portal hypertension, and five patients with biliary tract disease.

Diagnostic yield of capsule endoscopy for small bowel arteriovenous malformations in patients with hereditary

hemorrhagic telangiectasia: a systematic review and meta-analysis. Singh K, Ayla Zubair A, Prindle A, et al. *Endosc Int Open* 2019; 7: E282–9.

Recently published meta-analysis and systematic literature review, encompassing five studies and 124 patients with HHT, revealed capsule endoscopy had a diagnostic yield of 77.0% (95%; confidence interval of 65.8%–85.4%) for small bowel arteriovenous malformations (AVMs). Although capsule endoscopy, a minimally invasive test, has a superior diagnostic yield, it lacks therapeutic capabilities for treating AVMs to achieve hemostasis.

Evaluation of patients with hereditary hemorrhagic telangiectasia with video capsule endoscopy: a single-center prospective study. Chamberlain SM, Patel J, Carter Balart J, et al. *Endoscopy* 2007; 39: 516–20.

In a prospective study of 80 patients evaluated by capsule endoscopy for small intestinal bleeding, the 32 patients with known HHT had significantly more GI telangiectasias than the 48 control patients without HHT (75% vs. 8.3% of patients had ≥five telangiectasias). This study demonstrates the high sensitivity of capsule endoscopy in diagnosing small intestinal telangiectasias in patients who have HHT.

First-Line Therapies

For epistaxis or GI bleeding

- Transfuse packed erythrocytes for significant, acute bleeding **A**
- Oral iron therapy for iron-deficiency anemia from chronic blood loss **A**
- Non-specific therapy: avoid aspirin, other antiplatelet drugs, and anticoagulation **A**
- Reverse severe coagulopathy if patient is actively bleeding (e.g., transfuse platelets for severe thrombocytopenia and transfuse fresh frozen plasma for elevated international normalized ratio [INR]) **A**
- Bevacizumab **B**
- Estrogen and progesterone hormonal therapy **B**

For epistaxis

- Non-specific (and very safe) general therapy: room humidification and nasal moisteners **A**
- Nasal packing **A**
- Septal dermoplasty **A**
- APC **A**

For GI bleeding

- Endoscopic APC **A**
- Endoscopic thermocoagulation or electrocoagulation **B**
- Angiographic embolization for bleeding refractory to endoscopic therapy **B**
- Segmental bowel resection – for bleeding refractory to endoscopic and angiographic therapy **A**

For cutaneous lesions

- Cosmetic therapy: laser or other focal ablation techniques for cutaneous lesions **A**

Treatment of bleeding gastrointestinal vascular malformations with oestrogen-progesterone. van Custen E, Rutgeerts P, Vantrappen G. *Lancet* 1990(8695); 335: 953–5.

In a double-blind, placebo-controlled crossover trial of 10 patients with frequent and severe GI bleeding from HHT, the number of transfusions decreased significantly from a mean of 10.9 units of packed erythrocytes in controls receiving placebo to a mean of 1.1 units in patients treated with estrogen-progesterone during a 6-month period.

Use of estrogen in treatment of familial hemorrhagic telangiectasia. Harrison DFN. *Laryngoscope* 1982; 92: 314–20.

Report of successful control of epistaxis with estrogen therapy in 67 patients with HHT, with few complications.

Treatment of hereditary hemorrhagic telangiectasia with submucosal and topical bevacizumab therapy. Karnezis TT, Davidson TM. *Laryngoscope* 2012; 122: 495–7.

In a prospective trial of 19 patients, 2 months after intranasal, submucosal injection of bevacizumab, the epistaxis severity score significantly decreased to 2.00, compared with the baseline, pre-treatment severity score of 8.12 ($p < 0.0001$). Bevacizumab therapy statistically, significantly protected against epistaxis for all 12 months of the clinical trial.

Bevacizumab in patients with hereditary hemorrhagic telangiectasia and severe hepatic vascular malformations and high cardiac output. Dupuis-Girod S, Ginon I, Saurin JC, et al. *JAMA* 2012; 307: 948–55.

In a prospective, open-labeled study, 25 adult patients with severe HHT received bevacizumab intravenously for 2.5 months. The mean duration of epistaxis decreased from 221 min/mo at baseline to 43 min/mo at 6 mo ($p = 0.008$), and the mean number of episodes decreased from 26 episodes/mo at baseline to 11 episodes/mo at 6 mo. This study suggests that IV bevacizumab may decrease the frequency and duration of epistaxis in patients with HHT.

Intravenous bevacizumab for refractory hereditary hemorrhagic telangiectasia-related epistaxis and gastrointestinal bleeding. Iyer VN, Apala DR, Pannu BS, et al. *Mayo Clin Proc* 2018 Feb; 93: 155–66.

Study of 34 patients treated with intravenous bevacizumab for severe GI bleeding and/or epistaxis in patients with HHT from 2013 to 2016 conducted at the Mayo Clinic, Rochester, Minnesota. Twenty-eight patients (82%) had received transfusions of packed erythrocytes, including 16 patients (47%) who depended on frequent transfusions of packed erythrocytes. Median baseline hemoglobin level was 9.1 g/dL. Anemia was primarily related to severe epistaxis (44%), severe GI bleeding (12%), or both (44%). Patients were followed up for a mean of 17.6 months after initiating bevacizumab therapy. The epistaxis severity score (a semiquantitative subjective assessment based on patient responses to six questions) significantly declined from a mean of 6.6 ± 2.2 to 3.0 ± 1.4 ($p < 0.001$) and packed erythrocyte transfusion requirements from a median of 75 to 12 units of packed erythrocytes ($p = 0.007$) comparing before treatment with after treatment. This study suggests that intravenous bevacizumab may be an effective therapy for severe, refractory bleeding from HHT.

Outcome of septal dermoplasty in patients with hereditary hemorrhagic telangiectasia. Fiorella ML, Ross D, et al. *Laryngoscope* 2005; 115: 301–5.

Retrospective study reporting outcome of 32 consecutive patients undergoing septal dermoplasty in whom accurate records of transfusion requirements were available. Mean blood

transfusion requirements declined significantly from a mean of 21 units of packed erythrocytes in the year before surgery to a mean of one unit in the year after surgery ($p < 0.001$). This study illustrates the fairly extensive literature supporting the efficacy of septal dermoplasty for treating recurrent, relatively severe epistaxis from HHT.

Diagnosis and management of gastrointestinal bleeding in patients with hereditary hemorrhagic telangiectasia. Longacre AV, Gross CP, Gallitelli M, et al. *Am J Gastroenterol* 2003; 98: 59–65.

In a non-randomized, long-term, observational study, the mean hemoglobin level increased and the chronic transfusion requirements decreased in about three-quarters of 17 patients after instituting chronic estrogen hormonal therapy, either alone or with other therapies, for GI bleeding from HHT.

Argon plasma coagulation is an effective treatment for hereditary hemorrhagic telangiectasia patients with severe nosebleeds. Pagella F, Matti E, et al. *Acta Otolaryngol* 2013; 133: 174–80.

In this retrospective study, 26 patients with HHT were followed by telephone calls one or more years after undergoing APC treatment of nasal mucosa for severe epistaxis requiring blood transfusions. The epistaxis severity score decreased significantly from 8.5 before APC therapy to 4.3 after therapy ($p < 0.005$), as did the number of patients requiring blood transfusions ($p < 0.02$). The frequency, intensity, and duration of epistaxis also decreased significantly after APC therapy compared to baseline ($p < 0.0001$). The beneficial effects of therapy lasted 22.9 months. This work demonstrates that APC is an effective therapy for severe epistaxis from HHT.

Long-term outcome of argon plasma ablation therapy for bleeding in 100 consecutive patients with colonic angiodysplasia. Olmos JA, Marcolongo M, Pogorelsky V, et al. *Dis Colon Rectum* 2006; 49: 1507–16.

In this prospective trial, 85 of 100 patients with moderate-to-severe bleeding from colonic angiodysplasia treated at colonoscopy with APC (mean 3.9 angiodysplasias treated per patient) had no further overt bleeding and had a stable hemoglobin level without further blood transfusions or iron therapy during a mean follow-up of 20 months. Only two minor procedure complications occurred. Although not specifically addressing APC for telangiectasias in HHT, this large, prospective study demonstrated high efficacy of this therapy for preventing rebleeding from the similar lesions of sporadic colonic angiodysplasia.

Second-Line or Temporizing Therapies

For epistaxis

- Arterial ligation B
- Topical vasoconstrictors B
- Cryosurgery/electrocautery B
- Unilateral or bilateral surgical closure of nostrils B
- Arterial embolization B
- Tamoxifen B
- Submucosal resection C
- Topical aminocaproic acid D

For GI bleeding

- Thalidomide B
- Oral aminocaproic acid therapy D
- α -Interferon D

Antiestrogen therapy for hereditary hemorrhagic telangiectasia: a double-blind placebo-controlled clinical trial. Yaniv E, Preis M, Hadar T, et al. *Laryngoscope* 2009; 119: 284–8.

In a randomized, placebo-controlled trial of 21 patients with HHT, nine of 10 patients (90%) treated with orally administered tamoxifen, an estrogen antagonist, had cessation of clinically significant epistaxis vs. three of 11 patients receiving placebo ($p = 0.01$). This small, placebo-controlled trial suggests that tamoxifen may be effective in preventing epistaxis in HHT.

Efficacy and safety of thalidomide for the treatment of severe recurrent epistaxis in hereditary haemorrhagic telangiectasia: results of a non-randomised, single-centre, phase 2 study. Invernizzi R, Quaglia F, Klersy C, et al. *Lancet Haematol* 2015; 2: e465–73.

In a non-randomized, open-label, single-center Italian study conducted from 2011 to 2014, 31 patients received low-dose oral thalidomide to reduce severe recurrent epistaxis associated with HHT refractory to minimally invasive surgical procedures. During a median follow-up of 15.9 months, all 31 patients responded to thalidomide therapy with a significant decrease in all three monitored parameters of epistaxis severity: frequency of epistaxis of $> \text{once/day}$ decreased from 61% at baseline to 3% at 12 weeks ($p < 0.0001$); intensity of epistaxis decreased from 84% requiring a bowl (rather than a handkerchief) to hold the bleeding to 16% ($p < 0.0001$); and duration of epistaxis of > 10 minutes from 83% to 19% ($p < 0.0001$). Also, from baseline to 24 weeks after initiating therapy, the hemoglobin increased from approximately 8.2 g/dL to 10.8 g/dL ($p < 0.0001$), and number of units of packed erythrocytes transfused per week decreased from approximately 1.5 to 0.5 units ($p < 0.0001$).

Herpes genitalis

Ritu Swali, Radhika Shah, Stephen K. Tying

Herpes genitalis (genital herpes) is a recurrent vesicular eruption of the skin and mucosa arising in the region between the navel, thighs, and buttocks. It is a common sexually transmitted disease, usually preceded by prodromal symptoms including itching, burning, and tingling, and caused predominantly by herpes simplex virus type 2 (HSV-2) and less frequently by HSV-1. First-episode genital herpes due to HSV-1 has become increasingly common in certain populations – namely, heterosexual women and men who have sex with men. Primary infection may have associated systemic, influenza-like signs and symptoms, including fever, headache, malaise, and myalgias, which occur 2–20 days following exposure. Lesions of the initial infection typically last 2–3 weeks, during which time they progress from grouped papules on an erythematous base, to vesicles, to ulcers with eventual crusting. Recurrences generally lack systemic symptoms and are less severe than the primary outbreak. Recurrent lesions, which typically last 5–10 days, occur in the same area but are fewer in number and heal quickly. Genital herpes infection due to HSV-1 results in fewer symptomatic recurrences than infection by HSV-2. Residual hypopigmentation, hyperpigmentation, and scarring may occur with healing.

MANAGEMENT STRATEGY

Because no cure exists for herpes genitalis, treatment is focused on reducing the number of recurrences through suppressive therapy and on promoting rapid healing when a recurrence is present. In addition, treatment aims to reduce infectivity by reducing viral shedding and to reduce complications, such as urinary retention and aseptic meningitis. In the past, topical and oral *acyclovir* were used as first-line treatments for recurrences. Due to its low bioavailability, it requires frequent dosing. The standard dosing of oral acyclovir for a recurrence is 200 mg five times daily for 5 days. Alternative regimens have also been shown to be effective, including 400 mg three times daily for 5 days, 800 mg three times daily

for 2 days, and 800 mg twice daily for 5 days. The frequent dosing of acyclovir led to the development of *valacyclovir* and *famciclovir* (the prodrugs of acyclovir and penciclovir, respectively) as alternative therapies with improved bioavailability. The use of topical acyclovir should be discouraged because it has lower efficacy in comparison to oral acyclovir. Valacyclovir has been shown to be effective when dosed 500 mg twice daily for 3 days or 1000 mg once daily for 5 days. A dosing regimen of oral valacyclovir, given 2000 mg twice daily for 1 day, has been studied and shown to be more convenient; however, further comparative studies are needed. Famciclovir is effective when prescribed as 1000 mg twice daily for 1 day. It may also be taken as 125 mg twice daily for 5 days. Acyclovir, valacyclovir, and famciclovir may all be used for suppressive therapy.

Immunocompromised individuals have more frequent recurrences and can develop more severe lesions, thus requiring longer treatment periods with higher doses than those used in the immunocompetent. Severe cases may require intravenous therapy. Suppressive dosage regimens have been used in this population. Long-term therapy may lead to the selection of resistant strains of the virus. In acyclovir-resistant cases, intravenous therapy with foscarnet may be required.

Addressing psychosocial issues is another important aspect of genital herpes management. The recurrent nature of genital HSV infection can have a negative emotional and psychological impact on patients. Counseling serves to help patients cope with the infection and to prevent sexual and perinatal transmission.

Specific Investigations

- Type-specific serologic testing
- Polymerase chain reaction (PCR)
- Viral culture
- Skin biopsy of atypical lesion

Type-specific laboratory testing should be performed to distinguish HSV-2 infections from HSV-1 infections, as this has implications for disease course and patient counseling. Patients with confirmed genital herpes should be offered testing for HIV and other sexually transmitted diseases. Severe or refractory cases may be due to underlying immunosuppression, which should be further investigated.

Clinical evaluation and cost analysis of a Trioplex real-time PCR assay for the detection and differentiation of herpes simplex virus 1 and 2 in cutaneous and mucocutaneous lesions. Navidad J, Pfothenhauer B, Leigh N, et al. *J Med Microbiol.* 2019; 68: 748–54.

Precision of the Kalon herpes simplex virus type 2 IgG ELISA: an international interlaboratory assessment. Patel EU, Manucci J, Kahle EM, et al. *BMC Infect Dis* 2015; 15: 398.

Performance of the Focus HerpeSelect-2 EIA for the detection of herpes simplex virus type 2 antibodies in seven African countries. Mujugira A, Morrow RA, Celum C, et al. *Sex Transm Infect* 2011; 87: 238–41.

Effect of sexually transmitted disease (STD) coinfections on performance of three commercially available immunosorbent assays used for detection of herpes simplex virus type 2-specific antibody in men attending Baltimore, Maryland, STD clinics. Summerton J, Riedesel M, Laeyendecker O, et al. *Clin Vaccine Immunol* 2007; 14: 1545–9.

Using the evidence base on genital herpes: optimizing the use of diagnostic tests and information provision. Scoular A. *Sex Transm Infect* 2002; 78: 160–5.

First-Line Therapies

• Valacyclovir (Valtrex)	A
• Acyclovir (Zovirax)	A
• Famciclovir (Famvir)	A

Primary Genital Infection

Antiviral treatment should be initiated promptly, ideally within 72 hours of the appearance of lesions, and should be continued for 7–10 days. Treatment duration may be extended if adequate healing has not occurred. The following regimens may be used: acyclovir 400 mg three times daily or 200 mg five times daily; valacyclovir 1000 mg twice daily; or famciclovir 250 mg three times daily. Because acyclovir, valacyclovir, and famciclovir demonstrate similar efficacy, the initial drug choice may be based on factors such as provider preference, cost, and availability. Valacyclovir may be preferable due to the convenience of twice-daily dosing.

Genital herpes. Gnann JW Jr, Whitley RJ. *N Engl J Med* 2016; 375: 666–74.

Neonatal herpes simplex virus infections. Pinninti SG, Kimberlin DW. *Semin Perinatol* 2018; 42(3): 168–75.

Acute Reactivation Episodes

Standard-dose and high-dose daily antiviral therapy for short episodes of genital HSV-2 reactivation: three randomised, open-label, crossover trials. Johnston C, Saracino M, Kuntz S, et al. *Lancet* 2012; 379: 641–7. Erratum in: *Lancet* 2012; 379: 616.

Three open-label crossover studies compared no medication with acyclovir 400 mg twice daily (standard dose), valacyclovir 500 mg daily (standard dose) with acyclovir 800 mg three times daily (high dose), and standard-dose valacyclovir with valacyclovir 1 g three times daily (high dose). High-dose acyclovir was associated with less viral shedding than standard-dose valacyclovir, but there was no significant difference in time to lesion healing between the groups. High-dose valacyclovir had less viral shedding and shorter lesion healing time compared with its standard dose. Viral shedding persisted even in high-dose regimens.

Single-day therapy for recurrent genital herpes. Tyring S, Berger T, Yen-Moore A, et al. *Am J Clin Dermatol* 2006; 7: 209–11.

A multicenter, randomized, double-blind, placebo-controlled clinical trial found that famciclovir 1000 mg twice daily for 1 day, taken within 6 hours of prodrome onset, resulted in a significant reduction in lesion healing time and reduced the time of all symptom resolution compared with placebo. A greater proportion of subjects who took famciclovir did not progress to a

full genital herpes outbreak compared with those taking placebo (23.3% vs. 12.7%, respectively).

Sexually transmitted diseases treatment guidelines 2015. Centers for Disease Control and Prevention. *MMWR Recomm Rep* 2015; 64: 27–32.

Antiviral therapy should be initiated during the prodrome or within 24 hours of the appearance of lesions.

Single-day patient initiated famciclovir therapy for recurrent genital herpes: a randomized, double-blind, placebo-controlled trial. Aoki FY, Tyring S, Diaz-Mitoma F, et al. *Clin Infect Dis* 2006; 42: 8–13.

This study proved that in addition to being convenient, single-day therapy is safe and effective for the treatment of recurrent genital herpes. Subjects receiving 1000 mg famciclovir orally twice daily for 1 day healed approximately 2 days faster than those on placebo.

A randomized, placebo-controlled comparison of oral valacyclovir and acyclovir in immunocompetent patients with recurrent genital herpes infections. Tyring SK, Douglas JM, Corey LC, et al. *Arch Dermatol* 1998; 134: 185–91.

This multicenter, double-blind, placebo-controlled, randomized, parallel-design study showed that oral valacyclovir 1000 mg twice daily for 5 days was as effective and well tolerated as acyclovir five times daily for 5 days for the treatment of recurrent genital herpes.

Prophylactic Treatment

Prophylactic treatment for frequent reactivation, recurrent severe attacks, or before delivery.

Effect of valacyclovir on viral shedding in immunocompetent patients with recurrent herpes simplex virus 2 genital herpes: a US-based randomized, double-blind, placebo-controlled clinical trial. Fife KH, Warren TJ, Ferrera RD, et al. *Mayo Clin Proc* 2006; 81: 1321–7.

Over a 60-day period 1 g of valacyclovir daily was well tolerated and effectively reduced clinical and subclinical HSV-2 shedding compared with placebo.

Once-daily valacyclovir to reduce the risk of transmission of genital herpes. Corey L, Wald A, Patel R, et al. *N Engl J Med* 2004; 350: 11–20.

Among heterosexual HSV-2 discordant couples, once-daily valacyclovir (500 mg) significantly reduced the risk of transmission of genital herpes. Clinically symptomatic HSV-2 infection was reduced by 75%, and acquisition of HSV-2 was reduced by 48% in the valacyclovir group versus placebo.

Prevention and management of genital herpes simplex infection during pregnancy and delivery: Guidelines from the French College of Gynaecologists and Obstetricians. Sénat MV, Anselem O, Picone O, et al. *Eur J Obstet Gynecol Reprod Biol* 2018; 224: 93–101.

During pregnancy, the first episode of genital herpes should be treated with acyclovir (200 mg five times daily) or valacyclovir (1000 mg twice daily) for 5–10 days, and recurrent herpes should be treated with acyclovir (200 mg five times daily) or valacyclovir (500 mg twice daily) for symptom relief. There is no evidence suggesting that the risk of neonatal herpes can be reduced during pregnancy.

Effect of serologic status and cesarean delivery on transmission rates of herpes simplex virus from mother to infant. Brown ZA, Wald A, Morrow RA, et al. JAMA 2003; 289: 203–9.

Among women with HSV in genital secretions at the time of labor, the risk of neonatal HSV was significantly reduced in those who had a cesarean delivery.

Sexually transmitted diseases treatment guidelines 2015. Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 27–32.

Severe HSV infection, or complications requiring hospitalization, such as disseminated infection, requires intravenous antiviral therapy. A regimen of acyclovir 5–10 mg/kg intravenously every 8 hours for a minimum of 2 days until clinical improvement occurs is recommended. Transition to oral antiviral therapy is recommended to complete a 10-day course.

Frequent reactivation of herpes simplex virus among HIV-1-infected patients treated with highly active antiretroviral therapy. Posavad CM, Wald A, Kuntz S, et al. J Infect Dis 2004; 190: 693–6.

In HIV-infected individuals, antiretroviral therapy reduced the frequency and severity of symptomatic genital herpes. However, frequent asymptomatic viral shedding occurred.

The anti-human immunodeficiency virus drug tenofovir, a reverse transcriptase inhibitor, also targets the herpes simplex virus DNA polymerase. Andrei G, Gillemot S, Topalis D, et al. J Infect Dis 2018; 217: 790–801.

Through selection of tenofovir (TFV)-resistant HSV mutants, this study demonstrated that TFV and PMEO-DAPy (6-phosphorylmethoxyethoxy-2,4-diaminopyrimidine, an acyclic nucleoside phosphonate with dual anti-HSV and anti-HIV activity) can be used for prophylaxis in HIV patients.

Sexually transmitted diseases treatment guidelines 2015. Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 27–32.

Acyclovir, valacyclovir, and famciclovir are safe to use in immunocompromised patients. Treatment duration is generally for 5–10 days of the following: acyclovir 400 mg three times daily, famciclovir 500 mg twice daily, or valacyclovir 1 g twice daily. Intravenous therapy may be required in severe cases.

Second-Line Therapies

- Foscarnet **B**
- Cidofovir **A**

A multicenter phase I/II dose escalation study of single-dose cidofovir gel for treatment of recurrent genital herpes. Sacks SL, Shafran SD, Diaz-Mitoma F, et al. Antimicrob Agents Chemother 1998; 42: 2996–9.

A randomized, double-blind, clinic-initiated, sequential dose-escalation pilot study compared the safety and efficacy of single applications of 1%, 3%, and 5% cidofovir gel with placebo in the treatment of early lesional recurrent genital herpes. At all strengths, cidofovir significantly reduced the median time to negative virus culture in a dose-dependent fashion. Single-dose application of cidofovir gel confers a significant antiviral effect on lesions of recurrent genital herpes.

Clinical potential of the acyclic nucleoside phosphonates cidofovir, adefovir, and tenofovir in treatment of DNA virus and retrovirus infections. De Clercq E. Clin Microbiol Rev 2003; 16: 569–96.

The acyclic nucleoside phosphonate HPMPC (cidofovir) proved effective in vitro and in vivo against a wide variety of DNA viruses and retroviruses, including HSV-1 and 2.

Foscarnet treatment of acyclovir-resistant herpes simplex virus infection in patients with acquired immunodeficiency syndrome: preliminary results of a controlled, randomized, regimen-controlled trial. Hardy WD. Am J Med 1992; 92: 30s–5s.

Twenty-five patients with AIDS and acyclovir-resistant HSV infection were treated with foscarnet infusions for 2 weeks, followed by 8 more weeks either with 4 mg/kg daily or without further treatment. Lesions healed most quickly in those treated for a total of 10 weeks.

Third-Line Therapies

- Aspirin **B**
- Resiquimod **A**
- Topical imiquimod **E**

Aspirin in the management of recurrent herpes simplex virus infection. Karadi I, Karpatis S, Romics L. Ann Intern Med 1998; 128: 696–7.

This study showed that patients treated with aspirin 125 mg daily had significantly fewer days of active HSV infection than controls who took no antiviral or antiinflammatory drugs. Of the 21 subjects, only two had recurrent genital HSV; the remainder had recurrent oral HSV.

Topical resiquimod 0.01% gel decreases herpes simplex virus type 2 genital shedding: a randomized, controlled trial. Mark KE, Corey L, Meng TC, et al. J Infect Dis 2007; 195: 1324–31.

A randomized, double-blind, vehicle-controlled trial assessed the efficacy of resiquimod 0.01% gel for reducing human anogenital HSV-2 mucosal reactivation. Adults with genital HSV-2 applied topical resiquimod or vehicle to anogenital lesions twice weekly for 3 weeks. The median lesion and shedding rates were lower for the treatment group than in the vehicle group for both sampling periods. The length of recurrence was not influenced by resiquimod treatment.

Treatment of recalcitrant herpes simplex virus with topical imiquimod. Hirokawa D, Woldow A, Lee SN, et al. Cutis 2011; 88: 276–7.

In this case report, an HIV-positive man with valacyclovir-resistant genital HSV-2 was successfully treated with topical imiquimod 5% cream three times weekly for 8 weeks.

NOVEL AND OTHER THERAPIES

- Helicase-primase inhibitors
- Psychosocial counseling
- Hygiene techniques

Effect of pritelivir compared with valacyclovir on genital HSV-2 shedding in patients with frequent recurrence: a randomized clinical trial. Wald A, Timmler B, Magaret A, et al. JAMA 2016; 316: 2495–503.

This phase II, randomized, double-blind, crossover trial compared oral pritelivir, a novel HSV helicase-primase inhibitor, dosed at 100 mg once daily, to oral valacyclovir 500 mg once daily. The study demonstrated a significantly lower rate of genital HSV shedding and lesions in the pritelivir arm versus the valacyclovir arm. Pritelivir appears to be significantly more effective than valacyclovir, though further investigation into long-term safety and efficacy is needed.

Sexually transmitted diseases treatment guidelines 2015. Centers for Disease Control and Prevention. *MMWR Recomm Rep* 2015; 64: 27–32.

Counseling of infected individuals serves to prevent sexual and perinatal infection and to help individuals cope with infection. Education for infected individuals seems to be of benefit both at the time of diagnosis and after resolution of the acute infection to further their understanding of the chronic nature of the disease.

Genital herpes: a review. Beaman JG, Maj MC. *Am Fam Phys* 2005; 72: 1527–34, 1541–2.

Prevention of secondary infection and spread of the infection can be achieved by keeping the affected area clean and dry, wearing loose-fitting clothing and cotton underwear, avoiding contact with the lesions, and washing hands immediately should contact with any sores occur.

PREVENTION

- Condoms
- Vaccine
- Disclosure to sexual partners

Serologic screening for genital herpes infection: US Preventive Services Task Recommendation Statement. US Preventive Services Task Force. *JAMA* 2016; 316(23): 2525–30.

An evidence review on the accuracy, benefits, and harms of serologic screening for HSV-2 infections was performed by the US Preventive Services Task Force. Routine serologic screening for genital HSV infection in asymptomatic adolescents, adults, and pregnant patients is not recommended.

A pooled analysis of the effect of condoms in preventing HSV-2 acquisition. Martin ET, Krantz E, Gottlieb SL, et al. *Arch Intern Med* 2009; 169: 1233–40.

This pooled analysis of over 5000 HSV-2-negative individuals at baseline showed that consistent use of condoms was associated with a 30% reduction in risk of acquiring HSV-2 compared with those with no condom use (HR of 0.70, 95% confidence interval (CI), 0.40–0.94, $p = 0.01$).

Knowledge of partners' genital herpes protects against herpes simplex virus type 2 acquisition. Wald A, Krantz E, Selke S, et al. *J Infect Dis* 2006; 194: 42–52.

This study utilized a time-to-event design to demonstrate that disclosure of genital herpes to an individual's partner increased the mean time to HSV-2 acquisition (270 days vs. 60 days, $p = 0.03$) compared with those who did not disclose their condition. Disclosure of infection to sexual partners has the potential to serve as a protective factor against HSV-2 transmission.

Effects of different doses of GEN-003, a therapeutic vaccine for genital herpes simplex virus-2, on viral shedding and lesions: results of a randomized placebo-controlled trial. Van Wagoner N, Fife K, Leone PA, et al. *J Infect Dis*. 2018; 218: 1890–9.

This phase II, randomized, placebo-controlled trial of a 3-dose series, GEN-003 (20 mcg of glycoprotein D from HSV-2 with alum and 3-O-deacylated monophosphoryl lipid A as an adjuvant) decreased viral shedding for up to 12 months, with the 60/50 and 60/75 doses representing the most promising combinations for further evaluation.

Therapeutic HSV-2 vaccine decreases recurrent virus shedding and recurrent genital herpes disease. Bernstein DI, Flechtner JB, McNeil LK, et al. *Vaccine* 2019; 37(26): 3443–50.

HSV-2 seropositive persons with genital herpes were randomized into cohorts. Three doses of GEN-003 or placebo were administered 21 days apart. This study found that the 60/50 dose demonstrated the maximal effect, warranting further evaluation.

Herpes labialis

Alexander K.C. Leung, Benjamin Barankin

Herpes labialis (also known as 'cold sores') is characterized by recurrent vesicular eruptions primarily on the lips and perioral skin. The condition is contagious, can cause significant discomfort/pain, and can have an adverse effect on quality of life. Herpes labialis is caused by reactivation of herpes simplex virus type 1 (HSV-1). After a primary infection, HSV-1 establishes chronic latency within the trigeminal ganglion. When an appropriate trigger occurs, the virus reactivates, replicates in the trigeminal ganglion, descends along the sensory nerve axon to the perioral epithelium, and results in herpes labialis. A prodrome including irritation, pruritus, tingling, numbness, burning, and pain may occur at the site of future lesion development.

MANAGEMENT STRATEGY

Antiviral therapy shortens the duration of discomfort/pain, hastens healing, and reduces viral shedding, thereby reducing dissemination of HSV. Treatment should be initiated ideally in the prodromal stage and no later than 48 hours from the onset of lesions to obtain maximal clinical effect. Oral antiviral agents for herpes labialis include aciclovir, famciclovir, and valaciclovir and they are superior to topical antiviral agents. The metabolites of these nucleoside derivatives interfere with the synthesis of viral DNA. For episodic treatment, the recommended oral dose of aciclovir for children is 15 mg/kg (maximum 200 mg) and that for adults 400 mg five times a day for 5 days. Oral famciclovir and valaciclovir are alternate options for individuals ≥ 18 years and ≥ 12 years, respectively. Famciclovir and valaciclovir have greater oral bioavailability and are better absorbed than aciclovir and require less frequent dosing, but are more expensive. The recommended oral dose of famciclovir is 750 mg twice a day or a single dose of 1500 mg for 1 day and that of valaciclovir is 2000 mg twice a day for 1 day.

Topical antiviral agents such as 5% aciclovir cream/ointment alone or in combination with 1% hydrocortisone and 1% penciclovir cream are also available for the episodic treatment of herpes labialis. Topical aciclovir requires applications five times a day

whereas penciclovir requires applications nine times a day. The duration of treatment depends on the response to therapy. Topical aciclovir mucoadhesive buccal tablet once a day has also been shown to be effective.

Topical application of docosanol 10% cream five times daily has also been shown to be effective.

The use of intravenous aciclovir should be considered in immunocompromised patients and those with severe infections. The recommended dose of aciclovir is 5 mg/kg infused over an hour, delivered every 8 hours. The duration of treatment depends on the severity of symptoms and response to treatment.

Avoidance of known triggers such as emotional stress and ultraviolet radiation may diminish the number of recurrences. In patients with a history of solar-induced reactivation of herpes labialis, avoidance of sun exposure especially during hours of peak ultraviolet intensity (11 am–4 pm), regular use of broad-spectrum sunscreens, and wearing of protective wide-brimmed hats should be considered.

Chronic suppressive therapy with aciclovir or valaciclovir should be considered for patients with severe or frequent (six or more episodes per year) recurrences. The recommended oral dose of aciclovir is 400 mg 2–4 times a day and that of valaciclovir is 500 mg daily or twice a day. There is no data on the use of famciclovir for this purpose.

Other treatment modalities for the management and prevention of recurrent herpes labialis include laser therapy and photodynamic therapy.

Specific Investigations

- Real-time HSV polymerase chain reaction of specimen from mucocutaneous site
- Viral culture
- Direct fluorescent antibody testing
- Tzanck smear
- HSV serology

The diagnosis is mainly clinical. Laboratory investigations should be considered if the diagnosis is in doubt.

First-Line Therapies

• Oral aciclovir	A
• Oral famciclovir	A
• Oral valaciclovir	A

Efficacy and safety of nucleoside antiviral drugs for treatment of recurrent herpes labialis: a systematic review and meta-analysis. Chen F, Xu H, Liu J, et al. J Oral Pathol Med 2017; 46: 561–8.

A meta-analysis of 25 randomized controlled trials (RCTs) ($n = 8453$ patients) showed that both topical and systemic nucleoside antiviral agents decreased time to healing of all herpes labialis lesions and increased the percentage of aborted lesions. Oral antiviral agents were superior to topical antiviral agents and required less frequent applications. Oral valaciclovir was more effective than aciclovir in reducing the time of healing of all lesions and the time of resolution of pain.

Single-dose, patient-initiated famciclovir: a randomized, double-blind, placebo-controlled trial for episodic treatment of herpes labialis. Spruance SL, Bodsworth N, Resnick H, et al. J Am Acad Dermatol 2006; 55: 47–53.

An RCT for episodic treatment of herpes labialis ($n=701$) showed that single-dose famciclovir was as efficacious as single-day, twice-daily dosing in time to healing of herpes labialis lesions and was superior compared with placebo.

Oral acyclovir and herpes labialis: a randomized, double-blind, placebo-controlled study. Raborn GW, McGaw WT, Grace M, et al. *J Am Dent Assoc* 1987; 115: 38–42.

An RCT ($n=149$) showed oral acyclovir, 200 mg five times per day for 5 days, showed a significant antiviral effect in the treatment of herpes labialis, but that higher doses or a loading dose could improve its efficacy.

Treatment of recurrent herpes simplex labialis with oral acyclovir. Spruance SL, Stewart JC, Rowe NH, et al. *J Infect Dis* 1990; 161: 185–90.

In an RCT ($n=174$), patients treated with aciclovir 400 mg five times a day for 5 days had a decreased frequency of HSV culture-positive lesions, decreased duration of pain, and decreased duration of lesions compared with placebo.

High-dose, short-duration, early valacyclovir therapy for episodic treatment of cold sores: results of two randomized, placebo-controlled, multicenter studies. Spruance SL, Jones TM, Blatter MM, et al. *Antimicrob Agents Chemother* 2003; 47: 1072–80.

Two RCTs ($n=1247$) comparing the efficacy of valacyclovir administered upon the first prodromal symptoms of herpes labialis showed that the time to lesion healing and time to cessation of pain/discomfort were significantly reduced with valacyclovir compared with placebo, and that treatment for 1 day was as effective as treatment for 2 days.

Second-Line Therapies

• Topical aciclovir	A
• Topical aciclovir with hydrocortisone	A
• Topical penciclovir	A
• Topical aciclovir mucoadhesive buccal tablet	A

Acyclovir cream for treatment of herpes simplex labialis: results of two randomized, double-blind, vehicle-controlled, multicenter clinical trials. Spruance SL, Nett R, Marbury T, et al. *Antimicrob Agents Chemother* 2002; 46: 2238–43.

Two RCTs ($n=1385$) showed that topical application of 5% aciclovir cream five times daily for 4 days beginning within 1 hour of the onset of herpes labialis significantly reduced the duration of herpes labialis episodes and the duration of lesional pain.

Efficacy of topical 5% acyclovir-1% hydrocortisone cream (ME-609) for treatment of herpes labialis: a systematic review. Rosa MI, Souza SL, Farias BE, et al. *An Acad Bras Cienc* 2015; 87(2 Suppl): 1415–20.

A meta-analysis of two RCTs ($n=1213$) showed that treatment with a combination of 5% aciclovir and 1% hydrocortisone had a significant positive effect on developed ulcerative lesions in patients with herpes labialis (relative risk: 0.77; 95% confidence interval: 0.7–0.86; $p<0.001$).

Penciclovir cream for the treatment of herpes simplex labialis. A randomized, multicenter, double-blind, placebo-controlled trial. Topical Penciclovir Collaborative Study

Group. Spruance SL, Rea TL, Thoming C, et al. *JAMA* 1997; 277: 1374–9.

An RCT ($n=2209$) showed that topical application of 1% penciclovir cream decreased time to lesion healing, lesional pain, and viral shedding compared with patients treated with vehicle control cream.

Efficacy and safety of aciclovir mucoadhesive buccal tablet in immunocompetent patients with labial herpes (LIP Trial): a double-blind, placebo-controlled, self-initiated trial. Bieber T, Chosidow O, Bodsworth N, et al. *J Drugs Dermatol* 2014; 13: 791–8.

A multicenter RCT ($n=775$) showed that a single application of an aciclovir mucoadhesive buccal tablet (50 mg) significantly reduced the time to healing and the duration of herpes labialis episodes.

Third-Line Therapies

• Topical docosanol	A
• Intravenous aciclovir	A

Clinical efficacy of topical docosanol 10% cream for herpes simplex labialis: a multicenter, randomized, placebo-controlled trial. Sacks SL, Thisted RA, Jones TM, et al. *J Am Acad Dermatol* 2001; 45: 222–30.

A multicenter RCT ($n=370$) showed that topical application of docosanol 10% cream five times daily significantly reduced times from initiation of treatment to cessation of lesional symptoms and complete healing of lesions of herpes labialis.

Multicenter collaborative trial of intravenous acyclovir for treatment of mucocutaneous herpes simplex virus infection in the immunocompromised host. Meyers JD, Wade JC, Mitchell CD, et al. *Am J Med* 1982; 73: 229–35.

An RCT ($n=97$) of intravenous aciclovir in the treatment of immunocompromised patients with mucocutaneous herpes simplex infection showed that intravenous aciclovir significantly reduced periods of viral shedding, lesional pain, and healing of lesions.

Prophylactic Treatment

• Sunscreen	A
• Oral aciclovir	A
• Oral valacyclovir	A

Do sunscreen prevent recurrent herpes labialis in summer? Mazzaello V, Ferrari M, Piu G, et al. *J Dermatolog Treat* 2019; 30(2): 179–82.

A randomized crossover study performed on 20 adults who served as their own controls showed that in individuals with sun-block stick (SPF 30) protection, the number of herpes labialis attacks was significantly reduced.

Interventions for prevention of herpes simplex labialis (cold sores on the lips). Chi CC, Wang SH, Delamere FM, et al. *Cochrane Database Syst Rev* 2015; (8): CD010095.

A Cochrane meta-analysis of 32 RCTs ($n=2640$) showed that long-term use of oral aciclovir and valacyclovir had a modest beneficial effect in the prevention of recurrent herpes labialis.

OTHER THERAPIES

Efficacy of low-level laser therapy in management of recurrent herpes labialis: a systematic review. Al-Maweri SA, Kalakonda B, AlAizari NA, et al. *Lasers Med Sci* 2018; 33: 1423–30.

A systematic review of six clinical trials using low-level laser therapy found laser therapy was effective in the management and prevention of herpes labialis, without any adverse events. The wavelengths, power output, and energy density ranged between 632.5 and 870 nm, 5 and 80 W, and 2.04 and 48 J/cm², respectively. Because of the inconsistency in laser parameters and high variability in study designs, large-scale, well-designed RCTs with standardized laser parameters are warranted.

Efficacy of photodynamic therapy on the treatment of herpes labialis: a systematic review. Lotufo MA, Tempestini Horliana ACR, Santana T, et al. *Photodiagnosis Photodyn Ther* 2020; 29: 101536.

A systemic review of case reports and five studies showed that photodynamic therapy could be effective treatment for herpes labialis. The number of treated patients varied from two to six per article. Most studies used methylene blue as a photosensitizer, while one used 5-aminolevulinic acid. For light irradiation, most studies used laser while one used a red light from a halogen lamp. It is hoped that future, well-designed, large-scale RCTs will provide more information on the efficacy of photodynamic therapy in the treatment of herpes labialis.

Herpes zoster

Ritu Swali, Emily Haque, Stephen K. Tying

Reactivation of latent varicella zoster virus (VZV) produces the clinical syndrome herpes zoster (shingles), which manifests as a unilateral eruption along a single dermatome and is usually preceded by prodromal pain and paresthesia. The eruption lasts around 7–10 days and progresses from erythematous macules and papules to vesicles, then pustules, and finally crusts over. One of the most common complications of herpes zoster is postherpetic neuralgia (PHN), which is dermatomal pain persisting longer than 3 months.

MANAGEMENT STRATEGY

Early treatment – within the first 72 hours of vesicle formation – is important for antiviral efficacy, time to lesion healing, and minimizing zoster-associated pain (although initiating treatment after 72 hours may still be effective). *Aciclovir*, *valaciclovir*, and *famciclovir* are guanosine analogs that are phosphorylated by thymidine kinase to a triphosphate form that inhibits viral deoxyribonucleic acid (DNA) polymerase. The oral bioavailability of the antivirals determines the number of daily administrations. Patient compliance tends to decrease as the number of daily administrations increases. The most common side effects seen are headache and gastrointestinal upset, but these drugs are otherwise safe and well tolerated. Patients with renal insufficiency will need an adjusted dose, as these medications are excreted by the kidneys.

Aciclovir-resistant VZV infections have been reported in immunocompromised patients (i.e., acquired immune deficiency syndrome [AIDS], transplant patients), and in these cases *foscarnet*

(given intravenously 40 mg/kg three times daily) can be used as an alternative.

Acutely, *corticosteroids* may reduce zoster-associated pain, but they are associated with a risk of serious adverse events and have shown no benefit in reducing time to complete cessation of pain or prevention of PHN.

Pain management is especially difficult with conventional analgesics in zoster patients who develop PHN. Calcium channel $\alpha_2\text{-}\delta$ ligands (gabapentin and pregabalin), tricyclic antidepressants, opioids, topical lidocaine (Table 105.1), selective serotonin and norepinephrine reuptake inhibitors (duloxetine and venlafaxine), and topical capsaicin have been shown to reduce the pain associated with PHN. Of these medications, only gabapentin, pregabalin, 5% lidocaine patch, and 8% capsaicin patch have been approved by the Food and Drug Administration (FDA) specifically for the treatment of PHN. Adding gabapentin to an antiviral in patients with acute herpes zoster appears to significantly reduce the incidence of PHN. In January 2011, the FDA approved Gralise as a once-daily medication for the treatment of postherpetic neuralgia. Gralise is an extended-release form of gabapentin that not only has been shown to significantly decrease PHN pain scores but may also be associated with fewer side effects than its immediate-release counterpart. In 2012 the FDA approved Horizant, gabapentin enacarbil, for the once-daily therapy of PHN.

Vaccination of patients aged 50 years and over is the most promising option for preventing herpes zoster and, therefore, PHN. As of February 2020, there are two types of FDA-approved zoster vaccines. The first is Zostavax, a live attenuated varicella vaccine approved in 2006. The second is Shingrix, a recombinant zoster vaccine approved in 2017, which is the current recommended vaccine. Studies in adults aged 50 and older showed that five randomized controlled trials compared the live attenuated vaccine with the adjuvant recombinant subunit vaccine and placebo. Shingrix demonstrated a vaccine efficacy superior to both Zostavax and placebo (85% and 94%, respectively). In a clinical trial involving over 15,000 adults aged 50 or older, Shingrix reduced the risk of herpes zoster by 97.2%. However, there is an increased risk of injection site reactions with Shingrix compared with Zostavax. The Advisory Committee on Immunization Practices recommends two doses of Shingrix administered within 2–6 months for immunocompetent adults aged 50 years or older.

Specific Investigations

No investigation is usually required

- Tzanck smear
- Virology (culture, serology [acute plus chronic], electron microscopy, polymerase chain reaction)

First-Line Therapies

• Aciclovir 800 mg five times daily for 7 days	A
• Famciclovir 500 mg three times daily for 7 days	A
• Valaciclovir 1 g three times daily for 7 days	A

Valaciclovir compared with aciclovir for improved therapy for herpes zoster in immunocompetent adults. Beutner KR, Friedman DJ, Forszpaniak C, et al. *Antimicrob Agents Chemother* 1995; 39: 1546–53.

Table 105.1 Treatment options for postherpetic neuralgia

Drug class	Examples	Initial daily dose (mg)	Titration to maximum dose
Calcium channel $\alpha 2$ - δ ligands	Gabapentin	100–300	Start once at night and increase to three times daily dosing; increase by 100–300 mg every 3 days to total dose of 1800–2400 mg/day
	Gabapentin enacarbil		600 mg once daily in the morning for 3 days, then increase to 600 mg twice daily
Opioids	Pregabalin	150	Titrate up to 300 or 600 mg/day
	Hydrocodone	5–10	No titration
	Oxycodone (extended release)	20	Titrate up to 60 mg daily
Tricyclic antidepressants	Nortriptyline	10–25	Increase by 10–25 mg weekly, with a target dose of 75–150 mg daily; single dose or two divided doses
	Amitriptyline	10–25	Titrate up to 100 mg daily; single dose
	Desipramine	10–25	Increase every 3 days as needed up to 150 mg daily; single dose

Valaciclovir is comparable to aciclovir in the resolution of zoster eruption, but it accelerates the resolution of pain compared with aciclovir and is more convenient.

Famciclovir for the treatment of acute herpes zoster: effects on acute disease and postherpetic neuralgia. A randomized, double-blind, placebo-controlled trial. Tying S, Barbarash RA, Nahlik JE, et al. *Ann Intern Med* 1995; 123: 89–96.

Famciclovir recipients had faster resolution of pain after an acute episode than those receiving placebo.

Double-blind, randomized, aciclovir-controlled, parallel-group trial comparing the safety and efficacy of famciclovir and acyclovir in patients with uncomplicated herpes zoster. Shen MC, Lin HH, Lee SS, et al. *J Microbiol Immunol Infect* 2004; 37: 75–81.

Famciclovir is comparable to aciclovir in the resolution of zoster cutaneous eruption but is more convenient and had a more favorable adverse event profile.

A comparative study to evaluate the efficacy and safety of aciclovir and famciclovir in the management of herpes zoster. Gopal MG, Shannoma, Kumar S, et al. *Clin Diagn Res* 2013; 7: 2904–7.

Oral famciclovir given at 250 mg three times daily for 7 days is as effective as aciclovir 800 mg five times daily.

Second-Line Therapies

Agents to reduce postherpetic neuralgia

• Calcium channel $\alpha 2$ - δ ligands (gabapentin, pregabalin)	A
• Tricyclic antidepressants	A
• Lidocaine patch	A
• Oxycodone	A

Pregabalin for the treatment of postherpetic neuralgia: a randomized, placebo-controlled trial. Dworkin RH, Corbin AE, Young JP, et al. *Neurology* 2003; 60: 1274–83.

Pregabalin is effective in the treatment of pain and sleep interference associated with PHN.

Efficacy and safety of gabapentin 1800 mg treatment for postherpetic neuralgia: a meta-analysis of randomized controlled trials. Fan H, Yu W, Zhang Q, et al. *J Clin Pharm Ther* 2014; 39: 334–42.

A meta-analysis of randomized controlled trials found gabapentin 1800 mg significantly reduced postherpetic neuralgia up to 14 weeks. Treatment at this dose was safe up to 24 weeks. Comparison between once-daily and divided-dose gabapentin showed no significant difference in efficacy.

Incidence of postherpetic neuralgia after combination treatment with gabapentin and valaciclovir in patients with acute herpes zoster: open-label study. Lapolla W, Digiorio C, Haitz K, et al. *Arch Dermatol* 2011; 147: 901–7.

The addition of gabapentin to valaciclovir produced a significant reduction in PHN. Therefore, it is recommended that gabapentin be initiated in addition to antivirals for the treatment of acute zoster with moderate-to-severe pain at presentation.

Gabapentin versus nortriptyline in postherpetic neuralgia patients: a randomized, double blind clinical trial: the GONIP Trial. Chandra K, Shafiq N, Pandhi P, et al. *Int J Clin Pharmacol Ther* 2006; 44: 358–63.

Gabapentin and nortriptyline are equally efficacious, but gabapentin is better tolerated.

Topical lidocaine for the treatment of postherpetic neuralgia. Khaliq W, Alam S, Puri N. *Cochrane Database Syst Rev* 2007; 2: CD004846.

A meta-analysis combining two studies found that lidocaine is more effective than placebo, but there is insufficient evidence to recommend it as a first-line therapy. The studies cited in the review used 5% lidocaine gel applied for 8–24 hours or 5% lidocaine patch applied up to three times daily.

Efficacy of oxycodone in neuropathic pain: a randomized trial in postherpetic neuralgia. Watson CPN, Babul N. *Neurology* 1998; 50: 1837–41.

Patients on slow-release oxycodone had significantly greater pain relief and reduction in allodynia and disability.

Third-Line Therapies

• Vaccination of adults	A
• Contact with varicella or with children	C
• Topical capsaicin	A
• Topical non-steroidal antiinflammatory cream	C
• Tramadol	A
• Sympathetic nerve block	B
• Transcutaneous electrical stimulation	B
• Methylcobalamin injection	B

A vaccine to prevent herpes zoster and postherpetic neuralgia in older adults. Oxman MN, Levin MJ, Johnson GR, et al. *N Engl J Med* 2005; 352: 2271.

A randomized, double-blind, placebo-controlled trial live attenuated Oka/Merck VZV vaccine enrolled 38,546 immunocompetent adults aged 60 years or over. The vaccine significantly reduced morbidity from herpes zoster and PHN.

Efficacy of an adjuvanted herpes zoster subunit vaccine in older adults. Lal H, Cunningham AL, Godeaux O, et al. *N Engl J Med* 2015; 372: 2087–96.

A clinical trial involving over 15,000 adults aged 50 or older showed that Shingrix reduced the risk of developing herpes zoster by 97.2%.

Efficacy, effectiveness, and safety of herpes zoster vaccines in adults aged 50 and older: systematic review and network meta-analysis. Tricco AC, Zarin W, Cardoso R, et al. *BMJ* 2018; 363: k4029.

A meta-analysis found Shingrix to have a vaccine efficacy of 94%, superior to both Zostavax and placebo. Shingrix also demonstrated a greater risk of adverse injection site reactions compared to Zostavax and placebo.

Family history and herpes zoster risk in the era of shingles vaccination. Hernandez PO, Javed S, Mendoza N, et al. *J Clin Virol* 2011; 52: 344–8.

The most important risk factor for development of zoster, after age and immune status, is a family history of shingles. Therefore, patients over age 50 with a family history of shingles should be particularly encouraged to receive the zoster vaccine.

Shingrix, a new recombinant zoster vaccine approved in 2017, is the current recommended vaccine for shingles in the US for healthy adults aged 50 and over.

Shingrix for herpes zoster: a review. Shah RA, Limmer AL, Nwannunu CE, et al. *Skin Therapy Lett* 2019; 24: 5–7.

Shingrix was approved by the US FDA in October 2017 as a herpes zoster prophylaxis.

Contacts with varicella or with children and protection against herpes zoster in adults: a case-controlled study. Thomas SL, Wheeler JG, Hall AJ. *Lancet* 2002; 360: 678–82.

Social contact with many children outside the household, or occupational contacts with children ill with chickenpox, results in a graded protection against zoster.

A randomized vehicle-controlled trial of topical capsaicin in the treatment of postherpetic neuralgia. Watson CP, Tyler KL, Bickers DR, et al. *Clin Ther* 1993; 15: 510–26.

Capsaicin 0.075% cream applied three to four times per day was effective. The only side effect was burning or stinging at sites of application.

Benzydamine cream for the treatment of postherpetic neuralgia: minimum duration of treatment periods in a cross-over trial. McQuay HJ, Carroll D, Moxon A, et al. *Pain* 1990; 40: 131–5.

Some patients benefit from 3% benzydamine hydrochloride cream applied six times daily.

Tramadol in postherpetic neuralgia: a randomized, double-blind, placebo-controlled trial. Boureau F, Legallier P, Kabir-Ahmadi M. *Pain* 2003; 104: 323–31.

A double-blind study with 127 patients found tramadol to be effective in reducing pain intensity and increasing the percentage of pain relief compared with placebo. All patients were treated for 6 weeks with doses ranging from 100 to 400 mg based on therapeutic response. Patients over 75 years of age received divided doses (morning and night); others received a single-dose regimen.

Neuraxial and sympathetic blocks in herpes zoster and postherpetic neuralgia: an appraisal of current evidence. Kumar V, Krone K, Mathieu A. *Regional Anesth Pain Med* 2004; 29: 454–61.

Sympathetic blocks for herpes zoster and PHN appear to be useful but require randomized, controlled trials for validation.

Modified Jaipur block for the treatment of post-herpetic neuralgia. Puri N. *Int J Dermatol* 2011; 50: 1417–20.

Subcutaneous injections of 2% Xylocaine and 0.5% bupivacaine in 4 mg/mL methylprednisolone can provide significant pain relief in persistent PHN. Approximately 90% of patients in a recent study experienced complete pain relief after three rounds of subcutaneous injections administered at 6-week intervals.

Transcutaneous electrical nerve stimulation for chronic postherpetic neuralgia. Ing MR, Hellreich PD, Johnson DW, et al. *Int J Dermatol*. 2015; 54: 476–80.

A randomized study of patients with PHN refractory to other medical treatments found that transcutaneous electrical nerve stimulation produced significantly reduced pain scores.

Comparison of the efficacy of continuous epidural block with epidural electrical stimulation and conventional continuous epidural block for management of zoster-associated pain beyond the acute phase: a retrospective study. Lee CH, Choi SS, Lee MK, et al. *Medicine (Baltimore)* 2019; 98: e17026.

A retrospective study demonstrated reduced subacute PHN using epidural block via electrical stimulation catheters.

Cryoanalgesia for postherpetic neuralgia: a new treatment. Calandria L. *Int J Dermatol* 2011; 50: 746–50.

Liquid nitrogen applied in a non-freezing manner can safely reduce PHN pain. In a recent study, 75% of patients reported a >70% reduction in pain after a total of five weekly sessions.

A single-center randomized controlled trial of local methylcobalamin injection for subacute herpetic neuralgia. Xu G, Lv ZW, Feng Y, et al. *Pain Med* 2013; 14: 884–94.

Local methylcobalamin injection was effective in relieving pain and discomfort caused by subacute herpetic neuralgia and was well tolerated.

Corticosteroids for preventing postherpetic neuralgia. Han Y, Zhang J, Chen N, et al. Cochrane Database Syst Rev 2013; 3: CD005582.

A systematic review and meta-analysis of randomized controlled trials found moderate-quality evidence that corticosteroids given acutely during herpes zoster infection are ineffective in preventing postherpetic neuralgia.

Hidradenitis suppurativa

Gregor B.E. Jemec

Hidradenitis suppurativa (HS) is a chronic relapsing skin disease, characterized by recurring flares of inflamed painful nodules, abscesses, tunnels, and scarring involving apocrine-bearing skin. Pain and suppuration cause considerable morbidity. The disease is associated with comorbidities and an increased all-cause mortality and risk of suicide. Associated with HS are anxiety, depression, obesity, smoking, polycystic ovarian disease, inflammatory bowel disease, pyoderma gangrenosum, spondyloarthropathy, arthritis, metabolic syndrome, dyslipidemia, psychiatric disorders, drug dependence, hypertension, diabetes, thyroid disease, alcohol dependence, and lymphoma.

MANAGEMENT STRATEGY

HS is a clinical diagnosis, based on the identification of morphology, location, and the chronic/recurrent nature of lesions. The morphology may include non-inflamed or inflamed nodules, abscesses, non-draining or draining tunnels (sinus tracts), and scars. The locations are bilateral and must involve one or more of these areas: axillae, inframammary area, groin (including genitals). No pathognomonic test exists. Preclinical follicular changes can be identified with ultrasound. Age of onset is usually in the third decade of life and is rare before puberty. An underlying endocrine disorder must be considered in prepubertal cases.

Outcome assessment includes pain, e.g., a numerical rating scale, such as 0–10; health-related quality of life, e.g., Dermatology Life Quality Index (DLQI) or Hidradenitis Suppurativa Quality of Life (HISQOL); symptoms, physical signs, e.g., the

International Hidradenitis Suppurativa Severity Score System (IHS4); and global assessment and progression.

Early lesions are mainly painful 'blind' boils, i.e., deep and rounded nodules. These may be transient and flare to become abscesses that either subside or transform into draining or non-draining tunnels. Gradually, postinflammatory scarring and tunnel formation occur in separate areas of the affected regions, and ultimately coalesce to form stage III lesions. Early lesions can remit without treatment. Tunnels and scars are not generally amenable to medical treatment and thus indicate the need for surgical intervention.

Clinically, HS can be distinguished from furunculosis (randomly occurring boils, and not limited to inverse areas) or epidermal cysts, solitary clinically stable lesions, pyogenic granulomas, and scarring folliculitis. Microbiology is most useful when presentations are atypical and in later stages of disease when superinfection may occur. If there is suspicion that a mimic of HS is present, for example, mycobacterial infection, squamous cell carcinoma, or Crohn disease, skin biopsies and/or additional relevant tests should be performed.

Current medical practice is mainly empirical. Several guidelines have been suggested for the management of HS. They all share the use of multimodal management, i.e., simultaneously using a three-pronged approach:

1. Adjuvant therapy, which includes pain management, treatment of established superinfections, weight loss, and tobacco cessation. Treatment of superinfections is directed by bacterial culture sensitivities. Appropriate bandaging of suppurating lesions and patient support groups are helpful.
2. Medical therapy, which may be topical in mild cases. *Topical clindamycin* has been shown to have an effect on early lesions. *Resorcinol 15% BD* can also be used as first-line treatment. Systemic tetracycline (500 mg BD) or doxycycline (100 mg BD) may be used as an alternative for severe/refractory disease. Cohort studies support coadministering *oral clindamycin 300 mg BD* and *rifampicin 300 mg BD* for limited HS. Smaller studies indicate that long-term intensive antibiotic treatment, e.g., the oral combination of *rifampin* (10 mg/kg once daily), *moxifloxacin* (400 mg once daily), and *metronidazole* (250–500 mg TD) (RMoM) for 6 weeks, followed by 4 weeks of RMo alone, then by *cotrimoxazole* after remission may provide long-term disease control in mild cases. Antibiotic resistance is frequent in the microbiota of HS patients and calls for more stringent antibiotic stewardship. For localized flares, *intralesional corticosteroids* (3–5 mg single dose) may provide significant pain relief within 24 hours. *Adalimumab* has been shown to be effective in moderate-to-severe HS when administered weekly (week 0: 160 mg; week 2: 80 mg; and from week 4: 40 mg weekly). Onset of effect has been shown to be at week 2 of treatment. A post hoc analysis of a smaller trial indicated that *infliximab* 5 mg/kg may also be effective. *Anakinra* (100 mg daily) and *apremilast* (30 mg BD) may also be effective. An open-label study of *ustekinumab* (45 mg or 90 mg based on patient weight) also indicated utility. Palliative medication includes systemic antiinflammatory drugs such as *oral corticosteroid*, *dapsone*, and *ciclosporin*. Patients may also benefit from *acitretin* 25 mg BD/TID, although this treatment is often limited by side effects and teratogenicity. HS shows little sign of improvement with isotretinoin. Hormonal therapy with *cyproterone acetate* may be helpful in some females but requires high and continued use, which raises safety concerns. A study found that *spironolactone* at doses ranging from 25 mg BD to 100 mg BD might be useful.
3. Surgery, from local to extensive, can be helpful. Milder cases can benefit from localized excisions or de-roofing (exteriorization)

of single tunnels. Only fluctuant soft abscesses should undergo lancing. Lancing of inflamed nodules is painful to the patient, is ineffective, and causes additional scarring. Non-fluctuant symptomatic lesions are better treated using intralesional corticosteroids. A CO₂ laser can be used to evaporate lesions. More advanced cases require major surgery, which should involve excision of the affected tissue or careful de-roofing of all tunnels. The recurrence rate is inversely proportional to the extent of surgery, and wide excisions generally offer a better chance of remission. Similarly, it is suggested that secondary intention healing is superior to primary closure of postexcisional wounds. Secondary healing requires longer periods of wound management, but generally does not preclude resumption of work 3–4 weeks after treatment.

Specific Investigations

Diagnosis is based on morphology, location, and chronicity/recurrence. Specific investigations may be necessary to rule out other diagnoses depending on clinical findings.

- GI workup if Crohn disease suspected
- Biopsy if squamous cell carcinoma suspected
- Culture and sensitivity

First-Line Therapies

- Antibiotics – topical clindamycin or oral tetracycline **B**
- Oral clindamycin and rifampin for 10 weeks **B**
- Surgery **B**
- Intralesional triamcinolone **D**

Topical treatment of hidradenitis suppurativa with clindamycin. Clemmensen OJ. *Int J Dermatol* 1983; 22: 325–8.

Topical clindamycin 0.1% BD topical clindamycin for 3 months was significantly more effective than placebo in early lesions.

A randomised trial of topical clindamycin vs. systemic tetracycline in hidradenitis suppurativa with special reference to disease assessment. Jemec GBE, Wendelboe P. *J Am Acad Dermatol* 1998; 39: 971–4.

No difference of efficacy between topical clindamycin 0.1% BD and oral tetracycline 250 mg (two tablets twice daily) for 3 months in 46 patients.

Combination therapy with clindamycin and rifampicin for hidradenitis suppurativa: a series of 116 consecutive patients. Gener G, Canoui-Poitaine F, Revuz JE, et al. *Dermatology* 2009; 219: 148–54.

Disease severity assessed by Sartorius score reduced by 50% after 10 weeks.

De-roofing: a tissue-saving surgical technique for the treatment of mild to moderate hidradenitis suppurativa lesions. van der Zee HH, Prens EP, Boer J. *J Am Acad Dermatol* 2010; 63(3): 475–80.

De-roofing appears to be a useful form of limited surgery for tunnels.

Recurrence of HS after surgical management: a systematic review and meta-analysis. Mehdizadeh A, Hazen PG, Bechara FG, et al. *J Am Acad Dermatol* 2015; 73(5 Suppl 1): S70–7.

Drainage alone carries a recurrence rate of up to 100%; radical excision has a recurrence rate of 25% at a median interval of 20 months. Success of surgery is affected by such variables as location, extent, and duration of disease.

Intralesional corticosteroid injections as a treatment option for acute lesions in patients diagnosed with hidradenitis suppurativa. Maini P, Posso-De Los Rios C, Gooderham M. *J Amer Acad Derm* 2015; 72 (Suppl 1): AB51.

A total of 33 (29%) patients received intralesional triamcinolone acetone injections at concentrations of 2.5 mg/mL (14.3%), 3.33 mg/mL (34.7%), 5.0 mg/mL (38.8%), or 10 mg/mL (12.2%) as treatment to control acute lesions. Only 6/25 (25%) female subjects treated with intralesional injections required concomitant systemic antibiotics during flare-ups. The mean follow-up duration was 10.1 months for females and 23.2 months for males. An 8-year experience involving intralesional triamcinolone injections effectively treated inflammatory HS and reduced the use of systemic antibiotics.

Second-Line Therapies

- 1064 nm (for prevention rather than treatment of lesions) surgery **B**
- CO₂ laser **B**
- Metformin **C**
- Acitretin **C**
- Quinolone with rifampin and metronidazole **C**
- Spironolactone **C**
- Topical resorcinol **C**

Prospective controlled clinical and histopathologic study of hidradenitis suppurativa treated with the long-pulsed neodymium:yttrium-aluminum-garnet laser. Mahmoud BH, Tierney E, Hessel CL, et al. *J Am Acad Dermatol* 2010; 62: 637–45.

In patients with milder disease, treated with topical benzoyl peroxide and clindamycin, weekly treatment with long-pulsed neodymium:yttrium-aluminum-garnet laser for months was significantly more effective than topical treatment alone.

Surgical treatment of chronic hidradenitis suppurativa: CO₂ laser stripping-secondary intention technique. Lapins J, Marcussan JA, Emtestam L. *Br J Dermatol* 1994; 131(4): 551–6.

CO₂ evaporation of diseased tissue under visual control, followed by secondary healing.

Metformin for the treatment of hidradenitis suppurativa: a little help along the way. Verdolini R, Clayton N, Smith A, et al. *J Eur Acad Dermatol Venereol* 2013; 27: 1101–8.

Open case series describing benefits of monotherapy using metformin, gradually increasing dosing up to 500 mg TID, and dosing for 24 weeks.

Acitretin treatment for hidradenitis suppurativa: a prospective series of 17 patients. Matusiak L, Bieniek A, Szepietowski JC. *Br J Dermatol* 2014; 171(1): 170–4.

Eight of 17 patients (47%) experienced benefit of 50 mg once daily for 9 months; relapses occurred 2–8 months after stopping therapy.

A study on the management of hidradenitis suppurativa with retinoids and surgical excision. Puri N, Talwar A. *Indian J Dermatol* 2011; 56(6): 650–1.

The relapse rate following surgery was reduced from 40% to 20% by subsequent treatment with acitretin.

Efficacy of rifampin–moxifloxacin–metronidazole combination therapy in hidradenitis suppurativa. Join-Lambert O, et al. *Dermatology* 2011; 222: 49–58.

In this retrospective study, 28 consecutive HS patients, including 6, 10, and 12 Hurley stage I, II, and III patients, respectively, were treated with a combination of rifampin (10 mg/kg once daily), moxifloxacin (400 mg once daily), and metronidazole (250–500 mg TID) (RMoM) for 6 weeks, followed by 4 weeks of RMo alone, then by cotrimoxazole after remission. Complete remission, defined as a clearance of all inflammatory lesions including hypertrophic scars, was obtained in 16 patients, including 6/6, 8/10, and 2/12 patients with Hurley stage I, II, and III after up to 12 months of treatment.

Antiandrogen therapy with spironolactone for the treatment of hidradenitis suppurativa. Golbari NM, Porter ML, Kimball AB. *J Am Acad Dermatol* 2019; 80: 114–9.

Retrospective case series of 46 women treated with spironolactone (average 75 mg spironolactone for 7 months) describing reduced lesion count, HS-PGA score, and pain.

Topical 15% resorcinol for hidradenitis suppurativa: an uncontrolled prospective trial with clinical and ultrasonographic follow-up. Pascual JC, Encabo B, Ruiz de Apodaca RE, et al. *J Am Acad Dermatol* 2017; 77: 1175–8.

Open prospective case series of 32 patients applying resorcinol BD to individual lesions for 30 days. Clinical and ultrasonographic (US) resolution was achieved in 21/32 (65.6%) lesions at day 30; however, six showed only clinical but not US resolution, and five lesions persisted both clinically and on ultrasound. The mean pain score was significantly reduced at day 7 and at day 30.

Third-Line Therapies

• TNF- α monoclonal antibodies	A
• IL-1 blockade	B
• Apremilast	B
• Ustekinumab	C
• Immunosuppressants	D
• IV antibiotics	D

Adalimumab for the treatment of moderate to severe hidradenitis suppurativa: a parallel randomized trial. Kimball AB, Kerdell F, Adams D, et al. *Ann Intern Med* 2012; 157(12): 846–55.

Significant effect of adalimumab 40 mg every week.

Two phase 3 trials of adalimumab for hidradenitis suppurativa. Kimball AB, Okun MM, Williams DA, et al. *N Engl J Med* 2016; 375: 422–44.

Two similar randomized controlled studies with a total of 633 patients enrolled comparing adalimumab week 0: 160 mg, week 2: 80 mg, and from week 4: 40 mg weekly with matched controls.

Response rates at week 12 were significantly higher for the groups receiving adalimumab weekly.

Long-term adalimumab efficacy in patients with moderate-to-severe hidradenitis suppurativa/acne inversa: 3-year results of a phase 3 open-label extension study. Zouboulis CC, Okun MM, Prens EP, et al. *J Am Acad Dermatol* 2019; 80: 60–9.

Pooled results of the PIONEER phase 3 trials and an open-label extension study.

Responders and partial responders were evaluated. Response was maintained through week 168 in 52.3%–57.1%. Sustained improvement in lesion counts, skin pain, and DLQI score were also observed.

Infliximab therapy for patients with moderate to severe hidradenitis suppurativa: a randomized, double-blind, placebo-controlled crossover trial. Grant A, Gonzalez T, Montgomery MO, et al. *J Am Acad Dermatol* 2010; 62: 205–17.

A randomized controlled trial indicating effect of infliximab in post hoc analysis. With an initial placebo-controlled treatment phase of 8 weeks, patients were randomized to treatment with IFX (5 mg/kg) or placebo on weeks 0, 2, and 6. After week 8 and every 8th week until week 22, the patients crossed into a 30-week observational phase.

Safety and efficacy of anakinra in severe hidradenitis suppurativa: a randomized clinical trial. Tzanetakou V, Kanni T, Giatrakou S, et al. *JAMA Dermatol* 2016; 152(1): 52–9.

In this trial, 7/9 (78%) achieved clinical response in the actively treated group (100 mg daily) after 12 weeks.

Apremilast for moderate hidradenitis suppurativa: results of a randomized controlled trial. Vossen ARJV, van Doorn MBA, van der Zee HH, et al. *J Am Acad Dermatol* 2019; 80: 80–8.

Results showed that 8/15 (53%) achieved clinical response in the actively treated group (30 mg BD) after 16 weeks.

Ustekinumab in hidradenitis suppurativa: clinical results and a search for potential biomarkers in serum. Blok JL, Li K, Brodmerkel C, et al. *Br J Dermatol* 2016; 174: 839–46.

In this open-label study, 8/17 (47%) achieved clinical response at week 40 at dose 45/90 mg at weeks 0 and 12 and every 3 months.

Dapsone therapy for hidradenitis suppurativa: a series of 24 patients. Yazdanyar S, Boer J, Ingvarsson G, et al. *Dermatology* 2011; 222: 342–6.

Nine of 24 patients (38%) experienced benefits from therapy with dapsone.

Cyclosporine treatment of severe hidradenitis suppurativa – a case series. Anderson MD, Zauli S, Bettoli V, et al. *J Dermatol Treat* 2016; 27(3): 247–50.

Nine of 18 previously extensively treated patients (50%) experienced benefits from therapy with cyclosporin.

Histoplasmosis

Mahreen Ameen, Wanda Sonia Robles

Histoplasmosis is an endemic mycosis caused by a dimorphic fungus, *H. capsulatum*, of which there are two varieties that are pathogenic to humans. The most common variety worldwide is *H. capsulatum* var. *capsulatum*, which is highly endemic in the United States, particularly in the Mississippi and the Ohio valleys. *H. capsulatum* var. *duboisii* is endemic only in Central and West Africa (where it coexists with *H. capsulatum* var. *capsulatum*), and it is therefore sometimes referred to as African histoplasmosis. The infection is usually contracted through inhalation of spores in dry soil or bird or bat droppings. Disease progression and severity depend on the intensity of exposure to *H. capsulatum* and host immunity. There is a wide clinical spectrum of disease. Acute pulmonary disease is the most common presentation, and most cases are either asymptomatic or mild and self-limiting. Chronic pulmonary histoplasmosis, usually occurring in patients with underlying lung disease, produces cavities and later progression to pulmonary fibrosis. Haematogenous dissemination occurs within the first few weeks but resolves with the development of cell-mediated immunity to *H. capsulatum*. Progressive disseminated histoplasmosis occurs in the immunocompromised. Patient groups at risk include those with acquired immunodeficiency syndrome (AIDS), hematological malignancies, those on immunosuppressive therapy (including corticosteroids and tumor necrosis factor [TNF] antagonists), transplant recipients, and infants. Disseminated histoplasmosis is an AIDS-defining illness. It is usually a reactivation of prior infection and a sign of advanced immunosuppression, generally occurring in those with CD4 counts <150 cells/mm³.

Disseminated histoplasmosis can involve every organ system, most commonly presenting with hepatosplenomegaly and mucocutaneous lesions. Molluscum-like papules, nodules, or ulcerative lesions affect the skin, and are usually localized to the face, upper chest, and arms. Oropharyngeal ulcers affect the buccal mucosa, tongue, gingiva, lips, pharynx, and larynx. Histoplasmosis may also present to the dermatologist as a cause of erythema multiforme or erythema nodosum, which are thought to be a

hypersensitivity response to the *H. capsulatum* antigen. Rarely, primary cutaneous lesions may arise from direct inoculation.

MANAGEMENT STRATEGY

Pulmonary forms of histoplasmosis in the acute phase usually resolve spontaneously and only require treatment if symptoms persist for more than 1 month. Oral *itraconazole* is the treatment of choice for mild-to-moderate histoplasmosis. Severe pulmonary infection, disseminated histoplasmosis, and infection in the immunocompromised, particularly in association with AIDS, should be treated with *amphotericin B* (AmB) formulations (AmB deoxycholate, liposomal AmB, or AmB lipid complex). The lipid formulations carry a lower risk of nephrotoxicity but are more expensive. Treatment is commenced with AmB until there is clinical improvement, and then stepped down to oral itraconazole. *Fluconazole* and *ketoconazole* are second-line alternatives to itraconazole. Ketoconazole carries higher risks of adverse effects than the other azoles. The new triazoles, voriconazole and posaconazole, demonstrate *in vitro* activity against *H. capsulatum*, and have been successfully used in individual cases for different forms of histoplasmosis infection.

Patients with AIDS-related histoplasmosis who undergo antiretroviral treatment have better outcomes than those who are not treated with antiretrovirals. Some clinicians defer commencement of antiretroviral therapy until there is a reduction in fungal burden to avoid precipitating immune reconstitution inflammatory syndrome (IRIS). However, IRIS is a rare complication of histoplasmosis and is not usually severe. Therefore, others advocate early antiretroviral therapy to improve cellular immunity, a key defense against *H. capsulatum*.

Specific Investigations

- Culture
- Histology
- Serology
- Serology for human immunodeficiency virus (HIV) (where relevant)
- Imaging studies to detect disseminated disease (chest X-ray [CXR]/computed tomography [CT]/magnetic resonance imaging [MRI])

The gold standard method for diagnosing histoplasmosis is the isolation of *H. capsulatum* from culture. The use of several specimens (sputum, bronchoalveolar lavage, skin lesions, blood, bone marrow, or liver) for culture will increase the yield. Culture is highly specific but is limited by slow growth, and plates must be kept for as long as 12 weeks. Blood culture using the lysis-centrifugation system is more rapid and increases sensitivity. Histopathology is also more rapid, but its sensitivity is $<50\%$ in patients with disseminated disease, and even lower in pulmonary histoplasmosis. Biopsy specimens may demonstrate the distinctive 2–4-micrometer oval, narrow-based budding yeasts of *H. capsulatum*. Serological tests are rapid but may be falsely negative in immunosuppressed patients, and during the first 2 months following exposure while antibodies are still developing. In addition, elevated antibody titres persist for several years following initial infection. Antigen detection is a rapid means of diagnosis and can be useful in individuals who are immunocompromised when antibody production may be impaired. Sensitivity is greater with urine and plasma compared with other body fluids. Antigen quantitation enables treatment response to be monitored.

In disseminated disease, general laboratory tests will reveal a pancytopenia, hyperbilirubinemia, elevated liver enzyme and serum lactate dehydrogenase levels.

Histoplasmosis: up-to-date evidence-based approach to diagnosis and management. Hage CA, Azar MM, Bahr N, et al. *Semin Respir Crit Care Med* 2015; 36(5): 729–45.

This is a comprehensive and up-to-date review. Liposomal AmB is recommended for more severe cases and itraconazole for milder cases and ‘step-down’ therapy following response to AmB.

Histoplasmosis complicating tumor necrosis factor- α blocker therapy: a retrospective analysis of 98 cases. Vergidis P, Avery RK, Wheat LJ, et al. *Clin Infect Dis* 2015; 61(3): 409–17.

Disseminated histoplasmosis is a potential complication of anti-TNF- α therapy. This is a multicenter retrospective review of 98 patients diagnosed with histoplasmosis between 2000 and 2011. The most commonly used biologic agent was infliximab (67.3%). Based on these data the authors recommend that antifungal therapy is administered for at least 12 months. Thereafter resumption of TNF- α blocker therapy appears safe. They also conclude that disease outcomes were generally favorable.

HIV-associated histoplasmosis: current perspectives. Myint T, Leedy N, Cari EV, et al. *HIV AIDS* 2020; 12: 113–25.

This review outlines the impact of HIV on the prevalence and clinical manifestations of histoplasmosis. It assesses the clinical trial data of drug therapies for histoplasmosis in HIV-infected individuals. It recommends that liposomal AmB is given for 1–2 weeks followed by itraconazole for at least 1 year until CD4 counts are above 150 cells/mm³, HIV viral load is below 400 copies/mL, and *Histoplasma* urine antigen is negative. Serum itraconazole level should be monitored to avoid drug toxicity. Antigen should be measured periodically to establish that treatment is effective and to assist in identifying relapse. IRIS should be considered in patients failing antifungal treatment.

Treating progressive disseminated histoplasmosis in people living with HIV. Murray M, Hine P. *Cochrane Database Syst Rev* 2020; 4(4): CD013594.

This review concluded that liposomal AmB was a better choice compared with deoxycholate AmB for treating disseminated histoplasmosis in people with HIV. They concluded that fluconazole performed poorly compared with other azoles.

First-Line Therapies

• Amphotericin B	B
• Itraconazole	B

Disseminated histoplasmosis in patients with AIDS in Panama: a review of 104 cases. Gutierrez ME, Canton A, Sosa N, et al. *Clin Infect Dis* 2005; 40(8): 1199–1202.

In this study from Panama, the authors report that prior to the spread of AIDS, disseminated histoplasmosis was rarely seen. Now it is often the first manifestation of AIDS in this region, and must be suspected in anyone with fever, respiratory symptoms, weight loss, diarrhea, and a CD4 cell count <100 cells/microliter. Of 104 patients with AIDS-related disseminated histoplasmosis, 100 (96%) received AmB deoxycholate induction therapy, most receiving 1 g in total before being switched over to oral itraconazole. Forty patients had therapy-related adverse effects with hypokalemia reported in 50% and an increased creatinine level in 43%.

Itraconazole therapy for blastomycosis and histoplasmosis.

NIAID Mycoses Study Group; Dismukes WE, Bradsher RW Jr, Cloud GC, et al. *Am J Med* 1992; 93(5): 489–97.

This was a prospective, non-randomized, multicenter open trial where 37 patients with histoplasmosis received itraconazole 200–400 mg daily. After a median treatment period of 9 months, 81% ($n=30$) were cured. Treatment failure occurred only in those patients with chronic cavitary pulmonary disease. Minor adverse effects were experienced in 29% ($n=25$), requiring therapy withdrawal in only one patient.

Itraconazole treatment of disseminated histoplasmosis in patients with the acquired immunodeficiency syndrome. AIDS Clinical Trial Group; Wheat J, Hafner R, Korzun AH, et al. *Am J Med* 1995; 98: 336–42.

A multicenter, non-randomized prospective trial. Itraconazole 300 mg twice daily for 3 days followed by 200 mg twice daily was given for 12 weeks. Evaluation of 59 patients showed that 50 (85%) responded well to therapy. Five withdrew from the study because of progressive infection. One died within the first week of therapy, and two withdrew because of itraconazole-related adverse effects. Resolution of systemic symptoms occurred after a median of 3 weeks in the less severely affected, and 6 weeks in the moderately severe cases. Fungemia cleared after a median period of 1 week.

Itraconazole demonstrates efficacy in the treatment of mild disseminated histoplasmosis in patients with AIDS. For patients with moderately severe or severe histoplasmosis, AmB is the drug of first choice, which can be switched to itraconazole after clinical improvement.

Safety and efficacy of liposomal amphotericin B compared with conventional amphotericin B for induction therapy of histoplasmosis in patients with AIDS. Johnson PC, Wheat LJ, Cloud GA, et al; US National Institute of Allergy and Infectious Diseases Mycoses Study Group. *Ann Intern Med* 2002; 137: 105–9.

A multicenter, randomized, controlled trial compared AmB deoxycholate with liposomal AmB for induction therapy of moderate-to-severe disseminated histoplasmosis in patients with AIDS. The trial demonstrated a higher response rate (88% vs. 64%) and lower mortality rate (2% vs. 13%) in patients who were treated with liposomal amphotericin ($n=51$) than with AmB deoxycholate ($n=22$). Infusion-related side effects were greater with AmB deoxycholate (63%) than with liposomal AmB (25%) ($p=0.002$). Nephrotoxicity was also higher with AmB deoxycholate (37%) than with liposomal AmB (9%) ($p=0.003$).

This study demonstrated that liposomal amphotericin is associated with higher efficacy, lower mortality, and better tolerance during induction treatment of disseminated histoplasmosis.

Safety of discontinuation of maintenance therapy for disseminated histoplasmosis after immunologic response to antiretroviral therapy. Goldman M, Zackin R, Fichtenbaum CJ, et al; AIDS Clinical Trials Group A5038 Study Group. *Clin Infect Dis* 2004; 38: 1485–9.

Traditionally, lifelong maintenance therapy with itraconazole had been the standard of care to reduce the risk of relapse of histoplasmosis infection. This was a prospective observational study to assess the safety of stopping maintenance therapy for disseminated histoplasmosis in patients with HIV infection after treatment with antiretroviral therapy. The study concluded that discontinuation of antifungal therapy after 12 months appears to be safe in patients with previously treated disseminated histoplasmosis that have sustained immunological improvement with antiretroviral therapy.

Disseminated histoplasmosis: a comparative study between patients with acquired immunodeficiency syndrome and non-human immunodeficiency virus-infected individuals. Tobón AM, Agudelo CA, Rosero DS, et al. *Am J Trop Med Hyg* 2005; 73(3): 576–82.

In this study of 52 patients with disseminated histoplasmosis, 30 patients had AIDS. Skin lesions were significantly higher in patients with AIDS, occurring in 53% of them ($p=0.001$). *H. capsulatum* was isolated more often in AIDS patients ($p<0.05$), but antibodies to *H. capsulatum* were detected more frequently in non-HIV patients ($p<0.05$). Itraconazole treatment was less effective in AIDS patients ($p=0.012$), but in this group, too, HAART improved the response to antifungals when compared with individuals who were not given HAART ($p=0.003$), who exhibited higher mortality rates ($p=0.025$). These results indicate the need to promote restoration of the immune system in patients with AIDS and histoplasmosis.

The authors highlight that the skin constitutes a more important target organ for *H. capsulatum* in HIV-infected Latin American patients than in HIV-infected North American patients.

Literature review and case histories of *Histoplasma capsulatum* var. *duboisii* infections in HIV-infected patients. Loulergue P, Bastides F, Baudouin V, et al. *Emerg Infect Dis* 2007; 13(11): 1647–52.

African histoplasmosis caused by *Histoplasma capsulatum* var. *duboisii* is much rarer than histoplasmosis caused by variety *capsulatum*, and its association with HIV infection is rarely reported. This article reports three such cases and reviews the literature on similar cases. All cases were successfully treated, initially with AmB, which was subsequently switched to itraconazole. Conventional amphotericin was given at a dose of 1 mg/kg daily (total dose of 1200 mg) and liposomal amphotericin at 3 mg/kg daily (for 1 month). Itraconazole was commenced at a dose of 400 mg daily (for 1–2 years) and switched to a maintenance dose of 200 mg daily after clinical cure. No clinical trials or efficacy studies have been performed for African histoplasmosis, and therefore its treatment is usually extrapolated from the guidelines of the Infectious Diseases Society of America established for histoplasmosis due to variety *capsulatum*.

Disseminated primary cutaneous histoplasmosis successfully treated with itraconazole. Singhi MK, Gupta L, Kachawa D, et al. *Indian J Dermatol Venereol Leprol* 2003; 69(6): 405–7.

Primary cutaneous histoplasmosis is rare. This is a report of a case of disseminated primary cutaneous histoplasmosis caused by *H. capsulatum* in an immunocompetent patient. The patient presented with a 2-year history of progressive erythematous nodules and plaques distributed mainly over the trunk. There was no evidence of systemic involvement. There was an excellent response to itraconazole 100 mg BD. Lesions began improving within 4 weeks and cleared within 16 weeks, and the total treatment period was 24 weeks. There was no recurrence 6 months after cessation of treatment.

Second-Line Therapies

• Ketoconazole	B
• Fluconazole	B
• Posaconazole	D
• Voriconazole	D
• Isavuconazole	E

Treatment of blastomycosis and histoplasmosis with ketoconazole. Results of a prospective randomized clinical trial. Dismukes WE, Cloud G, Bowles C and the National Institute of Allergy and Infectious Diseases Mycoses Study Group. *Ann Intern Med* 1985; 103(6 Pt 1): 861–72.

This was a multicenter, prospective, randomized trial evaluating the efficacy and toxicity of low-dose (400 mg/day) and high-dose (800 mg/day) oral ketoconazole in the treatment of histoplasmosis. Among 19 patients with chronic cavitary histoplasmosis treated for 6 months or more, both regimens were equally effective (overall success rate, 84%). In 20 patients with localized or disseminated histoplasmosis treated for 6 months or more, low-dose treatment was more effective (100% vs. 57% success rate, $p=0.03$). The success rate for all patients with histoplasmosis treated for 6 months or more was 85%. Adverse effects occurred in 60% of patients, and were commoner with the high-dose regimen. Ketoconazole is effective for non-life-threatening histoplasmosis in immunocompetent patients. Because of the higher frequency of side effects associated with the high dose, the authors suggested that ketoconazole therapy should be initiated at the lower dose.

With the availability of better-tolerated and new generation azoles, there are no recent studies evaluating ketoconazole therapy for histoplasmosis. However, it is still a drug that is commonly used in endemic settings, because of its availability and low cost.

Fluconazole therapy for histoplasmosis. The National Institute of Allergy and Infectious Diseases Mycoses Study Group. McKinsey DS, Kauffman CA, Pappas PG, et al. *Clin Infect Dis* 1996; 23(5): 996–1001.

Of the 27 patients enrolled in this trial, two had acute pulmonary histoplasmosis, 11 had chronic pulmonary histoplasmosis, and 14 had disseminated histoplasmosis. Twenty patients received fluconazole 400–800 mg/day, and seven patients received fluconazole 200 mg daily. Successful treatment was reported in 17 patients (63%). There were no significant adverse effects. The authors concluded that fluconazole was only moderately effective and should be reserved for patients intolerant to itraconazole.

Treatment of histoplasmosis with fluconazole in patients with acquired immunodeficiency syndrome. National Institute of Allergy and Infectious Diseases, Acquired Immunodeficiency Syndrome Clinical Trials Group and Mycoses Study Group. Wheat J, MaWhinney S, Hafner R, et al. *Am J Med* 1997; 103: 223–32.

This was a multicenter, open-label, non-randomized prospective trial. The aim of the study was to assess the efficacy and safety of fluconazole in patients with AIDS and mild-to-moderate disseminated histoplasmosis. The initial protocol of fluconazole 1200 mg on day one followed by 600 mg daily for 8 weeks demonstrated a high failure rate of 50%. The therapy schedule was revised to 1600 mg on day 1 followed by 800 mg daily for 12 weeks, and then maintenance therapy with 400 mg daily for at least 1 year. Seven patients failed to respond to induction therapy with progression of histoplasmosis leading to death in one patient. Two withdrew due to liver toxicity. Seventy-three percent (36/49 patients) responded but 30.5% (11/36) subsequently relapsed and one died. On the basis of historical comparison, maintenance therapy to prevent relapse with fluconazole 400 mg daily was less effective than itraconazole 200–400 mg daily or AmB 50 mg weekly.

Fluconazole may have a role in the treatment of non-AIDS-related histoplasmosis. However, this study of AIDS-related infection demonstrated a comparatively poor efficacy rate with even high-dose

fluconazole induction therapy, and an unacceptably high relapse rate with maintenance therapy.

Salvage treatment of histoplasmosis with posaconazole. Restrepo A, Tobón A, Clark B, et al. *J Infect* 2007; 54(4): 319–27.

Six patients with severe histoplasmosis infection were successfully treated with oral posaconazole (800 mg/day in divided doses) having previously failed on AmB, itraconazole, fluconazole, or voriconazole. One patient had pulmonary disease and the rest had disseminated infection. Treatment duration ranged from 6 to 34 weeks. Significant clinical improvement was noted within the first month of treatment.

Although the patient numbers are small, this study suggests that posaconazole may be a useful treatment option for disseminated histoplasmosis refractory to other drug therapies

Voriconazole use for endemic fungal infections. Freifeld A, Proia L, Andes D, et al. *Antimicrob Agents Chemother* 2009; 53(4): 1648–51.

Nine patients with mostly disseminated histoplasmosis who had either failed or were intolerant of AmB and itraconazole were treated with voriconazole 200–400 mg daily. All of them improved or remained clinically stable after treatment and responses were apparent within the first 2 months of voriconazole initiation. However, two of the patients whose response was 'stable' had to discontinue treatment because of high costs of treatment. The others received treatment from 31 to 640 days.

HIV-associated disseminated histoplasmosis successfully treated with isavuconazole consolidation therapy. Mazzella A, Stone NRH, Pool ERM, et al. *Med Mycol Case Rep* 2019; 27: 42–3.

A 30-year-old man with advanced HIV and disseminated histoplasmosis deteriorated after stepping down from intravenous liposomal AmB to itraconazole. Liposomal AmB was reintroduced and step-down treatment was successfully switched to oral isavuconazole 200 mg daily given as long-term maintenance treatment.

Isavuconazole, one of the new antifungal azoles, has a broader pathogen spectrum and is increasingly being used in fungal infections refractory to other antifungals.

Clinical practice guidelines for the management of patients with histoplasmosis: 2007 update by the Infectious Diseases Society of America. Wheat LJ, Freifeld AG, Kleiman MB, et al.; Infectious Diseases Society of America. *Clin Infect Dis* 2007; 45(7): 807–25.

Evidence-based guidelines for the management of patients with histoplasmosis.

Mild Acute Pulmonary Histoplasmosis

Treatment is usually unnecessary unless symptoms persist for more than 1 month, when itraconazole is given at a loading dose

(200 mg three times daily for 3 days) followed by 200 mg once or twice daily for 6–12 weeks.

Severe Acute Pulmonary Histoplasmosis

Parenteral AmB (deoxycholate formulation, 0.7–1.0 mg/kg daily, or lipid formulation, 3.0–5.0 mg/kg daily) for 1–2 weeks followed by 'step-down' itraconazole therapy, with an initial loading dose and then 200 mg twice daily for a total of 12 weeks.

Chronic Cavitary Pulmonary Histoplasmosis

Itraconazole, initial loading dose and then 200 mg once or twice daily for at least 12 months.

Mild Disseminated Histoplasmosis

Itraconazole, initial loading dose and then 200 mg twice daily for at least 12 months.

Severe Disseminated Histoplasmosis

AmB (doses as above for severe pulmonary infection) for 1–2 weeks followed by oral itraconazole, initial loading dose and then 200 mg twice daily for at least 12 months.

Central Nervous System Histoplasmosis

Liposomal AmB (5.0 mg/kg daily for a total of 175 mg/kg given over 4–6 weeks) followed by itraconazole 200 mg two or three times daily for at least 1 year and until resolution of cerebrospinal fluid (CSF) abnormalities, including *Histoplasma* antigen levels.

Treatment of Histoplasmosis in Pregnancy

Azoles are teratogenic and therefore AmB is recommended.

Immunosuppressed patients may require lifelong suppressive therapy with itraconazole (200 mg daily) if immunosuppression cannot be reversed. For those on long-term itraconazole therapy, blood itraconazole levels need to be measured 2 weeks after initiation of treatment. Women of childbearing age who are being treated with azoles need to use effective contraception during treatment and for 2 months after the drug is stopped.

An official American Thoracic Society statement: treatment of fungal infections in adult pulmonary and critical care patients. Limper AH, Knox KS, Sarosi GA, et al.; American Thoracic Society Fungal Working Group. *Am J Respir Crit Care Med* 2011; 183(1): 96–128.

The American Thoracic Society convened a working group of experts in fungal infections to develop a concise clinical statement of current therapeutic options. The document discusses drug therapy for the different manifestations of histoplasmosis including asymptomatic as well as symptomatic lung disease in immunocompetent hosts and disease in immunocompromised hosts.

Hydroa vacciniforme

Hiva Fassihi, Robert P.E. Sarkany

Hydroa vacciniforme (HV) is a photosensitive dermatosis mainly found in children. It is rare in Europe and the United States, and more common in Asia and South America. It is one of the group of diseases caused by chronic active Epstein-Barr virus (EBV) infection. It is now grouped within the spectrum of diseases known as 'HV EBV-associated lymphoproliferative disorder' (HV EBV-associated LPD).

MANAGEMENT STRATEGY

Onset is generally in childhood between the ages of 5 and 8 years. It is characterized by sun exposure-induced eruptions of vesicular, bullous, and pustular lesions that leave scarring. Lesions develop a few hours after sun exposure, with itchy erythema, progressing over a few days to painful papules and then umbilicated vesicles that crust, and heal with scarring. The cheeks, ears, nose, and dorsum of the hands are the most commonly affected sites. Eye involvement is rare.

Differential diagnosis includes vesicular polymorphic light eruption, actinic prurigo, bullous photosensitive lupus erythematosus, and erythropoietic protoporphyria. However, HV differs from all these conditions, and the clinical diagnosis is usually clear cut.

The photosensitivity and scarring may be severe with a major impact on quality of life.

The rarity of HV explains the lack of large or randomized trials. Recommendations for treatment are based on evidence from case series and single case reports.

Photoprotection is crucial in this disease, which is resistant to specific treatments in most patients. Key measures include restriction of sun exposure, wearing ultraviolet (UV)-protective clothing, regular application of a broad-spectrum sunscreen containing an effective UVA filter, and covering windows in the car and home with films that filter out UV wavelengths below 380 nm.

In patients with the most severe photosensitivity, courses of narrowband UVB (NB-UVB) phototherapy or psoralen with UVA (PUVA) (usually twice weekly for 4–6 weeks as administered for polymorphic light eruption) may help. Phototherapy must be given cautiously to avoid provoking a flare.

More recently *antivirals* have been considered in view of the causative role of EB virus. A small case series has suggested that this may reduce photosensitivity, but the experience of the authors (HF and RS) is less positive.

Antimicrobial therapy has been tried, as have *antimalarials*. Systemic immunosuppressants (intermittent oral corticosteroids, azathioprine, and ciclosporin) have been tried in HV; however, none are reliably effective, and we do not recommend their use since they may be hazardous in chronic active EB virus infection. *β-Carotene*, used in several studies, has mostly been ineffective.

Dietary fish oil rich in omega-3 polyunsaturated fatty acids was associated with clinical improvement in a small number of patients in four older reports.

All HV is caused by chronic active EBV infection of NK or $\gamma\delta$ -T cells. HV is now grouped within the spectrum of diseases known as "HV EBV-associated lymphoproliferative disorders" (HV-LPD).

The higher incidence of HV-LPD in Asia and South America reflects the higher incidence of chronic active EBV infection (CAEBV) of T- and NK-cell types in these populations.

CAEBV infection of NK or $\gamma\delta$ -T cells causes a spectrum of severe lymphoproliferative diseases. The only diseases involving the skin are the 'hypersensitivity to mosquito bites' syndrome and 'classic' and 'severe' HV.

'Severe' HV has a similar eruption to 'classic' HV, but involvement of non-exposed skin, facial edema, and deep ulceration are common, and some patients develop 'hypersensitivity to mosquito bites' (necrotic and systemic reactions to insect bites). 'Severe' HV is a systemic illness with a bad prognosis, usually requiring treatment with allogeneic bone marrow transplantation.

The major determinant of prognosis is ethnicity. White children from the United States and Europe are unlikely to progress from 'classic' HV to 'severe' HV. Asian and Hispanic patients are likely to develop the severe disease with systemic involvement.

All patients with HV should be reviewed at least every 6 months for systemic involvement.

HV patients should be managed jointly with an infectious disease or haemato-oncology specialist. If that is not possible, they must be referred to such a specialist if any features are identified, suggesting possible transformation from 'classic HV' to a less benign EBV-associated disorder.

Specific Investigations at Presentation

- Monochromator phototesting and photoprovocation testing with UVA (*increased sensitivity to UVA in half the patients*)
 - Serological testing for antinuclear antibody and antibodies to extractable nuclear antigens (*to exclude bullous lupus erythematosus*)
 - Red cell porphyrin measurement (*to exclude erythropoietic protoporphyria*)
 - EBV viral load measurement from whole blood
- Skin biopsy is not usually required

Table 108.1 Prognostic assessment

Clinical variant's name	Cause	Incidence	Clinical features	Key predisposing factor	Prognosis	Treatment
Classic HV	Chronic active EBV infection of NK or $\gamma\delta$ -T cells	Rare: United States and Europe	Childhood presentation: photosensitive eruption (no systemic involvement)	Ethnicity: White children from United States and Europe	Good: general health unaffected. Often resolves by early adulthood	Treatment of photosensitivity
Severe HV	Chronic active EBV infection of NK or $\gamma\delta$ -T cells	Common: mainly Asia and Latin America	Childhood presentation: photosensitive eruption + • non-exposed skin affected • facial edema • deep ulceration • 'hypersensitivity to mosquito bites' (necrotic and systemic reactions to insect bites) • systemic features: • persistent fever • weight loss • lymphadenopathy • hepatosplenomegaly • hepatitis • leukopenia	Ethnicity: Asian and Hispanic patients	Poor: life-threatening systemic illness	Allogeneic bone marrow transplantation

Table 108.2 HV: 6-monthly review for systemic involvement**Ask about:**

- Severe cutaneous or systemic reactions to insect bites
- Persistent unexplained fever
- Unexplained weight loss
- Other unexplained health problems

Examine for:

- Facial swelling
- Skin ulcers
- Involvement of non-exposed skin
- Pyrexia
- Lymphadenopathy
- Hepatosplenomegaly

Investigations:

- EB viral load in blood (looking for significant upward trend)
- Full blood count: for leukopenia or other abnormality
- Abdominal ultrasound scan: once every 3 years (looking for hepatosplenomegaly)

Epstein-Barr virus-associated T- and NK-cell lymphoproliferative diseases: an update and diagnostic approach. Hue SS, Oon ML, Wang S, et al. *Pathology* 2020; 52: 111–27.

A review discussing the range of EBV-associated T- and NK-cell lymphoproliferative disorders. 'Hypersensitivity to mosquito bites' is classified with HV-LPD in the 'indolent/variable outcome group'.

Chronic EBV infection of T and NK cells also causes 'EBV-associated hemophagocytic lymphohistiocytosis' (with life-threatening immunological hyperactivation), leukemias, and lymphomas.

EBV involvement in the pathogenesis of hydroa vacciniforme: an assessment of seven adult patients with long-term follow-up. Verneuil L, Gouarin S, Comoz E, et al. *Br J Dermatol* 2010; 163: 174–82.

Chronic active EBV infection was present in and persisted long term in adult HV patients.

Hydroa vacciniforme is associated with increased numbers of EBV-infected $\gamma\delta$ T cells. Hirai Y, Yamamoto T, Kimura H, et al. *J Invest Dermatol* 2012; 132: 1401–8.

All 29 HV patients had raised levels of EBV DNA in peripheral blood mononuclear cells. Of 33 biopsied skin lesions, 31 contained EBER+ T cells.

Hydroa vacciniforme: a review of ten cases. Sonnex TS, Hawk JL. *Br J Dermatol* 1988; 118: 101–8.

A study of 10 White children in England. The disease resolved in two patients (mean disease duration 12 years) and slowly improved in another two. None developed systemic ill health.

Hydroa vacciniforme: a clinical and follow-up study of 17 cases. Gupta G, Man I, Kemmett D. *J Am Acad Dermatol* 2000; 42: 208–13.

A study of 17 White children with HV in Scotland. Spontaneous remission occurred in nine of the 17 patients after a mean period of 9 years. Disease prevalence in the Scottish population was estimated at 0.34/100,000.

Hydroa vacciniforme-like lymphoproliferative disorder: an EBV disease with a low risk of systemic illness in whites. Cohen JL, Manoli I, Dowdell K, et al. *Blood* 2019; 133: 2753–64.

Accompanying commentary: deciphering hydroa vacciniforme. Quintanilla-Martinez L, Fend F. *Blood* 2019; 133: 2735–37.

A study of 16 patients, 10 with 'classic' HV and six with 'severe' HV. All 16 had very high blood levels of EBV DNA in blood. Ethnicity correlated with disease severity. All 10 White patients were in good health at the end of follow-up, whereas four of the six non-White patients (Asian or Hispanic) had been treated with hematopoietic stem cell transplantation for severe systemic disease and persistent fever (accompanied by lymphoma in two patients).

This study explains the difference between cases of HV reported in Europe and in Asia/South America. Ethnic differences among patients determine whether chronic active EBV infection of T and NK cells causes the benign photodermatosis 'classic HV' or the severe systemic illness 'severe HV'. The features associated with the poor prognosis and systemic involvement of severe HV are reinforced.

Hydroa vacciniforme: a review of ten cases. Sonnex TS, Hawk JLM. *Br J Dermatol* 1988; 118: 101–8.

Monochromator phototesting responses were abnormal in three of the 10 patients with increased photosensitivity to UVA.

Hydroa vacciniforme: a clinical and follow-up study of 17 cases. Gupta G, Man I, Kemmett D. *J Am Acad Dermatol* 2000; 42: 208–13.

Nine of the 17 patients showed increased sensitivity to UVA on monochromator phototesting.

Action spectrum for UV erythema and reproduction of the skin lesions in hydroa vacciniforme. Sunohara A, et al. *Photodermatol* 1988; 5: 139–45.

Vesicles were successfully reproduced by repeated daily monochromatic irradiations of 330, 340, 350, and 360 nm for 5, 6, or 7 days in four HV patients.

First-Line Therapy for Photosensitivity

- High-factor, broad-spectrum sunscreens and behavioral sunlight avoidance

C

Hydroa vacciniforme: a clinical and follow-up study of 17 cases. Gupta G, Man I, Kemmett D. *J Am Acad Dermatol* 2000; 42: 208–13.

In 9 of 15 patients the disease was controlled satisfactorily with high-factor, broad-spectrum sunscreens and sunlight avoidance.

Hydroa vacciniforme: a review of ten cases. Sonnex TS, Hawk JLM. *Br J Dermatol* 1988; 118: 101–8.

Disease severity was reduced in 8 of 10 patients using either Coppertone Supershade 15 or RoC factor 10.

The sunscreens described do not meet current standards. Modern sunscreens now offer broad-spectrum protection against UVB and UVA.

Borrowing from museums and industry: two photo-protective devices. Dawe R, Russell S, Ferguson J. *Br J Dermatol* 1996; 135: 1016–7.

The Museum 200 Film (manufactured by Sun Guard, Florida, United States) prevents transmission of all wavelengths less than 380 nm. This clear, lightweight film can be stuck on any glass surface without being visible. It may be useful in HV but will be less helpful in patients sensitive in the 380–400 nm waveband.

Second-Line Therapies for Photosensitivity

- NB-UVB phototherapy (TL-01)
- PUVA
- Aciclovir/valaciclovir

C

D

D

Hydroa vacciniforme: a clinical and follow-up study of 17 cases. Gupta G, Man I, Kemmett D. *J Am Acad Dermatol* 2000; 42: 208–13.

Five patients who had not responded to photoprotective measures were treated with NB-UVB phototherapy: three had good or moderate disease control, and two had no response.

Hydroa vacciniforme: a review of ten cases. Sonnex TS, Hawk JLM. *Br J Dermatol* 1988; 118: 101–8.

Two of the 10 patients were treated with UVB and had improvement of their disease. There was a flare in the one patient treated with PUVA.

Broadband UVB was probably used in this report, though the methodology is unclear.

Narrow-band UVB (TL-01) phototherapy: an effective preventative treatment for the photodermatoses. Collins P, Ferguson J. *Br J Dermatol* 1995; 132: 956–63.

An open clinical trial of a standard regimen of narrowband UVB desensitization. Two of four HV patients reported an increase in tolerance to sunshine from 1 hour to 3–6 hours.

Antiviral therapy in children with hydroa vacciniforme. Lysell J, Wiegleb Edström D, Linde A, et al. *Acta Derm Venereol* 2009; 89: 393–7.

Four children with HV were treated with aciclovir and one also treated with valaciclovir therapy. All four reported improvement in photosensitivity, although one developed EBV-related lymphoma during treatment.

Antiviral treatment of a boy with EBV-associated hydroa vacciniforme. Pahlow Mose A, Fisker N, Clemmensen O, et al. *BMJ Case Rep* 2014. doi: 10.1136/bcr-2014-206488.

Marked improvement of EBV-associated HV photosensitivity reported in a 6-year-old boy treated initially with aciclovir, followed by valaciclovir.

The personal (unpublished) experience of the authors (HF and RS) of antiviral therapy in four patients with HV is less favorable.

Third-Line Therapies for Photosensitivity

- Antimalarials
- β -Carotene
- Dietary fish oil
- Antiinflammatory agents

D

E

E

E

Hydroa vacciniforme: diagnosis and therapy. Goldgeier MH, Nordlund JJ, Lucky AW, et al. *Arch Dermatol* 1982; 118: 588–91.

Treatment with hydroxychloroquine sulfate, but not indomethacin, reduced photosensitivity to sunlight and to artificial UV-A irradiation in one patient.

Hydroa vacciniforme: an unusual clinical manifestation. Leenutaphong V. *J Am Acad Dermatol* 1991; 25: 892–5.

One patient treated with chloroquine phosphate 500 mg daily did not find it helpful.

Hydroa vacciniforme. Ketterer R, Morier P, Frenk E. *Dermatology* 1994; 189: 428–9.

One patient treated with chloroquine 100 mg daily and broad-spectrum sunscreen showed good disease control.

It is unclear whether the response was due to chloroquine or the sunscreen.

Hydroa vacciniforme. Bickers DR, Demar LK, DeLeo V, et al. *Arch Dermatol* 1978; 114: 1193–6.

Two patients reported an improvement of the skin disease with β -carotene 180 mg daily.

Hydroa vacciniforme: induction of lesions with ultraviolet A. Halasz CLG, Leach EE, Walther RR, et al. *J Am Acad Dermatol* 1983; 8: 171–6.

One patient treated with β -carotene 180 mg daily reported subjective improvement of skin disease.

Hydroa vacciniforme: diagnosis and therapy. Goldgeier MH, Nordlund JJ, Lucky AW, et al. *Arch Dermatol* 1982; 118: 588–91.

β -Carotene 120 mg daily for 2 months in one patient was ineffective.

Hydroa vacciniforme treated by a combination of beta-carotene and canthaxanthin. Bruderer P, Shahabpour M, Christoffersen S, et al. *Dermatology* 1995; 190: 343–5.

One patient reported improvement with carotenoids (10 mg of β -carotene and 15 mg of canthaxanthin).

Efficacy of ω -3 polyunsaturated fatty acids for the treatment of refractory HV. Durbec F, Reguiai Z, Léonard F, et al. *Pediatr Dermatol* 2012; 29: 118–9.

One patient was successfully treated with dietary fish oil after unsuccessful treatment with other measures.

Dietary fish oil as a photoprotective agent in hydroa vacciniforme. Rhodes LE, White SI. *Br J Dermatol* 1998; 138: 173–8.

Three patients were treated with dietary fish oil, five capsules daily, for 3 months. A mild-to-good improvement was reported in two patients, but no improvement in the third.

Hydroa vacciniforme: dietary fish oil. Modeste AB, Cordel N, Balguerie X, et al. *Ann Dermatol Venereol* 2001; 128: 247–9.

A 15-year-old girl unresponsive to antimalarial drugs and photoprotection was treated with Maxepa and her skin lesions regressed within a few weeks. The treatment was stopped at the patient's request due to fetid breath.

Fish oil rich in omega-3 polyunsaturated fatty acids are thought to reduce inflammation by increasing the level of omega-3 polyunsaturated fatty acids in the epidermis and reducing the level of prostaglandins in the skin.

Two cases of hydroa vacciniforme-like lymphoproliferative disease controlled by anti-inflammatory agents. Kim YJ, Choi SY, Lee WJ, et al. *Photodermatol Photoimmunol Photomed* 2017; 33: 287–90.

One patient treated with sunscreen and minocycline 50 mg twice daily for 6 months reported improvement in skin lesions. A second patient treated with topical pimecrolimus cream 1% twice daily and sunscreen reported improvement after 3 months.

Hyperhidrosis

Michael E. Farrugia, Gina M. Kavanagh

Hyperhidrosis is a condition characterized by abnormally increased perspiration, beyond that required for thermoregulation. It may indicate an underlying medical disorder, but more commonly it is idiopathic and results in significant deterioration in quality of life, psychologically and socially. Sufferers typically describe the condition as highly embarrassing and frustrating.

Primary hyperhidrosis is idiopathic and is the more common form, affecting 90% of sufferers. It is typically localized to specific body areas, bilateral and symmetrical. One patient may have multiple focal areas affected. It tends to worsen with stress and heat (including local occlusion). Onset typically occurs in puberty and a family history of the condition is present in some 60% of cases. Hyperhidrosis does not usually occur during sleep, and further investigation is usually not necessary. The most commonly affected site is the axilla, followed by the palms and soles (the latter often complicated by bromhidrosis). Craniofacial involvement is seen more commonly in postmenopausal women. Other sites include the groin, buttocks, and inter- and inframammary folds. Stump amputee focal hyperhidrosis is largely due to inability of sweat to evaporate through the prosthesis silicone lining and can make wearing of prosthetic limbs very difficult.

Secondary hyperhidrosis may be generalized or localized and is less common, affecting 10% of sufferers. See [Table 109.1](#) for some causes of secondary hyperhidrosis.

MANAGEMENT STRATEGY

The treatments discussed here apply to primary idiopathic hyperhidrosis. Therapy for secondary hyperhidrosis should be directed

toward the underlying condition. Simple conservative measures can be advocated as an adjunct to treatment:

- Acknowledging what a difficult condition this can be is often validating
- Inform the patient about support groups such as *Hyperhidrosisuk.org* or *SweatHelp.org*
- Provide advice regarding practical measures such as:
 - wear absorbent underlayers such as loose-fitting cotton T-shirts
 - use adhesive underarm pads or absorbent insoles
 - wear cotton socks with leather shoes and, if necessary, change socks and shoes throughout the day

The evidence on all of the following treatments is of limited quality and predominantly comprises small, non-randomized, retrospective, observational studies and case series with a high risk of bias. Nevertheless, many patients respond well to available treatments and current recommendations are based on expert consensus. Plantar hyperhidrosis, as well as inframammary, groin, and buttock hyperhidrosis, may be complicated by secondary bacterial and fungal overgrowth and may require additional topical treatment.

Topical aluminum chlorohydrate ($Al_2Cl(OH)_6$) *antiperspirants* are the first-line treatment. Aluminum-based complexes react with the electrolytes in sweat to form a gel plug causing a functional inability of the gland to produce sweat. Correct application technique is crucial: in the axillae, the solution should be applied at night to unshaven skin and washed off the next morning before daytime sweating is established. The skin must be dry during application as the presence of moisture results in hydrochloric acid formation and skin irritation. To prevent this, the skin should be gently dabbed dry or blow-dried. Mild-potency topical corticosteroids may be used to reduce the common problem of skin irritation, which is the usual reason for treatment failure. Application of yellow soft paraffin to axillary margins can also minimize irritation. Hyperhidrosis may take 2–3 weeks to be controlled with aluminum chlorohydrate, at which time application can be reduced to once or twice a week, or any interval that maintains control. Formulas with concentrations of 15%–20% are commercially available and used for most areas of the body, although concentrations of 20%–40% are typically used for the soles of the feet.

Iontophoresis is a process of transdermal delivery of an ionized substance (typically sodium) through intact skin using a voltage gradient. It is predominantly reserved for palmoplantar hyperhidrosis. Several iontophoretic devices are commercially available and patients typically need to purchase them. Plug-in variants are superior to battery-operated ones. It is cost-effective in the long term. Cheap homemade variants are increasingly becoming popular, but their efficacy is not validated.

The precise mechanism through which sweating is reduced is unknown given that the current densities employed are below the threshold known to cause damage to the acrosyngium, as well as the fact that mechanical obstruction does not occur. Iontophoresis is contraindicated in patients with cardiac pacemakers or defibrillators and metal implants, as well as in pregnancy.

A direct current is transmitted to electrodes in two trays filled with hard tap water (or soft water with an added teaspoon of sodium bicarbonate/baking soda per tray), and the hands or feet are placed flat in the bottom of the trays. The current is increased until the patient experiences slight discomfort (typically 15 mA for the palms and 20 mA for the soles). Three sessions a week of 20–30 min each are continued for approximately 6 weeks until sweating is sufficiently reduced; thereafter, the frequency can be dropped to once weekly as maintenance. Treatments need to be

Table 109.1 Causes of secondary hyperhidrosis

Endocrine	Diabetes mellitus, hyperthyroidism, hyperpituitarism, hypoglycemia, pheochromocytoma, pregnancy, menopause
Febrile infections	Tuberculosis, malaria, subacute bacterial endocarditis
Malignancy	Lymphoma (night sweats), carcinoid syndrome, pheochromocytoma
Autonomic	Diabetic neuropathy, paraplegia, syringomyelia, stroke, shock
Neurological	Parkinson disease
Drugs	SSRIs, e.g., fluoxetine, opioid withdrawal
Gustatory	Frey syndrome
Hereditary	Chediak–Higashi syndrome, phenylketonuria, blue rubber bleb nevus syndrome
Localized	Amputation stump–related, cold injury, extensive segmental anhidrosis with compensatory hyperhidrosis (Ross syndrome), erythrocyanosis, functional nevus, arteriovenous malformation

conducted regularly and before sweating begins to return in order to maintain dryness.

The anticholinergic drug glycopyrrolate can be added (2 mg per tray) to increase efficacy. Alternatively, 2% glycopyrrolate cream can be applied the night before tap water iontophoresis. Unfortunately, glycopyrrolate can be expensive as it may need to be imported. A special electrode for axillary use is available for some iontophoretic devices, but appears to be less effective due to poor contact.

Botulinum toxin injected intradermally produces sustained anhidrosis by irreversibly blocking the release of acetylcholine from cholinergic junctions. New cholinergic junctions are produced through the natural process of tissue turnover and repair, so the effect is temporary. Anhidrosis occurs within 24 to 72 hours and lasts on average 6 months.

It has shown high efficacy in the treatment of axillary, palmar, craniofacial, postamputation stump hyperhidrosis, compensatory sweating, and Frey syndrome. The commercially available botulinum toxin A products (Botox, Dysport, Xeomin, and Jeuveau) differ in their potency and are not equivalent unit for unit.

Botulinum toxin injected into the axilla is simple and well tolerated with a 90% reduction in sweating expected. Multiple injections, 1–2 cm apart in a grid pattern, are performed in the axillary vault corresponding to the area of maximum sweating (an area of approximately 200 cm²). Typically, 50 units of Botox are injected into each axilla, but larger males ideally should be treated with 100 units per axilla. Several reports describe the increase in duration of efficacy of repeated treatments over time.

Palmar skin is responsive to botulinum toxin with good outcomes, but use is precluded by the need for regional anesthesia due to pain. Local anesthetic nerve blocks, cryoanesthesia, or nitrous oxide (Entonox) inhalation have been employed. The latter is a safe and simple method that provides adequate anesthesia for the duration required. Twice the number of injections as the axilla is required. Avoiding injection into the thenar eminence minimizes the risk of weakening small muscles of the hand. Administration of botulinum toxin to the palms by iontophoresis or by needle-free injectors is still largely experimental.

Botulinum toxin injections work well for craniofacial hyperhidrosis, injecting along the hairline. It is rarely used for plantar hyperhidrosis as it is less effective and more painful at this site.

Oral anticholinergic drugs produce a dose-related inhibition of sweating and are best suited for patients with generalized hyperhidrosis and craniofacial hyperhidrosis, and those with focal forms of hyperhidrosis that do not respond to more localized approaches. The main limitations of treatment are anticholinergic side effects. Medications in this class include glycopyrrolate, oxybutynin,

benztropine, and propantheline. In the UK, only propantheline is licensed for this indication; the other agents are used off-label.

Side effects include dry mouth and impaired taste, pupillary dilatation and blurred vision, glaucoma, urinary retention, constipation, and tachycardia. Overheating can occur due to too effective a block on sweating. There is some evidence that they may increase the risk of dementia in the elderly. Typical prescribed doses include glycopyrrolate 2 mg three times daily; slow release oxybutynin, starting at 5 mg daily, increasing to a maximum of 20 mg daily; and propantheline 15 mg three times daily (this should be taken on an empty stomach and has a half-life of 6 hours). Glycopyrrolate and oxybutynin have liquid formulations that can be prescribed to children and are also significantly cheaper.

Topical glycopyrrolate tosylate (Qbrexza) has been approved by the US Food and Drug Administration (FDA) in 2018 and comes in individually packaged cloths (or wipes) that are to be used at home once per day – with one wipe used for two axillae.

Other systemic drugs that have been used in hyperhidrosis include β -blockers and benzodiazepines, which inhibit the physical manifestations of anxiety and are best suited for patients with episodic or event-driven hyperhidrosis such as during oral presentations, examinations, or job interviews. Agents such as clonidine, indomethacin, gabapentin, and diltiazem all have a few anecdotal reports of their use. Clonidine at a dose of 0.1 mg twice daily is recommended for women beyond the menopause who suffer from troubling hyperhidrosis if anticholinergic agents are ineffective; however, drowsiness is the main limiting side effect.

Surgical and physical techniques are generally used as third-line options.

Microwave-based devices such as miraDry, approved by the FDA in 2011, are believed to work by causing thermolytic injury to localized sweat glands. Neodymium:yttrium-aluminum-garnet (Nd:YAG) laser used with an interstitial fiber; photodynamic therapy using an eosin photosensitizer; and fractional microneedle radiofrequency devices may also work by causing tissue destruction using electromagnetic energy.

Sympathectomy involves the selective ablation of the sympathetic innervation and reduces sweating effectively and with satisfactory long-term results, improved quality of life, and low recurrence rates. It is performed endoscopically through a trans-thoracic route using electrocautery or laser. It has been shown to be successful in children and adolescents. Unfortunately, it may result in a number of severe complications including compensatory hyperhidrosis (which for many patients is even more debilitating), Horner syndrome, pneumothorax, and intraoperative cardiac arrest. It is best reserved for severe palmar hyperhidrosis with an upper thoracic sympathectomy performed at the T2–T3

ganglion. Lumbar sympathectomy for plantar hyperhidrosis is not recommended due to the significant risks of ejaculatory failure, impotence, and anorgasmia.

Underarm surgery techniques include excision, subcutaneous curettage, and liposuction – all performed under local anesthesia. Combinations of these approaches can be employed, and the results are typically permanent due to the destruction of sweat glands. Several skin incisions and reconstructive flaps are described to gain access to the subcutaneous axillary tissues in order to trim away the deep dermis and subcutaneous tissue. The Shelley procedure is a minimally invasive procedure that involves the removal of dermal eccrine sweat glands and denervation of other sweat glands through a central axillary incision with reinnervation being disrupted by subsequent scar formation. This method is noted to have a higher rate of postoperative infection with both systemic and topical antimicrobial prophylaxis recommended.

Specific Investigations

- Starch iodine testing – defines area of sweating
- Gravimetric testing – quantifies sweating

Tests are not necessary for a diagnosis of most cases of focal hyperhidrosis; however, investigation appropriate to the clinical history and physical examination is necessary when hyperhidrosis is generalized.

First-Line Therapies

- Topical ACH solution in ethanol **B**
- Topical ACH in salicylic acid gel **C**

Generalised hyperhidrosis and its treatment. Boni R. *Curr Prob Dermatol* 2002; 30: 44–7.

A review on the more common as well as the rarer causes of secondary generalized hyperhidrosis and how these are treated.

Interventions for hyperhidrosis in secondary care: a systematic review and value-of-information analysis. Wade R, Rice S, Llewellyn A, et al. *Health Technol Assess* 2017; 21(80): 1–280.

A systematic review and economic model designed to establish the expected value of undertaking additional research to determine the most effective interventions for the management of refractory primary hyperhidrosis in secondary care. There was insufficient evidence to draw conclusions for most interventions assessed and the cost-effectiveness analysis was restricted to hyperhidrosis of the axilla.

Aluminium chloride hexahydrate versus palmar hyperhidrosis. Evaporimeter study. Goh CL. *Int J Dermatol* 1990; 29: 368–70.

A single-blind study of unilateral palmar treatment with 20% ACH daily for 4 weeks in 12 patients. Efficacy was reported for all patients; however, four experienced skin irritancy, three patients clearing after 1 week of stopping treatment, and one patient withdrew from the study.

Axillary hyperhidrosis. Local treatment with aluminium-chloride hexahydrate 25% in absolute ethanol with and without supplementary treatment with triethanolamine. Glent-Madsen L, Dahl JC. *Acta Derm Venereol* 1988; 68: 87–9.

A randomized, double-blind, half-sided experiment in 30 volunteers. Triethanolamine in 50% ethanol was applied after treatment to one axilla to neutralize the pH and reduce skin irritation. The combined treatment was found to be less irritating, but also less effective in reducing sweating, although the reduction in efficacy was not noted by the volunteers.

Aluminum chloride hexahydrate in a salicylic acid gel: a novel topical agent for hyperhidrosis with decreased irritation. Woolery-Lloyd H, Valins W. *J Clin Aesthet Dermatol* 2009; 2(6): 28–31.

A small case series of seven patients with a history of severe irritation from aluminum chloride who maintained excellent results with a switch to a 2% salicylic acid base without any significant irritation.

Second-Line Therapies

- Iontophoresis **B**
- Botulinum toxin A **A**
- Botulinum toxin A delivered by needleless injectors **C**
- Botulinum toxin A delivered by iontophoresis **D**
- Botulinum toxin B **C**
- Oral anticholinergics **B**

Iontophoresis for palmar and plantar hyperhidrosis. Pariser DM, Ballard A. *Dermatol Clin* 2014; 32(4): 491–4.

Review article indicating that iontophoresis is a safe, efficacious, and cost-effective primary treatment of palmar and plantar hyperhidrosis.

Iontophoresis with alternating current and direct current offset (AC/DC iontophoresis): a new approach for the treatment of hyperhidrosis. Reinauer S, Neusser A, Schauf G, et al. *Br J Dermatol* 1993; 129: 166–9.

Palmar hyperhidrosis was controlled after an average of 11 treatments, with both the conventional DC and the AC/DC iontophoresis units studied. The AC/DC method, however, eliminated skin irritation and discomfort.

Iontophoresis with glycopyrrolate for the treatment of palmo-plantar hyperhidrosis. Dolianitis C, Scarff CE, Kelly J, et al. *Australas J Dermatol* 2004; 45: 208–12.

A single-blinded, right–left comparison study of 20 patients with palmo-plantar hyperhidrosis to determine the comparative efficacy of tap water iontophoresis to iontophoresis with the anticholinergic glycopyrrolate. The results suggest glycopyrrolate iontophoresis is more effective due to both local and systemic effects on perspiration.

The effectiveness of tap water iontophoresis for palmo-plantar hyperhidrosis using a Monday, Wednesday, Friday treatment regime. Siah TW, Hampton PJ. *Dermatol Online J* 2013; 19: 14.

A retrospective study of 23 patients reported effective treatment with this regimen.

Botox™ delivery by iontophoresis. Kavanagh GM, Oh C, Shams K. *Br J Dermatol* 2004; 151: 1093–5.

Two patients with palmar hyperhidrosis had treatment with BTX-A (Botox) delivered by iontophoresis. Control of approximately 70% was achieved for 3 months, without side effects.

Treatment of primary hyperhidrosis with oral anticholinergic medications: a systematic review. Cruddas L, Baker DM. *J Eur Acad Dermatol Venereol* 2017; 31(6): 952–63.

This review of 23 articles assesses clinical evidence of efficacy, impact on quality of life, and adverse events associated with oral anticholinergic therapy for primary hyperhidrosis, specifically with oxybutynin, glycopyrrolate, and methantheline.

Oxybutynin as a treatment for generalized hyperhidrosis: a randomized, placebo-controlled trial. Schollhammer M, Brenaut E, Menard-Andivot N, et al. *Br J Dermatol* 2015; 173: 1163–8.

A prospective, randomized, placebo-controlled trial in 62 patients, most with generalized hyperhidrosis, using oxybutynin at an initial dose of 2.5 mg/day and increased gradually to 7.5 mg/day. The mean improvement in Hyperhidrosis Disease Severity Scale and Dermatology Life Quality Index (DLQI) were significantly better in the oxybutynin arm, with side effects infrequent and minor.

Use of oral glycopyrronium bromide in hyperhidrosis. Baja V, Langtry JAA. *Br J Dermatol* 2007; 157: 118–21.

In this retrospective analysis of 19 patients with idiopathic hyperhidrosis of varying distribution, 79% reported response to treatment at a dose of 2 mg twice daily, increasing to 2 mg three times daily. In one-third of patients, treatment was limited by side effects.

Systemic therapy for primary hyperhidrosis: a retrospective study of 59 patients treated with glycopyrrolate or clonidine. Walling HW. *J Am Acad Dermatol* 2012; 66: 387–92.

Results of systemic anticholinergic treatment in 71 patients of whom 59 (mean age 29 years, 37 females, mean follow-up 19.5 months) had at least 2 months' follow-up data. Forty-two had palmo-plantar or axillary, nine had generalized, and eight had craniofacial hyperhidrosis. Thirty out of 45 responded to glycopyrrolate at 1–2 mg twice daily. In the 15 treatment failures, six were non-responders and nine had adverse effects. Six out of 13 responded to clonidine 0.1 mg twice a day. In the seven treatment failures, three were non-responders and four had adverse effects relating to hypotension. One patient responded to treatment with oxybutynin 5 mg twice a day.

A randomized placebo-controlled trial of oxybutynin for the initial treatment of palmar and axillary hyperhidrosis. Wolosker N, de Campos JRM, Kauffamn P, et al. *J Vasc Surg* 2012; 55: 1696–700.

A study on 50 patients with palmar or axillary hyperhidrosis treated with either placebo or oxybutynin 5 mg twice a day for 6 weeks and assessed by clinical questionnaire and for quality of life. Improvement was noted in the oxybutynin-treated group in 70% with palmar and axillary hyperhidrosis, and in 90% with plantar hyperhidrosis; 65% showed improvement in quality of life, although 48% experienced dry mouth.

Individualized dosing of oral oxybutynin for the treatment of primary focal hyperhidrosis in children and teenagers. Del Boz J, Millán-Cayetano JF, Blázquez-Sánchez N, et al. *Pediatr Dermatol* 2016; 33(3): 327–31.

A prospective study to assess the effectiveness and safety of individualized dosing regimens of oral oxybutynin for treating primary focal hyperhidrosis in 16 children and teenagers. The study showed high response to treatment as well as persistent

efficacy with longer term use. Dry mouth was the most common side effect.

Oral glycopyrrolate as second-line treatment for primary pediatric hyperhidrosis. Paller AS, Shah PR, Silverio AM, et al. *J Am Acad Dermatol* 2012; 67(5): 918–23.

A retrospective study of 31 children performed to assess the response to oral glycopyrrolate in pediatric patients. In total, 90% of patients experienced improvement and 29% experienced adverse effects.

Botulinum toxin A for axillary hyperhidrosis (excessive sweating). Heckmann M, Ceballos-Baumann AO, Plewig G. *N Engl J Med* 2001; 344: 488–93.

A multicenter trial in 145 patients with axillary hyperhidrosis comparing 200 U and 100 U of BTX-A (Dysport) per axilla. Changes in the rates of sweat production were measured gravimetrically. Two weeks after injection, sweat production was slightly less in the axilla injected with 200 U, and sweat reduction in both was significantly more than with placebo. After 24 weeks, sweat rates after 100 and 200 U were almost identical and less than half the baseline rate. At questionnaire, 98% of the patients said they would recommend this therapy to others.

Botulinum toxin for axillary hyperhidrosis. Trindade de Almeida AR, Montagner S. *Dermatol Clin* 2014; 32(4): 494–504.

Review article on the use of botulinum toxin A in axillary hyperhidrosis and how this is performed.

Onabotulinum toxin A for sacral and intergluteal cleft hyperhidrosis. Totonchy MD. *JAMA Dermatol* 2020; 156: 470–1.

Hyperhidrosis of the groin, including the inguinal folds, perineum, gluteal cleft, anal fold, and buttocks, is an important cause of psychosocial distress that is not widely acknowledged. Botulinum toxin may be very effective in these locales.

Treatment of palmar hyperhidrosis with needle injection versus low-pressure needle-free jet injection of onabotulinum toxin A: an open label study. Vadeboncoeur S, Richer V, Nantel-Battista M, et al. *Dermatol Surg* 2017; 43: 264–9.

A prospective open-label study showing efficacy of onabotulinum toxin A treatment with needle-free injector.

A comparative trial of ice application versus EMLA cream in alleviation of pain during botulinum toxin injections for palmar hyperhidrosis. Alsantali A. *Clin Cosmet Investig Dermatol* 2018; 11: 137–40.

An unblinded comparative trial of 23 patients between ice and topical anesthetic showing statistically significant lower pain scores in the group receiving botulinum toxin after prior ice application.

Botulinum toxin therapy for hyperhidrosis: reduction of injection site pain by nitrous oxide/oxygen mixtures. Paracka L, Kollewe K, Dengler R, et al. *J Neural Transm (Vienna)* 2015; 122(9): 1279–82.

A case series of 13 patients showing the efficacy, safety, and ease of use of nitrous oxide as a non-sedative inhaled analgesic.

Botulinum toxin type B: a new therapy for axillary hyperhidrosis. Nelson L, Bachoo P, Holmes J. *Br J Plast Surg* 2005; 58: 228–32.

The efficacy of BTX-B (NeuroBloc) was demonstrated in the treatment of 13 patients with axillary hyperhidrosis.

Third-Line Therapies

• Topical anticholinergics	B
• Microwave-based devices	B
• Thoracoscopic sympathectomy	B
• Surgical excision inc. Shelley procedure (axillae only)	C
• Fractional microneedle radiofrequency devices	C
• Lasers and photodynamic therapy	D
• Biofeedback and behavioral modification	D
• Diltiazem, clonazepam, clonidine	E

Topical glycopyrronium tosylate for the treatment of primary axillary hyperhidrosis: results from the ATMOS-1 and ATMOS-2 phase 3 randomized controlled trials. Glaser DA, Hebert AA, Nast A, et al. *J Am Acad Dermatol* 2019; 80(1): 128–38.

Two replicate randomized, double-blind, 4-week phase 3 trials comparing glycopyrronium tosylate as a topical anticholinergic once-daily for primary axillary hyperhidrosis with a vehicle control. The treatment reduced sweat production as measured gravimetrically and was generally well tolerated in patients.

Clinical evaluation of a microwave-based device for treating axillary hyperhidrosis. Hong HC, Lupin M, O'Shaughnessy KF. *Dermatol Surg* 2012; 38: 728–35.

Thirty-one patients with primary axillary hyperhidrosis had one to three microwave-based device treatments to both axillae over 6 months and by 12 months 90% had a 50% reduction in axillary sweating from baseline and 85% had a reduction of at least 5 points on the DLQI. The case series was funded by Miramar labs who produce miraDry.

Efficacy of fractional microneedle radiofrequency device in the treatment of primary axillary hyperhidrosis: a pilot study. Kim M, Shin JY, Lee J, et al. *Dermatology* 2013; 227(3): 243–9.

Uncontrolled prospective study using a fractional microneedle radiofrequency device receiving two sessions at 4-week intervals

with significant improvement in disease severity scores and starch iodine tests.

New treatment techniques for axillary hyperhidrosis. Mordon SR, Trelles MA, Leclerc FM, et al. *J Cosmet Laser Ther* 2014; 16: 230–5.

Review article looking at the recent evidence as well as outlining the specific techniques for using Nd:YAG laser, microwave devices, and photodynamic therapy as potential new treatments for axillary hyperhidrosis.

Shelley procedure in axillary hyperhidrosis. Hussain AB, Holme SA, Kavanagh GM. *Clin Exp Dermatol* 2016; 41(2): 229–31.

Case series involving 31 patients (mostly female) with axillary hyperhidrosis treated at a single center using this minimally invasive procedure. Of the 31 patients, 29 experienced a clinically significant reduction in sweating and an improvement in DLQI scores. The paper outlines the procedure itself and provides recommendations for perioperative care.

A prospective cohort study on quality of life after endoscopic thoracic sympathectomy for primary hyperhidrosis. Dhar-maraj B, Kosai NR, Gendeh H, et al. *Clin Ter* 2016; 167(3): 67–71.

Questionnaire on quality of life and self-esteem filled in by 50 patients undergoing the procedure, the results showing that it can significantly improve the quality of life and self-esteem of patients, but the rate of compensatory hyperhidrosis is high (78%).

Transthoracic endoscopic sympathectomy for palmar hyperhidrosis in children and adolescents: analysis of 350 cases. Lin TS. *J Laparoendosc Adv Surg Tech A* 1999; 9: 331–4.

A total of 699 sympathectomies were performed in 350 patients with highly satisfactory results reported in 95% of patients, although compensatory hyperhidrosis (86%) affected the axillae (12%), back (86%), abdomen (48%), or lower limbs (78%). The recurrence rates of palmar hyperhidrosis were 0.6% in the first year, 1.1% in the second, and 1.7% in the third.

Hypertrichosis and hirsutism

Katherine Glaser, Wilma F. Bergfeld

INTRODUCTION

Hirsutism is the excessive growth of terminal hair in women in male androgen-dependent areas (face, breasts, thighs, abdomen, back). Approximately 5–10% of women are affected worldwide with significant impacts on quality of life. The Ferriman–Gallwey (F-G) scoring system is the gold standard for diagnosis in which nine androgen-sensitive body areas are evaluated and rated on a scale of 0–4 (no hair to frankly virile). A cumulative score ≥ 8 is diagnostic but must be modified for certain races and ethnicities.

Hirsutism results from endogenous androgens (ovarian or adrenal), exogenous androgens, or from increased hair follicle sensitivity to androgens. Most hirsute women have raised circulating androgen levels; however, in idiopathic hirsutism circulating androgen levels can be normal. Polycystic ovarian syndrome (PCOS) and idiopathic hirsutism are the most common causes. Rarer etiologies must also be considered including endocrinopathies, non-classical congenital adrenal hyperplasia, and androgen-secreting tumors.

Hypertrichosis, by contrast, results from increased vellus hair growth in a generalized androgen-independent distribution and usually is familial or drug-induced (e.g., phenytoin, ciclosporin).

Main Causes of Hirsutism

Ovarian

- **Polycystic ovarian syndrome (PCOS)** – menstrual irregularities, metabolic syndrome,* polycystic ovaries on ultrasound

- **HAIR-AN syndrome** – hyperandrogenism, acanthosis nigricans, metabolic syndrome*
- **Ovarian hyperthecosis** – gradual hirsutism, adult-onset virilization, metabolic syndrome*
- **Ovarian tumors** – rapidly progressive hirsutism and virilization

Adrenal

- **Classical congenital adrenal hyperplasia** – ambiguous genitalia, menstrual irregularities, prepubertal virilization
- **Non-classical congenital adrenal hyperplasia** – menstrual irregularities, family history of hirsutism, certain ethnic groups (Mediterranean, Hispanic, Ashkenazi Jew)
- **Cushing syndrome** – Cushingoid (striae, central obesity, easy bruising, acanthosis nigricans, proximal muscle wasting, mood disturbances, insulin resistance)
- **Adrenal tumors** – rapidly progressive hirsutism and virilization, Cushingoid

Pituitary†

- **Cushing disease** – skin hyperpigmentation, Cushingoid
- **Acromegaly** – coarse facies, large hands, doughy skin
- **Hyperprolactinemia** – galactorrhea

Idiopathic

- Abnormal peripheral 5 α -reductase activity or androgen receptor – hirsutism, normal menses

Exogenous

- **Medications** – testosterone, anabolic steroids, androgenic progestins, adrenocorticotrophic hormone (ACTH), valproic acid

*Metabolic syndrome: obesity, insulin resistance/diabetes mellitus type 2, lipid abnormalities, cardiovascular disease

†Pituitary tumors can also present with visual field defects and cranial nerve palsies

MANAGEMENT STRATEGY

A thorough history and complete physical examination is critical to identify the etiology of hypertrichosis and hirsutism. Offending drugs, if implicated, should be promptly discontinued. Laboratory screening for elevated androgen levels should be performed in women with a positive F-G score or clinical signs of hyperandrogenism (e.g., menstrual irregularities, infertility, galactorrhea, acanthosis nigricans, central obesity). Ultimately, treatments are tailored based on the underlying cause.

For women with localized hair growth or a normal F-G score, treatments are typically limited to *physical hair removal methods*. Women with true hirsutism require additional systemic pharmacologic therapy, often indefinitely. *Combined estrogen–progestin oral contraceptive pills (OCP)* and *antiandrogens* are preferred first-line therapies. Less common and less efficacious therapies include *gonadotropin-releasing hormone agonists (GnRH)*, *insulin-lowering drugs*, and *topical antiandrogens*.

Signs of metabolic syndrome may be seen in PCOS, HAIR-AN syndrome, and ovarian hyperthecosis. In obese women with these conditions, weight loss improves markers of metabolic syndrome and reduces cardiovascular risk.

Hirsutism that is acute, rapidly progressive, or accompanied by signs of virilization (clitoromegaly, deep voice, or increased muscularity) indicates potential androgen-secreting tumors or congenital adrenal hyperplasia (CAH). Additional laboratory and/or radiographic screening is required in these cases. *Glucocorticoid therapy* is utilized in CAH to suppress adrenal androgen production and induce ovulation, but OCPs and/or systemic antiandrogens are often required for the hirsutism.

Specific Investigations

Detailed medication history

Screening test

- Testosterone level (free and total)*

If testosterone level elevated or signs of hyperandrogenism/virilization†

- 17-hydroxyprogesterone*
- Sex hormone-binding globulin
- β -hCG level
- Dehydroepiandrosterone sulfate (DHEAS)
- Androstenedione
- Thyroid-stimulating hormone (TSH)
- Follicular-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Prolactin
- Dexamethasone suppression test
- 24-hour urinary free cortisol
- Somatomedin C (IGF-1)

Imaging if PCOS or tumor suspected‡

- Transvaginal ultrasound
- Computed tomography/magnetic resonance imaging (CT/MRI) of abdomen/pelvis
- MRI brain

*Ideally obtained in the morning in the follicular phase of the menstrual cycle

†Additional screening should be tailored based on the suspected underlying etiology

Physical Hair Removal Methods

Hair removal therapies offer significant cosmetic benefits and can be used first-line or adjunctively. *Bleaching* with hydrogen peroxide preparations disguises dark hair. *Depilation* removes the hair shaft at the skin surface such as with *shaving* or with *chemical depilatory creams* to dissolve the hair. Importantly, depilation does not affect the diameter or rate of hair growth. Skin irritation, discomfort, and dyspigmentation are known side effects.

Epilation removes the entire hair shaft, including the root. Temporary epilation therapies include *tweezing*, *threading*, or *waxing*. *Electrolysis* is a form of permanent epilation that can be used on any skin or hair color but is time consuming, requires multiple treatments, and is operator dependent. A fine needle is inserted into the hair follicle to deliver direct current (galvanic electrolysis), high-frequency alternating current (thermolysis), or a blend of the two to damage the hair follicle. In addition to the aforementioned side effects, folliculitis, pseudofolliculitis, infection, and scarring are possible.

Photoepilation is a popular form of permanent epilation using pulses of light absorbed by melanin in the hair shaft to cause selective photothermolysis. Devices include ruby (694 nm),

alexandrite (755 nm), diode (800–810 nm), or Nd:YAG (1064 nm) lasers and IPL (intense pulsed light) non-coherent light (590–1200 nm). While significant pigmented hair reduction can be achieved with photoepilation, no device can guarantee complete or persistent hair removal. Efficacy improves greatly with repeat treatments. Caution should be taken in darker skin types and around the eye due to high melanin concentrations. Side effects include erythema, pain, blistering, dyspigmentation, burns, scarring, and, rarely, paradoxical hypertrichosis.

Pharmacologic Therapies for Hirsutism

Although several meta-analyses and treatment guidelines are published, evidence is limited by small sample sizes and inconsistent methodology. Systemic therapy is not recommended for women planning pregnancy due to teratogenic potentials.

Combined OCPs are first-line, which work by suppressing ovarian androgen synthesis, increasing sex hormone-binding globulin levels, and suppressing free plasma testosterone levels. OCPs with low androgenic progestins (desogestrel, gestodene, norgestimate) and progestins with antiandrogenic properties (cyproterone acetate, drospirenone) are preferred. Importantly, progestin-only contraception is ineffective for hirsutism. The risks of venous thromboembolism should be considered in higher risk patients (e.g., older, obese, smoker), which can be mitigated using lower ethinyl estradiol (EE) doses and lower risk progestins (levonorgestrel). Clinical response requires 6 months of treatment. Combination treatment with another antiandrogen (spironolactone, finasteride) is recommended if response to monotherapy is inadequate.

Spironolactone inhibits 5- α -reductase activity and blocks androgen receptors. Common dosing is 100–200 mg daily. Side effects include hyperkalemia, hypotension, and irregular menses. Tumorigenicity has been shown in animals, but relevance in humans is questionable. Spironolactone is pregnancy category C; however, all antiandrogens have feminizing teratogenic potential and should be used with a reliable form of contraception. For this reason, OCPs are preferred first-line over antiandrogens except in women who have undergone permanent sterilization, are not sexually active, or are using long-acting reversible contraception.

Finasteride inhibits type II 5- α -reductase activity and is typically dosed as 2.5–5 mg daily. It is considered pregnancy category X, limiting its use in certain populations, as previously mentioned. No reports exist for dutasteride, a type I and II 5- α -reductase inhibitor, in the treatment of hirsutism.

Cyproterone acetate (CPA) is another antiandrogen, though currently unavailable in the US, with various mechanisms of action including androgen receptor blockade, weak 5- α -reductase inhibition, and gonadotrophin reduction. It can be prescribed as a combination OCP (2 mg CPA and 35 mcg EE) or used cyclically (50–100 mg CPA daily on menstrual cycle days 1–10 and 35 mcg EE on days 1–21). Side effects are similar to other OCPs.

Flutamide is an antiandrogen, which inhibits androgen receptors in a dose-dependent fashion. Lower doses (62.5–250 mg daily) may be equally as efficacious as higher doses (500 mg daily). However, serious reports of hepatotoxicity and even death reduced its use in clinical practice.

GnRH agonists, such as leuprolide, reduce luteinizing hormone and downstream ovarian androgens. Side effects include hot flashes and osteoporosis, for which supplementary low-dose estrogen is often required. These medications are expensive, injectable, and show no advantages over first-line therapies; thus, they are not recommended except in severe forms of hirsutism that have already failed OCPs and antiandrogens.

Eflornithine hydrochloride 13.9% cream is approved by the Food and Drug Administration (FDA) for facial hirsutism. It slows the rate of hair growth by irreversibly inhibiting ornithine decarboxylase. Results require 6–8 weeks of twice-daily application; however, benefits reverse approximately 8 weeks after discontinuation. Side effects include acne, pseudofolliculitis, and contact dermatitis. Adjuvant use with photoepilation improves efficacy.

Several therapies are no longer recommended as more recent studies show little to no efficacy in the treatment of hirsutism. *Insulin-lowering drugs* such as metformin and thiazolidinediones, *topical finasteride*, and *topical canrenone* (the active metabolite of spironolactone) demonstrate inconsistent results but generally offer minimal to no benefits.

Evaluation and treatment of hirsutism in premenopausal women: an Endocrine Society Clinical Practice Guideline. Martin KA, Anderson RR, Chang RJ, et al. *J Clin Endocrinol Metab* 2018; 103: 1233–57.

The most up-to-date practice guideline that reviews etiology, diagnostic approach, and evidence-based treatment algorithms for hirsutism. Recommendations have been incorporated throughout this chapter.

American Association of Clinical Endocrinologists, American College of Endocrinology, and Androgen Excess and PCOS Society disease state clinical review: guide to the best practices in the evaluation and treatment of Polycystic Ovary Syndrome—Part 1. Goodman NF, Cobin RH, Futterweit W, et al. *Endocr Pract* 2015; 21: 1291–300.

Current PCOS diagnostic guidelines require two of the following criteria: chronic oligoovulation, hyperandrogenism, and polycystic ovaries on transvaginal ultrasound. Metabolic screening is important but not incorporated into the diagnostic criteria.

First-Line Therapies

Screening and treatment of underlying pathology

• Weight loss if obese	B
• Combined OCPs	B
• Spironolactone	A
• Finasteride	A
• Cyproterone acetate	B
• Eflornithine cream	B
• Mechanical hair removal, bleaching, or camouflage	B
• Electrolysis	B
• Photoepilation	A

Lifestyle changes in women with polycystic ovary syndrome. Moran LJ, Hutchison SK, Norman RJ, et al. *Cochrane Database Syst Rev* 2011; 7: CD007506.

Meta-analysis of four PCOS studies ($n = 132$) showed lifestyle changes alone improve hirsutism and markers of metabolic syndrome (weight and fasting insulin concentrations). Serum testosterone levels and F-G scores improved slightly (mean difference -1.19 , with 95% confidence interval -2.35 to -0.03).

Anti-androgenic therapy in young patients and its impact on intensity of hirsutism, acne, menstrual pain intensity and sexuality – a preliminary study. Fuchs A, Matonóg A, Sieradzka P, et al. *Ginek Pol* 2019; 90: 520–6.

Combined OCPs with antiandrogen properties improved acne severity, menstrual pains, and F-G scores in premenopausal women ($n = 570$) after 3 months. Women with excessive hairiness ($n = 192$) noted greater improvements with CPA, chlormadinone, and drospirenone (though not with dienogest) than those taking OCPs without antiandrogen properties. Head-to-head studies are lacking, and guidelines generally do not suggest one OCP over another. However, OCPs containing low androgenic or antiandrogen progestins are preferred.

Comparison of spironolactone, flutamide, and finasteride efficacy in the treatment of hirsutism: a randomized, double blind, placebo-controlled trial. Moghetti P, Tosi E, Tosti A, et al. *J Clin Endocrinol Metab* 2000; 85: 89–94.

Spironolactone 100 mg daily, flutamide 250 mg daily, and finasteride 5 mg daily were compared in a small 6-month double-blind, placebo-controlled randomized controlled trial (RCT). Measured outcomes included patient questionnaires, endocrine labs, F-G scores, and hair shaft diameter. Despite variable mechanisms of action, each antiandrogen demonstrated similar positive efficacy. Tolerability was overall good; only mild polymenorrhea was reported with spironolactone (50%).

Cyproterone acetate for hirsutism. Van der Spuy ZM, Le Roux PA. *Cochrane Database Syst Rev* 2003; 4: CD001125.

No studies to date compare CPA with placebo; however, a small placebo-controlled trial demonstrates efficacy of CPA 2 mg with EE. Another small trial shows when combined with EE, there is no significant difference in F-G score or endocrine labs when comparing CPA 2 mg with CPA 25–100 mg.

Evidence based review of hair removal using lasers and light sources. Haedersdal M, Wulf HC. *J Eur Acad Dermatol Venerol* 2006; 20: 9–20.

Meta-analysis of nine RCTs and 21 controlled trials suggests photoepilation is superior and preferred by patients to conventional hair removal treatments (shaving, waxing, electrolysis). Short-term partial hair reduction up to 6 months postprocedure can be expected with improved efficacy with repetitive treatments.

Meta-analysis of hair removal laser trials. Sadoghha A, Mohaghegh Zahed G. *Lasers Med Sci* 2009; 24: 21–5.

A systematic review of laser hair removal clinical trials showed hair reductions of 57.5%, 42.3%, 54.7%, and 52.8% at 6 months posttreatment after three sessions with diode, Nd:YAG, alexandrite, and ruby lasers, respectively.

Laser-assisted hair removal for facial hirsutism in women: a review of evidence. Lee CM. *J Cosmet Laser Ther* 2018; 20: 140–4.

Lasers are highly effective for unwanted hair removal; however, the mean hair reduction following multiple laser sessions is, on average, one-third less in individuals with hyperandrogenism. Long-term follow-up data is lacking but most women with androgen excess require maintenance sessions. Patients with darker skin types require lower fluences and have less adverse events using long-pulsed Nd:YAG.

Photoepilation with a diode laser vs. intense pulsed light: a randomized, inpatient left-to-right trial. Klein A, Steinert S, Baeumler W, et al. *Br J Dermatol* 2013; 168: 1287–93.

Diode laser more effectively decreased axillary hair counts compared with IPL ($n = 30$). Mean hair reductions 12 months after six treatment sessions were 69.2% for diode and 52.7% for IPL ($p < 0.01$). Diode treatment was more painful than IPL.

Randomized, double blind clinical evaluation of the efficacy and safety of topical eflornithine HCl 13.9% cream in the treatment of women with facial hair. Wolf JE, Shander D, Huber F, et al. *Int J Dermatol* 2007; 46: 94–8.

Using a physician's global assessment and evaluating facial hair length and mass, 58% of eflornithine-treated patients ($n = 393$) were improved compared to 34% with vehicle ($n = 201$) after 24 weeks of twice-daily application. Cutaneous adverse events were generally mild, self-resolving, and comparable between treatment groups.

Combination of intense pulse light and topical eflornithine therapy versus intense pulse light therapy alone in the treatment of idiopathic facial hirsutism: a randomized controlled trial. Zahoor H, Noor SM, Paracha MM. *J Pak Med Assoc* 2019; 69: 930–3.

Topical eflornithine is substantially more effective when used in combination with a light-based treatment such as IPL. In this RCT, 78 women were treated with monthly IPL sessions or twice-daily eflornithine application with IPL. After 6 months, a statistically significant mean hair reduction was noted in the combination group (90.44%) compared with IPL only (59.23%).

Second-Line Therapy

- Combination of OCPs with antiandrogen

B

Antiandrogens for the treatment of hirsutism: a systematic review and metaanalyses of randomized controlled trials. Swiglo BA, Cosma M, Flynn DN, et al. *J Clin Endocrinol Metab* 2008; 93: 1153–60.

Meta-analysis identified five small RCTs comparing OCPs with a combination OCP and antiandrogen: 1) OCP containing 2 mg CPA versus with 100 mg CPA for 10 days per month; 2) OCP containing desogestrel versus with 50 mg spironolactone, and 3–5) OCP containing 2 mg CPA versus with 5 mg finasteride. Overall methodological quality was low and not standardized but combination treatment showed mild advantages over monotherapy. Subgroup analyses by antiandrogen type suggest benefit with additional spironolactone or finasteride but no added benefit of higher dose CPA when taken with an OCP containing CPA.

Long-term response of hirsutism and other hyperandrogenic symptoms to combination therapy in polycystic ovary syndrome. Ezeh U, Huang A, Landay M, et al. *J Womens Health (Larchmt)* 2018; 27: 892–902.

Menstrual irregularities, acne, and F-G scores improved more in PCOS patients treated with combination spironolactone 100–200 mg/day and OCP ($n = 138$) when compared to OCP monotherapy or other therapies ($n = 62$). While the second treatment group received variable therapies making interpretation complex, the study offers long follow-up over an average 34 months and statistically significant measured outcomes.

Third-Line Therapies

• Flutamide	A
• GnRH agonists	B
• Glucocorticoids	B
• Insulin-lowering drugs	A
• Topical finasteride	B
• Topical canrenone	C

Very low dose of flutamide in the treatment of hyperandrogenism. Fulghesu AM, Melis F, Murru G, et al. *Gynecol Endocrinol* 2018; 34: 394–8.

Adolescent females ($n = 145$) with severe hirsutism noted statistically significant reductions in F-G scores (–39.99%) after 18 months of treatment with flutamide 62.5 mg daily and a contraceptive (EE and gestodene) compared to controls ($n = 30$) on OCP monotherapy (EE and drospirenone). One case of self-resolving mild transaminitis was reported. Other studies in adults have reported more severe liver toxicities and, thus, flutamide should be used with caution.

Interventions for hirsutism (excluding laser and photoepilation therapy alone): review. Van Zuuren EJ, Fedorowicz Z, Carter B, et al. *Cochrane Database Syst Rev* 2015; 4(4): CD010334.

GnRH analogs show inconsistent results in several studies and have significant side effects.

Management of the female with non-classical congenital adrenal hyperplasia (NCCAH): a patient-oriented approach. Livadas S, Bothou C. *Front Endocrinol (Lausanne)* 2019; 10: 366.

CAH treatment should be individualized and implemented for symptomatic females with adjustments based on age-group. Hydrocortisone 10–15 mg/m² divided in three doses is more commonly prescribed in childhood, and prednisone 5 mg daily or dexamethasone 0.25 mg daily in adolescence.

Insulin sensitizers for the treatment of hirsutism: a systematic review and metaanalyses of randomized controlled trials. Cosma M, Swiglo BA, Flynn DN, et al. *J Clin Endocrinol Metab* 2008; 93: 1135–42.

Meta-analysis suggests metformin and thiazolidinediones provide little benefit compared with placebo and no significant benefit when compared or added to OCPs or antiandrogens. Usage for insulin sensitivity is appropriate but generally not recommended solely for hirsutism.

Topical finasteride in hirsutism: a double blind randomized clinical trial on adult women. Iraj F, Karbasioun S, Aminoroaya A. *Int J Res Med Sci* 2005; 10: 337–42.

A double-blind, split-face, placebo-controlled trial ($n = 35$) showed no difference in mean hair thickness or count after 6 months of twice-daily application of finasteride (0.5%) cream in the treatment of facial hirsutism.

Lack of effect of a spironolactone-containing cream on hair growth in hirsute women. Gomez F, Ramelet AA, Rüedi B, et al. *Dermatologica* 1987; 174: 102–3.

A small ($n = 12$), double-blind, placebo-controlled trial of spironolactone (5%) cream applied twice daily for 3 months to the face, thighs, and legs showed no improvements in hirsutism. Newer studies are unavailable.

Hypopigmented disorders

Ramiro Rodriguez Jr., Amit G. Pandya

Progressive macular hypomelanosis

Hypopigmented disorders present as areas of skin that are lighter than normal due to reduced melanin. In contrast, depigmented lesions, such as those caused by vitiligo, present as milky-white patches due to complete absence of melanocytes. Classification of these disorders may be based on lesion pattern and distribution, underlying cause, or time of lesion onset. In general, hypopigmentation occurs due to alterations in the melanin synthesis pathway, a decrease in melanocytes, or impairment in the melanocyte-melanin transfer system. This chapter briefly discusses common hypopigmented disorders with an overview of treatment options.

Nevus Depigmentosus

This disorder is a non-progressive, congenital form of cutaneous mosaicism affecting melanin synthesis and transfer from melanocyte to keratinocyte. Clinically, lesions present in early childhood as well-defined hypopigmented patches with serrated borders. Three variants have been described (localized, segmental, and linear or whorled) with the localized type being the most common. A negative diascopy test is helpful to rule out nevus anemicus.

Postinflammatory Hypopigmentation

Inflammatory reactions in various dermatoses may lead to hypopigmentation after resolution of the inflammatory phase.

Cutaneous injuries, burns, and cosmetic procedures (dermabrasion, chemical peels, cryosurgery) can also lead to pigment loss through postinflammatory changes. Severity of pigment loss and distribution coincides with the distribution of original lesions and the degree of previous inflammation. This disorder is seen most frequently in darker-skinned individuals, due to contrast of the lesions with surrounding skin. The lesional course may vary from spontaneous resolution to permanent hypopigmentation.

Pityriasis Alba

A form of postinflammatory hypopigmentation, this self-limiting, benign disorder is associated with eczema and is especially common among children with a personal or family history of atopy. Lesions present as hypopigmented macules with or without associated scaling, erythema, and/or pruritus. Involvement of the face, neck, shoulders, and upper extremities is common. In contrast with pityriasis versicolor, lesions tend to have more facial involvement, are less numerous, and show no yeast elements on KOH (potassium hydroxide) preparations of overlying scale.

Idiopathic Guttate Hypomelanosis

Idiopathic guttate hypomelanosis (IGH), also called *senile depigmented spots*, is an acquired leukoderma common among older persons. Lesions present as 1–6 mm hypopigmented to porcelain-white, oval-to-round guttate macules on sun-exposed areas, especially the legs. Although asymptomatic, lesions tend to increase with age and may be of cosmetic concern. Etiology of this disorder is unknown; however, the *HLA-DQ3* gene, autoimmunity, trauma, and chronic sun exposure are among suspected culprits. Light microscopy of lesions reveals a hyperkeratotic stratum corneum, an atrophic epidermis, and flattened rete ridges with senescent melanocytes and decreased melanin content.

Chemical Leukoderma

Lesions of chemical leukoderma present as hypo- or depigmented macules at sites of contact with chemicals, especially phenols, catechols, or hydroquinone. A history of onset of lesions after chemical exposure and distribution involving only the exposed sites or similar cases in individuals in the same workplace are needed to establish a diagnosis and distinguish it from vitiligo or other causes of hypo- and depigmentation.

Pityriasis Versicolor

Also known as *tinea versicolor*, this is an infectious disorder affecting the epidermal keratin layer. The responsible agent is a lipophilic budding yeast, *Pityrosporum orbiculare*, found in normal skin flora. The disease is active when the yeast changes to its hyphal form. Skin involvement is seen on sites with a high density of sebaceous glands, especially the shoulders, chest, and upper back. Lesions present as well-defined hypopigmented macules or small patches with overlying scale. The pigment loss is attributed to the inhibition of the enzyme tyrosinase by azelaic acid, a dicarboxylic acid formed by the organism. Less commonly, the lesions may be hyperpigmented to erythematous in color. Diagnosis is confirmed with a KOH preparation of scale obtained from a lesion demonstrating the 'spaghetti and meatball' appearance of the organism. Wood lamp examination helps with diagnosis, as *tinea versicolor* often has a yellow-white or coppery-orange fluorescence.

Progressive Macular Hypomelanosis

This is an acquired hypomelanosis presenting as round, pale, poorly circumscribed and coalescent macules over the trunk, with a tendency toward confluence at the midline. Lesions are non-scaly and are not preceded by inflammation, differentiating it from pityriasis versicolor and postinflammatory hypopigmentation, respectively. Although the pathogenic factors are not known, hormonal interactions and colonization of *Propionibacterium* spp. around the pilosebaceous units are thought to be contributors. Wood lamp examination may reveal a characteristic punctate red fluorescence at the center of lesions suggestive of *Propionibacterium* colonization. Microscopic analysis reveals a disruption in melanosome maturation and distribution. The course of the disorder is unpredictable, as spontaneous cure has been reported over time in some patients.

Leprosy (Hansen Disease)

This is an infectious disorder caused by *Mycobacterium leprae*, a bacterium that affects skin and peripheral nerves. Lesions may present as hypopigmented or erythematous macules with varying degrees of scale and induration; hypoesthesia and peripheral nerve enlargement are characteristic findings.

Hypopigmented Variants of Common Dermatoses

Mycosis fungoides, morphea, scleroderma, and sarcoidosis are dermatoses that may present as hypopigmented variants.

In patients with mycosis fungoides, lesions present as ill-defined, light-colored macules and patches, which characteristically occur in sun-protected areas. Histopathologic examination of a skin biopsy helps confirm the diagnosis by revealing atypical lymphocytes within the epidermis, also known as epidermotropism.

In lichen sclerosis, a chronic inflammatory disorder, lesions present with hypo- and depigmented porcelain-white macules and thin plaques, which may be associated with associated pruritus and/or pain. The distribution commonly involves anogenital areas and affects women after the fourth decade of life.

Morphea and systemic sclerosis may also present with patches of hypopigmentation, with characteristic perifollicular hyperpigmentation and associated induration, giving a 'salt and pepper' appearance.

Less commonly, sarcoidosis may present as a hypopigmented variant that predominantly affects dark-skinned individuals. These lesions are often indurated, favor the extremities, and have a yellow tinge on diascopy.

Specific Investigations

- Diascopy
- Wood lamp exam
- Scraping for yeast and fungus
- Skin biopsy

MANAGEMENT STRATEGY

A thorough history and clinical exam are essential for diagnosis of hypopigmented dermatoses. Details of lesion duration, age of onset, preceding history, associated symptoms, exposure to chemicals, and family history aids to narrow the differential. On exam, one must assess the nature of pigment loss (hypo/depigmentation), the site and distribution of lesions, and the

presence of associated findings (induration, scaling, erythema, pruritus, or sensory loss). A Wood lamp exam helps differentiate hyperpigmentation from depigmentation. Confocal microscopy helps assess the melanin content and distribution of lesions and histopathologic analysis of a skin biopsy helps identify specific diseases.

The most important aspect of management is to *treat the underlying inflammatory disorder*. Once the inflammation has resolved, various strategies can be used to bring back normal pigmentation. Sun exposure aids with repigmentation of lesions through residual functional melanocytes. *Ultraviolet light therapy* may help stimulate melanin synthesis; however, overexposure may risk increased contrast from tanning of surrounding normal skin.

First-Line Therapies

• Phototherapy	D
• Topical corticosteroids	D
• Topical calcineurin inhibitors	D

Laser resurfacing induced hypopigmentation: histologic alterations and repigmentation with topical photochemotherapy. Grimes PE, Bhawan J, Kim J, et al. *Dermatol Surg* 2001; 27: 515–20.

In this study, 10 patients with postlaser resurfacing hypopigmentation underwent treatment with topical 0.001% 8-methoxypsoralen ointment applied to the lesions twice weekly for 30 min followed by ultraviolet A exposure at an initial dose of 0.2–0.5 J/cm² and increased by 0.2–0.5 J/cm² weekly. Moderate-to-excellent repigmentation was seen in 71% of patients. Adverse effects were minimal.

Benzoyl peroxide/clindamycin/UVA is more effective than fluticasone/UVA in progressive macular hypomelanosis: a randomized study. Relyveld GN, Kingswijk MM, Reitsma JB, et al. *J Am Acad Dermatol* 2006; 55: 836–43.

A total of 45 patients participated in this left–right randomized trial. Patients applied benzoyl peroxide 5% hydrogel on one side of the body affected by lesions of progressive macular hypomelanosis and fluticasone 0.05% on the contralateral side nightly. Clindamycin 1% lotion was applied in the morning on the benzoyl peroxide site. UVA therapy was provided three times a week for 20 min at 233 J/cm². Pigment was measured by colorimeter at baseline, 2, 6, 10, and 14 weeks of treatment. After 14 weeks, patients stopped treatment and underwent a 12-week period without treatment for final measurement. While the benzoyl peroxide/clindamycin/UVA side showed superior results, both groups showed improvement by colorimeter and visual evaluation.

Pilot trial of 1% pimecrolimus cream in the treatment of seborrheic dermatitis in African American adults with associated hypopigmentation. High WA, Pandya AG. *J Am Acad Dermatol* 2006; 54: 1083–8.

Five African American patients with seborrheic dermatitis-induced hypopigmentation were treated with pimecrolimus applied to the affected areas twice daily for 16 weeks. Hypopigmentation was assessed using a Mexameter. Marked improvement was noted starting at 2 weeks in all patients, which continued until the end of treatment.

Topical tacrolimus significantly promotes repigmentation in idiopathic guttate hypomelanosis: a double blind, randomized, placebo-controlled study. Rerknimitr P, Disphanurat W, Achariyakul M. *J Eur Acad Dermatol Venereol* 2013; 27: 460–4.

In this within-patient, left–right comparison study, 26 patients with IGH were randomized. One side was randomly assigned to be treated with 0.1% tacrolimus while the other side received placebo. Both topicals were applied twice daily for 6 months, with measurements at 2, 4, and 6 months. Colorimeter measurements and patient self-evaluation at 6 months showed that tacrolimus treated lesions improved more than placebo.

Second-Line Therapies

• Laser	D
• Cosmetic camouflage	B
• Melanocyte grafting	C

The safety and efficacy of the 308-nm excimer laser for pigment correction of hypopigmented scars and striae alba. Alexiades-Armenakas MR, Bernstein LJ, Friedman PM, et al. *Arch Dermatol* 2004; 140: 955–60.

A group of 31 adults with hypopigmented scars (22) and striae alba (9) were enrolled. Lesions were treated with xenon chloride excimer laser (308 nm, 3.2 cm², 30 ns) starting at 50 mJ/cm² minus the minimal erythema dose of the patient. Treatment was performed biweekly until a maximum of 10 treatment

sessions, 75% improvement with colorimetry, and 100% visual pigment correction. If no improvement was noted, the dose was increased by 50 mJ/cm² per treatment; otherwise, the same dose was maintained throughout treatment. Posttreatment evaluation was performed at 1, 2, and 4 months. Statistically significant improvement was noted using colorimetric analysis after the first treatment; 60%–70% visual improvement was noted compared with control sites.

Melanocyte autologous grafting for treatment of leukoderma. Suvanprakorn P, Dee-Ananlap S, Pongsomboon C, et al. *J Am Acad Dermatol* 1985; 13: 968–74.

Patients with vitiligo, IGH, and postinflammatory hypomelanosis were included in the study. Blisters were created by suction/liquid nitrogen at the affected and healthy site. The roof of the bullae from the donor site was transferred to the affected area. Repigmentation was noted 7–14 days later.

Cosmetic camouflage. Antoniou C, Stefanaki C. *J Cosmet Dermatol* 2006; 5: 297–301.

Cosmetic camouflage may be helpful for patients not relieved by conventional treatment, especially when lesions are located over a cosmetically important area such as the face. The products may be oil or water based, depending on patient skin type.

Ichthyoses

Qisi Sun, Keith Choate

Mutations in over 50 genes cause ichthyosis, resulting in abnormal barrier function with increased transepidermal water loss (TEWL) and compensatory epidermal hyperproliferation. Most are inherited and classified as either non-syndromic (findings limited to the skin) or syndromic (involving other organs). Acquired ichthyosis can arise from malignancy, autoimmune or inflammatory disease, nutritional deficiency, and medications.

MANAGEMENT STRATEGY

Newborns (0–2 Months)

Newborns with ichthyosis can present with a range of phenotypes including collodion membrane, widespread erosions, armor-like scale, red/scaly skin, or normal skin that subsequently develops scaling and erythema. In recessive ichthyosis, collodion membrane presentations are common and are characterized by a taut, translucent layer of skin, which sheds within a month of birth to reveal scaly and/or red skin. A minority of collodion babies heal spontaneously, leaving mild scaling. In severe cases, morbidity is possible due to increased TEWL, difficulties in thermoregulation, and increased infection risk, especially with *Staphylococcus aureus* and dermatophytes. It is also important to recognize that other disorders such as Omenn syndrome and neonatal Gaucher disease can also cause collodion membrane. Therefore, genetic testing is the cornerstone of diagnostic workup.

It is common practice to place collodion babies in a 40–60% humidified incubator to minimize dehydration and prevent fissures. Since eclabium can interfere with oral feeding, newborns may require modified bottle nipples or nasogastric feeding.

Newborn care also includes pain control, ophthalmologic attention to prevent conjunctivitis and keratitis secondary to ectropion, and close monitoring for infection and fluid and electrolyte imbalances, especially hyponatremia. Prophylactic antibiotics are discouraged given a lack of evidence supporting their efficacy. Medicated ointments, such as salicylic acid, lactic acid, and sulfadiazine cream, should be avoided, given the risk of percutaneous absorption. *Bland emollients* including white petrolatum and Aquaphor are preferred.

Newborns with epidermolysis bullosa (EB) can present with widespread blistering, so epidermolysis bullosa and staphylococcal scalded skin infection are in the differential. A biopsy can distinguish among these diagnoses because suprabasal vacuolar degeneration, coarse keratohyalin granules, and hyperkeratosis are pathognomonic for EB. Treatment includes use of a humidified incubator, pain control, infection surveillance, and nutritional intervention to compensate for increased metabolic demands.

Harlequin ichthyosis (HI) has a severe neonatal presentation and while formerly often lethal, advances in intensive care have enabled survival in a large fraction of infants who are born encased in a thick stratum corneum separated by deep, red fissures that form geometric plates of skin. Surviving infants ultimately shed the hyperkeratosis to evolve to an ichthyosiform erythroderma phenotype. Upon birth, coordinated care with attention to fluid and electrolyte balance, signs of infection, and respiratory compromise is appropriate. Treatment recommendations include pain control, nutritional supplementation, and daily bathing with hypochlorite baths followed by application of bland emollients every 4–6 hours. Those surviving the neonatal period should be monitored for achievement of developmental milestones since many are at risk for growth and developmental delay.

Oral *retinoids* are employed in HI if there is evidence that the thick scale is causing respiratory compromise. Retinoids, including isotretinoin and acitretin, promote desquamation, improving motion, respiration, ectropion, and eclabium. Acitretin is preferred for its fewer side effects and shorter half-life. Dosing should be 0.5–1 mg/kg/day. Retinoids are discontinued when the scale sheds and respiration improves. If oral retinoids cannot be tolerated, topical retinoids such as 0.1% tazarotene cream are also beneficial if used in limited areas, such as around the eyes, to relieve ectropion.

Infants (2 Months–1 Year)

Ichthyosis vulgaris (IV) and *X-linked ichthyosis* (XLI) are among the most common forms of ichthyosis. IV typically develops during infancy, revealing fine, rough, white scales most prominent on the extensor surfaces of the extremities with flexural sparing. XLI is sex-linked recessive and only affects males; the translucent, loosely adherent scales seen at birth are quickly replaced by adherent brown scales, most notably on the abdomen and extensor surfaces of lower limbs with flexural sparing. Baths and daily application of bland emollients to reduce scaling are preferred.

Rarely, infants may have normal skin at birth and subsequently develop ichthyosis. Disorders within the erythrokeratoderma variabilis et progressiva (EKVP) spectrum can present with migratory erythema and fixed, well-demarcated, hyperkeratotic plaques or symmetrically distributed, transient stationary, keratotic plaques on an erythematous base with palmoplantar keratoderma (PPK). Lesions appear on the extensor surfaces of extremities, buttocks, and face and can become confluent.

It is also essential to monitor growth and development because failure to thrive (FTT) is common among ichthyosis

patients. Appropriate consults and a gastrostomy feeding tube (G-tube) may be required. Infection and extracutaneous symptoms such as spastic diplegia in Sjögren–Larsson syndrome can also arise.

Children and Adults

Ichthyosis treatment in adults and children is tailored to age-specific needs. In infants and young children, treatment is focused on improving function and quality of life. In older children and adults, the significant impact of a visible disease motivates therapy. In such cases, first-line therapy includes baths and topical agents to reduce scaling and improve comfort. Since the skin of ichthyosis patients is susceptible to bacterial superinfection, dilute bleach baths can decrease risk of infection and improve odor. Bathing with two handfuls of baking soda is especially effective at removing scales, because the increased alkalinity may increase serine protease activity and promote desquamation. Despite its strong odor, topical 10% *N*-acetylcysteine with 5% urea has also demonstrated efficacy for scaling and ectropion and is another therapeutic option.

Emollients applied two to four times daily, ideally after bathing, can help retain moisture. Although discouraged in children because of stinging, adults can apply *keratolytics* including urea ($\geq 10\%$) and alpha-hydroxyacids (5–12%) to remove scale more effectively. Salicylic acid ($>2\%$) and topical tazarotene should be used on localized areas and can also relieve scaling.

Systemic retinoids, especially acitretin, are third-line therapeutics for scale-predominant disorders. For children and adults, we seek the lowest effective dose, and most respond to a dose between 0.5 and 1 mg/kg/day. Common side effects include dry lips, dry eyes, and photosensitivity. Rare side effects include long-term musculoskeletal effects, dyslipidemia, and liver injury. Therefore, serum vitamin D, lipid, and liver function tests are obtained at baseline, 1 month after initiating retinoids, and every 3 months afterwards. Retinoids should be used with caution in females of child-bearing potential; acitretin is relatively contraindicated in this population given the risk of retinoid embryopathy if conception occurs within 3 years of the last dose.

For epidermolytic ichthyoses, first-line therapies include emollients and bicarbonate baths to facilitate desquamation. Thick scales harbor a myriad of microorganisms, but antibiotics, antibacterial soaps, and bleach baths can control odor and reduce infection risk. Keratolytics and topical retinoids are second-line strategies that further reduce hyperkeratosis. Tolerance of keratolytics varies, and usage is limited to adolescents and adults. While topical retinoids and third-line systemic retinoids decrease infections and greatly improve skin appearance and function, they can exacerbate skin fragility. Therefore, it is important to initiate retinoids at a low dose and gradually increase to efficacy.

Exfoliative scale is seen in Netherton syndrome (NS) and treatment with emollients and focal use of topical steroids is standard of care. While corticosteroids can alleviate inflammation, impaired skin barrier increases risk of systemic toxicity of topical agents such as iatrogenic Cushing syndrome, especially among children. Therefore, monitoring serum drug levels is imperative, especially if using the topical immunomodulator, tacrolimus, to treat NS. Third-line therapies include biologics such as infliximab, a TNF- α inhibitor that targets inflammatory markers such as thymic stromal lymphopoietin (TSLP), interleukin-6, and interleukin-8 in the skin, resulting in clinical improvement in isolated case reports. Retinoids exacerbate desquamation and are contraindicated.

Psychosocial Management

The appearance of ichthyosis can be striking and intimidating, and families may feel guilty and reproachful. Without proper psychosocial support and education, there is a risk of delayed parental–infant bonding and child neglect after discharge. The ichthyoses profoundly impact quality of life from childhood to adulthood, and there is a high prevalence of depression and anxiety among affected individuals. Psychological assessment, support, and intervention is therefore crucial.

Resources

Foundation for Ichthyosis & Related Skin Types (for providers and patients): <http://www.firstskinfoundation.org/>

Free tele-ichthyosis service offering providers expert guidance on ichthyosis management: <https://www.firstskinfoundation.org/teleichthyosis>

Specific Investigations

Inherited ichthyosis

- Developmental milestones
- Growth and development, FTT
- Joint mobility
- Electrolyte balance (neonates and infants)
- Extracutaneous findings for syndromic ichthyoses (e.g., Sjögren–Larsson syndrome)
- Vitamin D status
- Mental health screening (depression, anxiety)
- Genetic testing

Acquired ichthyosis

- Malignancy screening
- Infection screen, including human immunodeficiency virus (HIV)
- Metabolic screening

Pathophysiologic basis for growth failure in children with ichthyosis: an evaluation of cutaneous ultrastructure, epidermal permeability barrier function, and energy expenditure. Moskowitz DG, Fowler AJ, Heyman MB, et al. *J Pediatr* 2004; 145(1): 82–92.

Growth failure and developmental delay have been observed in many types of ichthyosis. The abnormal skin barrier may contribute to FTT through chronic transepidermal water loss and calories.

Recognition and diagnosis of neuro-ichthyotic syndromes. Rizzo WB, Jenkins SM, Boucher P. *Semin Neurol* 2012; 32(1): 75–84.

This review describes the extracutaneous features of neuro-ichthyoses, including Sjögren–Larsson syndrome and trichothiodystrophy. Contractures and other joint mobility problems are common among these ichthyoses and must be considered in the diagnostic approach.

Ichthyosis in the newborn. Craiglow BG. *Seminars in perinatology* 2013; 37(1): 26–31.

A review of neonatal ichthyosis presentations and treatment options. Common complications mentioned include electrolyte imbalances and calorie malnutrition.

Vitamin D deficiency and rickets in children and adolescents with ichthyosiform erythroderma in type IV and V skin. Chouhan K, Sethuraman G, Gupta N, et al. *Br J Dermatol* 2012; 166: 608–15.

There is a potential for vitamin D deficiency in ichthyosis patients. All patients in this cross-sectional study had rickets.

Ichthyosis affects mental health in adults and children: a cross-sectional study. Sun Q, Ren I, Zaki T, et al. *J Am Acad Dermatol* 2020. doi:10.1016/j.jaad.2020.01.052.

Mental health problems such as depression and anxiety are prevalent among adults and children with ichthyosis.

Acquired ichthyosis. Patel N, Spencer LA, English JC, et al. *J Am Acad Dermatol* 2006; 55(4): 647–56.

A review of the assessment and treatment of acquired ichthyosis. The algorithm for evaluation includes malignancy, infection, and metabolic screening.

First-Line Therapies

• Bathing/soaking with or without bicarbonate and bleach	A
• Emollients	A

Rediscovering baking soda. Milstone LM. *J Am Acad Dermatol* 2010; 62(5): 885–6.

Sodium bicarbonate baths effectively remove scale in ichthyosis with no known risks.

Use of emollients in the treatment of dry skin conditions. Dyble T, Ashton J. *Br J Community Nurs* 2011; 16(5): 214–8.

Emollients are widely used to effectively treat dry skin conditions such as ichthyosis. This article discusses factors to consider when choosing the type of emollient in order to improve outcomes and compliance.

Association of glycerol and paraffin in the treatment of ichthyosis in children: an international, multicentric, randomized, controlled, double-blind study. Blanchet-Bardon C, Tadini G, Machado Matos M, et al. *J Eur Acad Dermatol Venerol* 2012; 26: 1014–9.

This large, double-blind study revealed that a 15% glycerol and 10% paraffin emollient significantly improved ichthyosis in children.

Efficacy of urea therapy in children with ichthyosis. A multicenter randomized, placebo-controlled, double-blind, semilateral study. Kuster W, Bohnsack K, Rippke F, et al. *Dermatology* 1998; 196: 217–22.

In this study, 60 children were treated with 10% urea lotion on one side and urea-free lotion on the other. After 8 weeks, 78% improved with 10% urea lotion and 72% improved without urea.

Second-Line Therapies

• Keratolytics (salicylic acid [avoid in infants, children under 12], urea, α -hydroxyacids, propylene glycol)	A
• Topical retinoids (tretinoin, tazarotene)	A
• Topical <i>N</i> -acetylcysteine	D

*Avoid for Netherton syndrome

Topical treatment of ichthyoses. Fleckman P, Newell BD, van Steensel MA, et al. *Dermatologic Therapy* 2013; 26(1): 16–25.

Discusses bathing, moisturization using emollients, keratolytics, retinoids, steroid ointments, calcineurin inhibitors, and future therapies in treating the ichthyoses.

Topical tazarotene for the treatment of ectropion in ichthyosis. Craiglow BG, Choate KA, Milstone LM. *JAMA Dermatol* 2013; 149(5): 598–600.

A 77-year-old woman with bilateral lower eyelid ectropion was successfully treated with 0.1% tazarotene cream.

Effect of topical tazarotene in the treatment of congenital ichthyoses. Hofmann B, Stege H, Ruzicka T, et al. *Br J Dermatol* 1999; 141(4): 642–6.

Twelve patients with congenital ichthyoses were treated with 0.05% tazarotene unilaterally and 10% urea cream on the contralateral side for 28 days. Tazarotene was more effective.

Successful treatment with topical *n*-acetylcysteine in urea in five children with congenital lamellar ichthyosis. Bassotti A, Moreno S, Criado E. *Pediatric Dermatology* 2011; 28(4): 451–5.

The authors reported 10% *N*-acetylcysteine and 5% urea markedly improved lamellar ichthyosis after 4 months.

Third-Line Therapies*

• Acitretin	A
• Isotretinoin	B
• Alitretinoin	D
• Dupilumab	E

*Avoid for Netherton syndrome

An appraisal of acitretin therapy in children with inherited disorders of keratinization. Lacour M, Mehta-Nikhar B, Atherton DJ, et al. *Br J Dermatol* 1996; 134(6): 1023–9.

In this review, 29 children with keratinization disorders received acitretin with an average dose of 0.47 mg/kg/day. Data supports long-term use.

Mutations in *KDSR* cause recessive progressive symmetric erythrokeratoderma. Boyden LM, Vincent NG, Zhou J, et al. *Am J Hum Genet* 2017; 100(6): 978–84.

Isotretinoin nearly resolved all features of progressive symmetric erythrokeratoderma (PSEK) caused by *KDSR* mutations.

Alitretinoin reduces erythema in inherited ichthyosis. Onnis G, Chiaverini C, Hickman G, et al. *Orphanet J Rare Dis* 2018; 13(1): 46.

While acitretin is the main retinoid used to treat severe ichthyosis, alitretinoin is a safer option for those who are pregnant or planning to become pregnant. Alitretinoin was shown to be more effective than acitretin at reducing erythema but less effective at reducing scaling.

Oral alitretinoin in congenital ichthyosis: a pilot study shows variable effects and risk of central hypothyroidism. Gånemo A, Sommerlund M, Vahlquist A. *Acta Derm Venerol* 2012; 92: 256–7.

Four patients with ichthyosis were treated with alitretinoin 10–30 mg once daily. Hypothyroidism was observed in two cases.

Treatment of Netherton syndrome with dupilumab. Steuer AB, Cohen DE. *JAMA Dermatol.* 2020 Mar 1;156(3):350–351.

A patient with Netherton syndrome reported 75% improvement of disease severity and functioning after two months of treatment with dupilumab and sustained improvement thereafter. Controlled trials are necessary to determine the role of dupilumab for treating Netherton syndrome.

Emerging Therapies

- Ex vivo cutaneous gene therapy
- Small molecule inhibitors (e.g., kallikrein inhibitors in NS)
- RNA interference (RNAi) for ichthyoses caused by dominant negative mutations (e.g., epidermolytic ichthyosis)

Congenital ichthyosis: an overview of current and emerging therapies. Vahlquist A, Gånemo A, Virtanen M. *Acta Derm Venereol* 2008; 88(1): 4–14.

Discusses emerging therapies such as gene therapy and RNAi technology in treating ichthyosis.

Pathogenesis-based therapies in ichthyoses. Lai-Cheong JE, Elias PM, Paller AS. *Dermatol Ther* 2013; 26(1): 46–54.

Discussed targeted treatment, such as delivering fragments of a deficient protease inhibitor, to treat NS.

Other

Life threatening salicylate poisoning caused by percutaneous absorption in severe ichthyosis vulgaris. Germann R, Schindera I, Kuch M, et al. *Hautarzt* 1996; 47(8): 624–7.

A 7-year-old boy with IV developed metabolic acidosis after topical 10% salicylic acid treatment.

Improved management of harlequin ichthyosis with advances in neonatal intensive care. Glick JB, Craiglow BG, Choate KA, et al. *Pediatrics* 2017; 139(1): e20161003.

A review of neonatal HI management, including family counseling.

Oral retinoid therapy for dermatologic conditions in children and adolescents. Brecher AR, Orlow SJ. *J Am Acad Dermatol* 2003; 49(2): 171–82.

A 0.45–1 mg/kg/day retinoid dosage is safe and efficacious in children.

Cushing syndrome from percutaneous absorption of 1% hydrocortisone ointment in Netherton syndrome. Halverstam CP, Vachharajani A, Mallory SB. *Pediatr Dermatol* 2007; 24(1): 42–5.

An 11-year-old boy with NS treated with 1% hydrocortisone for 1 year developed iatrogenic Cushing syndrome, emphasizing the necessity of proper monitoring.

Netherton syndrome: successful use of topical tacrolimus and pimecrolimus in four siblings. Bin Saif G, Al-Khenaizan S. *Int J Dermatol* 2007; 46(3): 290–4.

There was no significant difference in efficacy between tacrolimus and pimecrolimus.

Oral retinoid therapy for disorders of keratinization: single-center retrospective 25 years' experience on 23 patients. Katugampola RP, Finlay AY. *Br J Dermatol* 2006; 154: 267–76.

Children and adults with keratinization disorders taking oral retinoids developed skeletal, lipid, and liver abnormalities.

Oral liarozole versus acitretin in the treatment of ichthyosis: a phase II/III multicenter, double-blind, randomized, active-controlled study. Verfaillie CJ, Vanhoutte FP, Blanchet-Bardon C, et al. *Br J Dermatol* 2007; 156: 965–73.

In this study, 32 patients were randomized to liarozole 75 mg twice daily or acitretin 10 mg in the morning and 25 mg at night for 12 weeks. Both groups improved, with fewer side effects in the former.

Acknowledgment

We thank Dr. Mary Williams for her role in helping to edit this chapter.

Impetigo

R. Matthew McLarney, Warren R. Heymann

Impetigo is a common superficial bacterial infection of the skin, caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. The infection is highly contagious and can easily spread to other body sites or close contacts. Impetigo usually affects children but can occur in people of any age. The worldwide population of children suffering from impetigo at any one time is estimated in excess of 162 million, making impetigo a global major public health problem.

Impetigo can be primary, with direct bacterial invasion of previously normal skin, or secondary, where infection develops when the skin barrier is disrupted by underlying disease, such as scabies.

Impetigo is classified as non-bullous or bullous. In the more common non-bullous form, thin-walled vesicles rupture to form superficial erosions with yellowish-brown crusts, which eventually heal without scarring. Bullous impetigo is characterized by larger bullae or blisters, which may continue to develop for several days.

Most cases of non-bullous impetigo are caused by *S. aureus*, but *S. pyogenes*, alone or in combination with *S. aureus*, may be implicated. In cooler climates, staphylococcal impetigo predominates, whereas in warmer and more humid climates, streptococcal impetigo is more common. Bullous impetigo is almost always caused by exfoliative toxin-producing strains of *S. aureus*. Secondary impetigo is usually caused by *S. aureus*.

MANAGEMENT STRATEGY

Impetigo is a self-limiting condition that will self-resolve in 2–3 weeks. The goal of treatment is to eradicate the infecting bacteria to allow rapid skin healing and control the spread of infection.

The ideal treatment should be effective, inexpensive, easily accessible, have limited adverse effects, and not promote bacterial resistance. This requires the use of an appropriate antimicrobial delivered in an effective manner. *Antibiotics may be administered either orally or topically.* The choice between topical or oral therapy depends on:

- The experience of the practitioner
- The preference of the patient
- The extent and severity of the disease
- The local bacterial resistance patterns
- The cost and availability of local resources

Topical or oral antibiotics with proven efficacy against *S. aureus* are the first choice of therapy. It is reasonable to use short courses of topical antibiotics for mild, limited impetigo, while reserving oral antibiotics for recalcitrant, extensive disease. In developing countries, topical agents are expensive and may be unavailable. Treatment strategies have to be sufficiently flexible to meet local needs.

Strains of bacteria causing impetigo are often extremely virulent. Patients therefore need to be educated on methods to avoid the spread of infection. Evidence regarding the value of disinfecting measures is limited; however, cleaning lesional skin with soap and water or a mild, non-irritant antiseptic will presumably aid the application of topical antibiotics and reduce the spread of infection.

Nasal carriage of *S. aureus* occurs in a high proportion of both patients, asymptomatic family members, and healthcare workers. Therefore, in recurrent, multiple familial, or nosocomial cases, treatment of nasal carriage may be necessary. Nasal swabs from the patient and immediate relatives should be performed to identify asymptomatic nasal carriers of *Staphylococcus aureus*. In the case of outbreaks on wards and in nurseries, healthcare professionals should also be swabbed. Eradication should be performed in asymptomatic carriers. The choice of antibiotic should be based on the sensitivities of organisms cultured from the pretreatment swab. This may require the use of a systemic antibiotic in conjunction with the nasal application of a topical antibiotic and an antiseptic skin cleanser.

Emerging antibiotic resistance has prompted the development of new therapies. Resistance to mupirocin and retapamulin is well-documented. Globally, the majority of isolates of *S. aureus* are resistant to penicillin; erythromycin resistance is also becoming more common. Methicillin-resistant *S. aureus* (MRSA) is an important cause of impetigo. MRSA poses a challenge because of its enhanced virulence and resistance to standard antibiotic therapy. Antibiotic treatment should be guided by knowledge of the likely causative agent and local resistance patterns, as well as bacterial susceptibility testing.

Specific Investigations

- Skin swabs for microbiologic assessment (Gram stain), culture, and sensitivity
- Nasal swabs from patients and immediate relatives in recalcitrant cases

A Gram stain of a swab from the lesion or exudate will reveal Gram-positive cocci, confirming the clinical diagnosis. Bacterial culture and sensitivity from a pretreatment swab are recommended to assess suitable alternative antibiotics for cases that do not respond to conventional treatment.

The global epidemiology of impetigo: a systematic review of the population prevalence of impetigo and pyoderma. Bowen AC, Mahé A, Hay RJ, et al. PLoS One 2015; 28; 10: e0136789.

The global prevalence of childhood impetigo is estimated to be in excess of 162 million.

Contemporary causes of skin and soft tissue infections in North America, Latin America, and Europe: report from the SENTRY Antimicrobial Surveillance Program (1998–2004). Moet GJ, Jones RN, Biedenbach DJ, et al. *Diagn Microbiol Infect Dis* 2007; 57: 7–13.

Antimicrobial surveillance confirms that *S. aureus* is the predominant pathogen causing skin and soft tissue infections in all studied geographic areas.

Impetigo in epidemic and nonepidemic phases: an incidence study over 4½ years in a general population. Rortveit S, Rortveit G. *Br J Dermatol* 2007; 157: 100–5.

S. aureus was the causal bacterium in 89% (117/132) and 68% (84/123) of impetigo cases during epidemic and non-epidemic periods, respectively ($p < 0.01$). *S. aureus* was resistant to fusidic acid in 84% (98/117) and 64% (54/84) of cases in epidemic and non-epidemic periods, respectively ($p < 0.01$).

DNA heterogeneity of *Staphylococcus aureus* strains evaluated by SmaI and SgrA1 pulsed field gel electrophoresis in patients with impetigo. Capoluongo E, Giglio A, Leonetti F, et al. *Res Microbiol* 2000; 151: 53–61.

Samples from lesional skin, nose, and pharynx were taken from 26 patients and their families, and the strain of *S. aureus* was typed; 54% of the patients had the same strain in both the nose and the lesion. In over half the families at least one other family member was found to be carrying the same strain as the patient's lesion.

High prevalence of mupirocin resistance in *Staphylococcus aureus* isolates from a pediatric population. Antonov NK, Garzon MC, Morel KD, et al. *J Antimicrob Chemother* 2015; 59(6): 3350–6.

In this study, 400 isolates from patients with skin infections from 2010 to 2012 were selected from a *S. aureus* surveillance study: 9.5% of isolates demonstrated retapamulin resistance, of which 58% were MRSA and 9.8% of isolates were found to have mupirocin resistance. *S. aureus* resistance to topical antimicrobials increased during the study period.

First-Line Therapies

• Topical mupirocin, fusidic acid, retapamulin, or ozenoxacin	A
• Oral flucloxacillin, cloxacillin, dicloxacillin, cephalexin, trimethoprim-sulfamethoxazole, or erythromycin	A
• Oral trimethoprim-sulfamethoxazole, clindamycin, fluoroquinolones, and tetracyclines in areas with high prevalence of MRSA	C
• Intravenous antibiotics	C
• Handwashing promotion for primary prevention	B

Interventions for impetigo (Cochrane Review). Koning S, van der Sande R, Verhagen AP, et al. *Cochrane Database Syst Rev* 2012; 1: D003261.

A systematic review of 68 trials, including 5578 participants, reporting on 50 different treatments, including placebo. There is good evidence that topical mupirocin and topical fusidic acid are equal to, or more effective than, oral antibiotics for people with limited impetigo. Fusidic acid, mupirocin, and retapamulin are

probably equally effective. Due to lack of studies in patients with extensive impetigo, it is unclear whether oral antibiotics are superior to topical antibiotics in this group.

No clear preference can be given for β -lactamase-resistant narrow-spectrum penicillins, broad-spectrum penicillins such as amoxicillin with clavulanic acid, cephalosporins, or macrolides. Penicillin was not as effective as most other antibiotics.

Treatment of impetigo in the pediatric population: consensus and future directions. Schachner LA, Torrelo A, Grada A, et al. *J Drugs Dermatol* 2020; 19: 281–90.

This review tabulates treatment regimens for impetigo.

Treatment of impetigo: oral antibiotics most commonly prescribed. Bolaji RS, Dabade TS, Gustafson CJ, et al. *J Drugs Dermatol* 2012; 11: 489–94.

Oral antibiotics are the most common class of medications used to treat impetigo in the United States. A shift toward topical antibiotics would likely decrease adverse effects associated with use of oral agents.

Short-course oral co-trimoxazole versus intramuscular benzathine benzylpenicillin for impetigo in a highly endemic region: an open-label, randomized, controlled, non-inferiority trial. Bowen AC, Tong SYC, Andrews RM, et al. *Lancet* 2014; 384(9960): 2132–40.

A total of 508 Australian children aged 3 months to 13 years with impetigo were assigned to receive a single dose of intramuscular benzathine benzylpenicillin, oral cotrimoxazole 4 mg/kg plus 20 mg/kg twice daily for 3 days, or oral cotrimoxazole 8 mg/kg plus 40 mg/kg once daily for 5 days. At day 7, 85% of patients were successfully treated, regardless of whether they received benzathine benzylpenicillin or pooled cotrimoxazole. There were similar results with 3-day and 5-day regimens of cotrimoxazole. Cotrimoxazole was better tolerated than benzathine benzylpenicillin.

Topical retapamulin ointment (1% wt/wt) twice daily for 5 days versus oral cephalexin twice daily for 10 days in the treatment of secondarily infected dermatitis: results of a randomized controlled trial. Parish LC, Jorizzo JL, Breton JJ, et al. *J Am Acad Dermatol* 2006; 55: 1003–13.

Retapamulin was as effective as cephalexin 500 mg BID (clinical success rates: 85.9% and 89.7%, respectively) in the treatment of patients with secondarily infected dermatitis. Microbiologic success rates were 87.2% for retapamulin and 91.8% for cephalexin. Retapamulin was well tolerated, and the topical formulation was preferred over the oral drug.

Ozenoxacin 1% cream in the treatment of impetigo: a multicenter, randomized, placebo- and retapamulin-controlled clinical trial. Gropper S, Albareda N, Chelius K, et al. *Future Microbiol* 2014; 9(9): 1013–23.

Patients received ozenoxacin 1% cream, retapamulin 1% ointment, or placebo cream twice daily for 5 days. At the final visit, the clinical success rate of ozenoxacin was 35%, retapamulin 38%, and placebo 19%. All treatments were well tolerated.

Topical mupirocin treatment of impetigo is equal to oral erythromycin therapy. Mertz PM, Marshall DA, Eaglstein WH, et al. *Arch Dermatol* 1989; 125: 1069–73.

Seventy-five patients were treated in an investigator-blinded study comparing topical mupirocin applied three times daily with oral erythromycin 30–50 mg/kg daily. The mupirocin-treated patients experienced similar clinical results to those treated with

oral erythromycin, although mupirocin was superior in the microbiological eradication of *S. aureus*.

The emergence of resistance to penicillin and erythromycin is so common in isolates of *S. aureus* that alternative antibiotics should be considered.

Disseminated bullous impetigo and atopic dermatitis: case series and literature review. Mannschreck D, Feig J, Selph J, et al. *Pediatr Dermatol* 2020; 37: 103–8.

Disseminated bullous impetigo was reported in 12 children, 11 of whom had atopic dermatitis. All children required IV or oral antibiotic therapy. Symptoms resolved in 24–72 hours for all except one child. The authors recommended cephalosporins as first-line for disseminated bullous impetigo.

Effect of handwashing on child health: a randomised controlled trial. Luby SP, Agboatwalla M, Feikin DR, et al. *Lancet* 2005; 366: 225–33.

In squatter settlements in Karachi, children younger than 15 years in households that received plain soap and handwashing promotion had a 34% lower incidence of impetigo than controls (95% CI, –52% to –16%).

Second-Line Therapies

• Addition of oral rifampin to standard oral antibiotic therapy	E
• Topical hydrogen peroxide	B
• Topical minocycline	B
• Topical gentian violet	C

Addition of rifampin to cephalexin therapy for recalcitrant staphylococcal skin infections – an observation. Feder HM Jr, Pond KE. *Clin Pediatr* 1996; 35: 205–8.

Two children with staphylococcal infections failing to respond to standard antibiotics responded when rifampin was added.

Topical gentian violet for cutaneous infection and nasal carriage with MRSA. Okano M, Noguchi S, Tabata K, et al. *Int J Dermatol* 2000; 39(12): 942–4.

In this study, 0.5% gentian violet was applied once daily to skin infections caused by MRSA in 28 patients, and 0.3% solution was applied to the anterior nares in nine cases of nasal MRSA colonization. Disinfection required a mean of 10.6 days for all cases (range 2–28). The only adverse reaction was purple color of the skin.

Hydrogen peroxide cream: an alternative to topical antibiotics in the treatment of impetigo contagiosa. Christensen OB, Anehus S. *Acta Dermatol Venereol* 1994; 74: 460–2.

A prospective comparison of hydrogen peroxide 1% cream with fusidic acid 2% cream (both applied 2–3 times daily) in 256 patients with impetigo. Over a 3-week treatment period, 92 patients of 128 (72%) in the hydrogen peroxide group were classified as healed, compared with 105 of 128 (82%) in the fusidic acid group. This difference was not statistically significant.

Topical minocycline foam for the treatment of impetigo in children: results of a randomized, double-blind, phase 2 study. Chamny S, Miron D, Lumelsky N, et al. *J Drugs Dermatol* 2016; 15(10): 1238–43.

Thirty-two children with impetigo were randomized to topical minocycline foam (TMF) 1% or TMF 4% twice daily for 7 days. Clinical cure was achieved in 57.1% of the TMF 1% and 50.0% of the TMF 4% groups. Both regimens were well tolerated.

Third-Line Therapy

• Povidone-iodine in controlling nosocomial spread of impetigo caused by MRSA	E

Prevention and control of nosocomial infection caused by methicillin-resistant *Staphylococcus aureus* in a premature infant ward: preventive effect of a povidone-iodine wipe of neonatal skin. Aihara M, Sakai M, Iwasaki M, et al. *Postgrad Med J* 1993; 69: S117–21.

An outbreak of MRSA causing impetigo was halted by wiping the body surface of the infants once daily with a diluted Iodine solution (10% povidone-iodine; 1:100 dilution).

Inducible urticarias, aquagenic pruritus, and cholinergic pruritus

Clive E.H. Grattan, Frances Lawlor

INDUCIBLE URTICARIAS

About 25% of patients with chronic urticaria have a definable and reproducible inducing trigger that distinguishes them from those with spontaneous urticaria and urticarial vasculitis. Inducible urticarias are defined by the predominant inducing stimulus (Table 114.1). More than one inducing stimulus elicits urticaria in some patients, and inducible urticarias can overlap with spontaneous urticaria. Physical urticarias caused by a physical stimulus (symptomatic dermatographism, delayed pressure, heat and cold contact and solar urticarias, and vibratory angioedema) are now included within the inducible urticarias.

MANAGEMENT STRATEGY

Pharmacologic

The presentation of inducible urticarias may vary in morphology and severity. Milder forms may require little more than *avoidance of triggers* and a preemptive dose of H_1 antihistamine around 1 hour before anticipated exposure, whereas a very severe attack involving anaphylaxis could potentially require emergency treatment with *intramuscular epinephrine (adrenaline)*. Acute presentations of severe inducible urticaria may require short courses of *oral corticosteroids* (e.g., prednisolone 0.5 mg/kg body weight daily for 5 days) in addition to regular non-sedating H_1 antihistamines. Drug management should be guided by the degree of disability or impairment in quality of life.

Non-pharmacologic

The triggering stimulus should be avoided where possible. Cold tolerance induction in cold urticaria and exercise tolerance induction in cholinergic urticaria has been described but is difficult to achieve and sustain. There is no evidence that exclusion diets are effective.

Specific Investigations

- Challenge (provocation) tests
- Blood tests (cryoproteins, specific IgE)

With the exceptions of testing for cryoglobulins in cold urticaria and specific IgE in food- and exercise-induced anaphylaxis, laboratory investigations are unnecessary and should not be undertaken except to monitor treatment or screen for eligibility (e.g., glucose-6-phosphatase dehydrogenase in patients being considered for dapsone or sulfasalazine).

The EAACI/GA²LEN/EDF/WAO guideline for the definition, classification, diagnosis and management of urticaria. Zuberbier T, Aberer W, Asero R, et al. *Allergy* 2018; 73(7): 1393–414.

The latest and most quoted European guideline on urticaria.

Chronic inducible urticaria: a systematic review of treatment options. Dressler C, Werner RN, Eisert L, et al. *J Allergy Clin Immunol* 2018; 141(5): 1726–34.

Thirty studies on chronic inducible urticarias were identified and reviewed to inform the 2017 EAACI guideline revision.

The definition, diagnostic testing, and management of chronic inducible urticarias – the EAACI/GA(2)LEN/EDF/UNEV consensus recommendations 2016 update and revision. Magerl M, Altrichter S, Borzova E, et al. *Allergy* 2016; 71(6): 780–802.

A comprehensive summary of provocation testing protocols.

Cold urticaria syndromes: historical background, diagnostic classification, clinical and laboratory characteristics, pathogenesis and management. Wanderer AA. *J Allergy Clin Immunol* 1990; 85: 965–81.

A classic review of cold urticaria and its investigation still relevant today.

Treatments of cold urticaria: a systematic review. Kulthanan K, Hunnangkul S, Tuchinda P, et al. *J Allergy Clin Immunol* 2019; 143(4): 1311–31.

A recent systematic review of treatment confirming the benefit of non-sedating antihistamines, up-dosing them to fourfold, and the place of omalizumab.

Heat urticaria: a revision of published cases with an update on classification and management. Pezzolo E, Peroni A, Gisondi P, et al. *Br J Dermatol* 2016; 175: 473–8.

A comprehensive review of this rare subtype of inducible urticaria.

First-Line Therapy

- Non-sedating ('second generation') H_1 antihistamines (can be used at up to fourfold the approved dose in the absence of contraindications) **A**

Non-sedating antihistamines (Table 114.2) should be prescribed in preference to classical antihistamines, which are often sedating and can impair psychomotor performance. Up-dosing of second-generation H_1 antihistamines is now widely practiced, although sedation at higher-than-licensed doses is a potential risk.

Table 114.1 Classification of inducible urticarias by the eliciting stimulus (in approximate reducing frequency of occurrence)

Symptomatic dermatographism	Stroking or rubbing the skin
Cholinergic urticaria (pale, papular wheals with red flares)	Rise in core temperature and other causes of sweating (exercise, hot baths, spicy food, and stress)
Cold urticaria	Rewarming of skin after cooling (localized or systemic)
Delayed pressure urticaria	Sustained perpendicular pressure
Solar urticaria	Ultraviolet or visible solar radiation
Heat urticaria	Local heat contact
Aquagenic urticaria	Water contact at any temperature
Vibratory angioedema	Vibration

Table 114.2 Examples of non-sedating and mildly sedating H₁ antihistamines

Acrivastine	Non-sedating, three-times-daily dosing
Bilastine	Non-sedating, once-daily dosing
Cetirizine	May be mildly sedating, once-daily dosing
Levocetirizine	Active enantiomer of cetirizine
Fexofenadine	Non-sedating, once-daily dosing
Loratadine	Non-sedating, once-daily dosing
Desloratadine	Active metabolite of loratadine
Mizolastine	Non-sedating, once-daily dosing
Rupatadine	Non-sedating, once-daily dosing

High-dose desloratadine decreases wheal volume and improves cold provocation thresholds compared with standard-dose treatment in patients with acquired cold urticaria: a randomized, placebo-controlled, cross-over study. Siebenhaar F, Degener F, Zuberbier T, et al. *J Allergy Clin Immunol* 2009; 123: 672–9.

Fourfold up-dosing a second-generation antihistamine has additional inhibitory effects on wheal formation in cold urticaria.

Rupatadine and its effects on symptom control, stimulation time, and temperature thresholds in patients with acquired cold urticaria. Metz M, Scholz E, Ferrán M, et al. *Ann Allergy Asthma Immunol* 2010; 104: 86–92.

A crossover, randomized, double-blind, placebo-controlled study of double-dose rupatadine, a second-generation H₁

antihistamine. Fifty-two percent of patients showed a complete response. There was also a significant improvement in critical cold stimulation time and critical temperature threshold.

Second-Line Therapies

Symptomatic dermatographism

- Omalizumab **B**
- Narrowband UVB (NB-UVB) phototherapy **C**
- H₂ antihistamines **B**

Cholinergic urticaria

- Omalizumab **B**
- Danazol **B**
- Anticholinergics **E**

Cold urticaria

- Omalizumab **B**
- Leukotriene receptor antagonists **E**
- Cold tolerance (desensitization) **E**

Heat urticaria

- Omalizumab **D**

Delayed pressure urticaria

- Omalizumab **D**
- Leukotriene receptor antagonists **B**
- Sulfasalazine **C**
- Dapsone **C**

Solar urticaria

- Omalizumab **C**
- Induction of tolerance (phototherapy and photochemotherapy) **D**

SYMPTOMATIC DERMOGRAPHISM

Omalizumab is effective in symptomatic dermatographism – results of a randomized placebo-controlled trial. Maurer M, Schütz A, Weller K, et al. *J Allergy Clin Immunol* 2017; 140(3): 870–3. e5.

Narrow-band ultraviolet B phototherapy is beneficial in antihistamine-resistant symptomatic dermatographism: a pilot study. Borzova E, Rutherford A, Konstantinou G, et al. *J Am Acad Dermatol* 2008; 59: 752–7.

A small, open study of H₁ antihistamine-unresponsive symptomatic dermatographism showing subjective and objective improvement in itch and whealing after 6 weeks' treatment, but relapse 6–12 weeks after stopping.

In dermatographic urticaria H₂ receptor antagonists have a small but therapeutically irrelevant additional effect compared with H₁ antagonists alone. Sharpe GR, Shuster S. *Br J Dermatol* 1993; 129: 575–9.

In this double-blind, crossover study, 19 patients were randomized to treatment with cetirizine 10 mg at night plus either ranitidine 150 mg twice daily or placebo. There was an increase in whealing threshold with additional H₂ blockade, but no subjective benefit on itch.

Addition of an H_2 to an H_1 antihistamine may provide better control of some inducible urticarias despite a lack of trial evidence. They may benefit wheal and erythema but not itch.

CHOLINERGIC URTICARIA

Efficacy and safety of omalizumab (Xolair) for cholinergic urticaria in patients unresponsive to a double dose of antihistamines: a randomized mixed double-blind and open-label placebo-controlled clinical trial. Gastaminza G, Azofra J, Nunez-Cordoba JM, et al. *J Allergy Clin Immunol Pract* 2019; 7(5): 1599–609. e1.

About a third of cholinergic urticaria patients became negative on an exercise challenge test after 48 weeks of treatment with omalizumab, demonstrating some benefit under conditions of the study but disappointing overall. Relapse of symptoms was seen in the majority 3 months after finishing treatment.

Real-life treatment of cholinergic urticaria with omalizumab. Altrichter S, Chuamanochan M, Knoth H, et al. *J Allergy Clin Immunol* 2019; 143(2): 788–91. e8.

In this retrospective analysis, six (37%) of 16 cholinergic urticaria patients had a complete response and five (31%) had useful benefit from omalizumab at different doses, the majority receiving 300 mg at some point in their treatment.

Beneficial effects of danazol on symptoms and laboratory changes in cholinergic urticaria. Wong E, Eftekhari N, Greaves MW, et al. *Br J Dermatol* 1987; 116: 553–6.

Seventeen male patients treated with danazol 200 mg three times daily in a double-blind, crossover study had sustained improvement in the number of exercise-induced wheals over 12 weeks.

Anabolic steroids should only be considered for severe cholinergic urticaria not responding adequately to up-dosed H_1 antihistamines, because of their potential for virilization and hepatotoxicity. Danazol should be reserved for severe cases and avoided during pregnancy. Androgenic adverse effects may be dose-limiting in women.

Severe cholinergic urticaria successfully treated with scopolamine butylbromide in addition to antihistamines. Ujiie H, Shimizu T, Natsuga K, et al. *Clin Exp Dermatol* 2006; 31: 978–81.

Although this case report suggests that anticholinergics may be successful for cholinergic urticaria, the general experience with this class of drugs is disappointing, and unwanted effects often outweigh any benefits.

Scopolamine butylbromide is better known as hyoscine butylbromide, approved for gastrointestinal spasm and not to be confused with hyoscine hydrobromide used for motion sickness.

COLD URTICARIA

Omalizumab is effective in cold urticaria-results of a randomized placebo-controlled trial. Metz M, Schütz A, Weller K, et al. *J Allergy Clin Immunol* 2017; 140(3): 864–7. e5.

Improvement of cold urticaria by treatment with the leukotriene receptor antagonist montelukast. Hani N, Hartmann K, Casper C, et al. *Acta Derm Venereol* 2000; 80: 229.

A case report of a patient with acquired cold-contact urticaria responding subjectively and objectively to montelukast 10 mg daily after only 4 days.

Cold urticaria: a clinico-therapeutic study in 30 patients, with special emphasis on cold desensitization. Henquet JM, Martens BPM, van Volten WA. *Eur J Dermatol* 1992; 2: 75–7.

Cold desensitization in four patients with severely disabling cold urticaria resulted in symptom-free follow-up ranging from 4 to 14 years. Induction of cold tolerance took 1–2 weeks.

Patients had to take cold showers (around 15°C) for 5 min twice a day to maintain the tolerance, so this approach is not for the faint-hearted. Cold tolerance is now outdated.

Cold urticaria: tolerance induction with cold baths. Von Mackensen YA, Sticherling M. *Br J Dermatol* 2007; 157: 799–846.

Nine of 23 patients desensitized with cold water immersions 15 years earlier responded to a questionnaire survey. Only one of them was able to continue the cold baths for 6 months, two for 3 months, and the others stopped almost immediately.

This report introduces a little realism concerning the likelihood of cold desensitization being an effective and well-tolerated long-term therapy for cold-contact urticaria.

HEAT URTICARIA

Treatment of severe heat urticaria with omalizumab – report of a case and review of the literature. Bonnekoh H, Terhorst-Molawi D, Buttgerit T, et al. *J Eur Acad Dermatol Venereol* 2020 Apr 1. doi: 10.1111/jdv.16407 [Epub ahead of print].

Heat urticaria is very rare. There are a small number of cases responding to omalizumab.

DELAYED PRESSURE URTICARIA

Rapid response to omalizumab in 3 cases of delayed pressure urticaria. Quintero OP, Arrondo AP, Veleiro B. *J Allergy Clin Immunol Pract* 2017; 5: 179–80.

Efficacy of montelukast, in combination with loratadine, in the treatment of delayed pressure urticaria. Nettis E, Pannafino A, Cavallo E, et al. *J Allergy Clin Immunol* 2003; 112: 212–3.

In a small, randomized study, objective pressure rechallenge after 15 days showed that montelukast 10 mg once daily with loratadine 10 mg once daily was more effective than either drug alone.

Desloratadine in combination with montelukast suppresses the dermatographometer challenge test papule, and is effective in the treatment of delayed pressure urticaria: a randomized, double-blind, placebo-controlled study. Nettis E, Colanardi MC, Soccio AL, et al. *Br J Dermatol* 2006; 155: 1279–82.

Although this study suggests that pressure urticaria can be controlled without steroids, clinical experience with montelukast in delayed pressure urticaria is usually disappointing.

Delayed pressure urticaria: response to treatment with sulfasalazine in a case series of seventeen patients. Swerlick RA, Puar N. *Dermatol Ther* 2015; 28: 318–22.

This open study supports the use of sulfasalazine in delayed pressure urticaria.

Potential side effects include bone marrow depression and hypersensitivity reactions, so patients need careful monitoring. Sulfasalazine should only be considered in patients who are not sensitive to aspirin and other non-steroidal drugs.

Delayed pressure urticaria – dapsons heading for first-line therapy. Grundmann SA, Kiefer S, Luger TA, et al. J Dstch Dermatol Ges 2011; 9: 908–12.

Of 31 patients with pressure urticaria treated with dapsons over a 6-year period surveyed retrospectively, 74% showed a good or very good response.

Dapsons can also be a useful and inexpensive treatment of delayed pressure urticaria.

SOLAR URTICARIA

Clinical and photobiological response in eight patients with solar urticaria under treatment with omalizumab, and review of the literature. Morgado-Carrasco D, Fustá-Novell X, Podlipnik S, et al. Photodermatol Photoimmunol Photomed 2018; 34(3): 194–9.

Omalizumab for the treatment of solar urticaria: case series and systematic review of the literature. Snast I, Kremer N, Lapidoth M, et al. J Allergy Clin Immunol Pract 2018; 6(4): 1198–204. e3.

Two small series of solar urticaria patients responding well to omalizumab, which can now be considered the treatment of choice after H₁ antihistamines for this rare condition before considering phototherapy or photochemotherapy.

Narrowband ultraviolet B phototherapy is a suitable treatment option for solar urticaria. Calzavara-Pinton P, Zane C, Rossi M, et al. J Am Acad Dermatol 2012; 67: e5–9.

Patients without an urticarial response to phototesting with NB-UVB were given an alternate-day exposure for 4 weeks. Those with an urticarial response to phototesting with NB-UVB were treated three times a day for 5 days in the first week and then subsequently the same as the first group for 3 weeks. Thirty-nine patients completed the study and reported good tolerance to the sun afterward.

Solar urticaria: long-term rush hardening by inhibition spectrum narrow-band UVB 311 nm. Wolf R, Herzinger T, Grathovac M, et al. Clin Exp Dermatol 2013; 38: 446–7.

UVA rush hardening for the treatment of solar urticaria. Beissert S, Ständer H, Schwarz T. J Am Acad Dermatol 2000; 42: 1030–2.

Protection was achieved within 3 days of exposing three patients to multiple incremental UVA irradiations at 1-hour intervals. Rush hardening with UVA did not cause sunburn reactions and provided protection against visible light and UVB-induced urticaria in two of the three patients.

UV-induced tolerance should be considered for patients who need more than antihistamines.

Successful and long-lasting treatment of solar urticaria with UVA rush hardening therapy. Masuoka E, Fukunga A, Kishigami K, et al. Br J Dermatol 2012; 167: 198–201.

Two patients with solar urticaria who reacted to intradermal injection of their own serum that had been preirradiated with visible light were treated with multiple UVA incremental exposures at 1-hour intervals for 2–3 days and became symptom free, and their postirradiation skin tests became negative. Maintenance UVA exposures were performed every 1 or 2 weeks for 4 months in one patient and 5 months in the other. The first patient remained clear off treatment for 6 months.

Successful treatment with UVA rush hardening in a case of solar urticaria. Mori N, Makino T, Matsui K, et al. Eur J Dermatol 2014; 24: 117–9.

A direct comparison between NB-UVB, psoralen UVA (PUVA), and UVA hardening for solar urticaria has not been performed to date.

Third-Line Therapies

• Intravenous immunoglobulins	D
• Ciclosporin	E
• Plasmapheresis	E
• Etanercept	E

Effect of high-dose intravenous immunoglobulin in delayed pressure urticaria. Dawn G, Urcelay M, Ah-Weng A, et al. Br J Dermatol 2003; 149: 836–40.

Three of eight patients went into remission after one or more infusions of intravenous immunoglobulin (IVIG) at 2g/kg and two improved, but confirmation of pressure-induced wheals by objective testing was not done, and all patients had spontaneous chronic urticaria. It was not clear whether the benefit of treatment was mainly on the pressure urticaria or the spontaneous urticaria.

Cold urticaria responding to systemic ciclosporine. Marsland AM, Beck MH. Br J Dermatol 2003; 149: 214.

One patient with acquired cold-contact urticaria of over 1 year's duration and unresponsive to antihistamines improved within a week of starting ciclosporin at 3 mg/kg daily, and the improvement was maintained at 1.7 mg/kg/day. It was not stated what happened on stopping treatment.
